THE commercial availability of zonal rotors and centrifuges within the past 3–4 years has permitted the exploitation of zonal centrifugation for large scale fractionation of cellular components. In particular, attention has been focused on the isolation of relatively large components such as cell organelles and sub-fractions, viruses and RNA, although the technique has also been applied to enzyme purification[1].

Our work has been concerned with the enzyme isocitrate dehydrogenase (EC 1.1.1.42) of *Acinetobacter lwoffi*. We have found[2] that in this organism, and certain other bacteria, there are two distinct NADP-linked isocitrate dehydrogenases which can be separated by DEAE-cellulose chromatography or gel filtration on 'Sephadex *G*-200'. We have termed these IDH-I and IDH-II. The two isoenzymes differ in kinetic, molecular and electrophoretic properties, and it is particularly interesting that IDH-II (the higher molecular weight enzyme) is strongly activated (about five-fold) by low concentrations (0·2 mM) of either glyoxylate or pyruvate. The considerable difference in molecular size of the two isoenzymes, as shown by their separation on 'Sephadex *G*-200', prompted an investigation of the usefulness of zonal centrifugation for their preparative separation.

A. lwoffi was cultured aerobically at 30° C on acetate as the sole carbon source. The cells were collected towards the end of logarithmic growth, washed, resuspended in buffer containing 20 mM Tris, *p*H 8·0, 10 mM $MgCl_2$, 1 mM EDTA, and disrupted by ultrasonication. After centrifugation, nucleic acid was removed by treatment of the extract with protamine sulphate (1·3 mg per 10 mg protein) and the mixture was again centrifuged. The clear supernatant solution was then fractionated with ammonium sulphate and the material precipitating between 45 per cent and 75 per cent saturation was redissolved in 50 mM phosphate, *p*H 8·0, containing 10 mM $MgCl_2$ and 1 mM EDTA and dialysed overnight at 4° C against this buffer. The dialysed solution, which contained 27 mg of protein/ml., was used in the zonal centrifugation experiments.

Isocitrate dehydrogenase activity was determined at 340 nm by following the formation of NADPH in a reaction mixture at 25° C containing 20 mM Tris, *p*H 8·0, 10 mM $MgCl_2$, 1 mM EDTA, 2 mM isocitrate and 0·2 mM NADP. Activation by glyoxylate was examined by incorporating 0·2 mM glyoxylate in the assay mixture.

A linear sucrose density gradient (5–20 per cent w/v) in buffer of composition 5 mM Tris, *p*H 8·0, 10 mM $MgCl_2$, 1 mM EDTA, was fed into an MSE *B* XIV titanium zonal rotor rotating at 2,500 r.p.m. in an MSE 'Superspeed 65' centrifuge. Enzyme solution (5 ml.) was introduced to form a layer at the core of the rotor, on the light end of the gradient, and then pushed further into the centrifugal field with 15 ml. of buffer. Centrifugation was carried out at 47,000 r.p.m. and 10° C for the times given in the figure legend, after which the rotor was slowed to 2,500 r.p.m. and the gradient gently displaced to a collector by pumping in 30 per cent sucrose solution. Fractions (20 ml.) were collected and assayed for enzyme activity.

Fig. 1*A* shows the separation of isoenzymes achieved after 12·5 h of centrifugation, and Fig. 1*B* shows the increased separation after 20 h. The activation of IDH-II by glyoxylate is also depicted. These results show that IDH-I and IDH-II may indeed be fractionated by this technique. Similar resolution has been achieved with as much as 25 ml. of applied enzyme solution. Moreover, centrifugation removes the enzymes isocitrate lyase and glutamate dehydrogenase, both of which sediment faster than either IDH-I or IDH-II. The removal of these enzymes is an added advantage of this zonal separation, for their presence interferes with kinetic studies of the IDHs; moreover, they are difficult to remove by other means.

For comparison, Fig. 1*C* shows the pattern obtained after 18 h of centrifugation of an extract of acetate-grown *Escherichia coli* prepared in the same way as before. We have not observed activation of *E. coli* isocitrate dehydrogenase by glyoxylate or pyruvate, and have found no evidence for the existence of isoenzymes. Consistent with this, the sedimentation pattern reveals a single peak of IDH activity.

This application of the technique of zonal centrifugation to the separation of IDH isoenzymes should, when sedi-

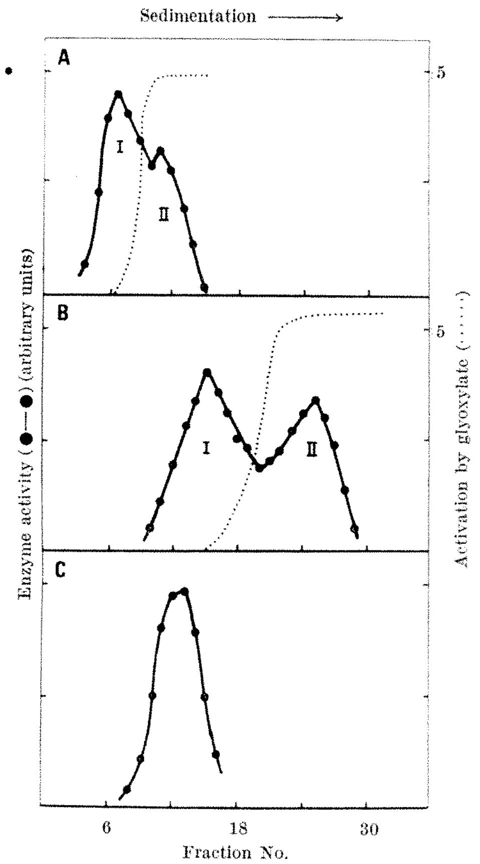

Fig. 1. Sedimentation patterns of isocitrate dehydrogenases of *A. lwoffi* and *E. coli*. Experimental details are given in the text. *A*, *A. lwoffi*, 12·5 h centrifugation at 47,000 r.p.m.; *B*, *A. lwoffi*, 20 h; *C*, *E. coli*, 18 h. The dotted lines show the activation by glyoxylate (0·2 mM) found only with the IDH-II of *A. lwoffi*. This activation is defined as the ratio of the additional enzyme activity in the presence of glyoxylate to that in its absence.

mentation characteristics are sufficiently distinct, prove useful in studies on other isoenzyme systems. Furthermore, our results with IDH-I demonstrate the applicability of the technique to relatively small molecules (molecular weight $< 100,000$).

This work was supported, in part, by the Science Research Council and was conducted during the tenure (by C. H. S.) of an MRC postgraduate training scholarship.

Antigenic Expression of a Murine Lymphoma during Growth *in vitro*

While studying a Moloney virus (MV) induced lymphoma in culture, we were puzzled by the disappearance of the antibody-mediated cytotoxic sensitivity of the cells several days after explantation. After a longer time in culture, however, these cells regained sensitivity to the same sera with complement. The experiments have been repeated in better controlled conditions, and some of the results obtained are reported here.

The mouse lymphoma YCAB was induced by intraperitoneal inoculation of MV in newborn mice of (A/Sn × A.CA)F_1 origin. The resulting solid tumour was converted to ascites form and later explanted in minimal essential medium (MEM) supplemented with 10 per cent foetal calf serum, L-serine and sodium pyruvate[1]; to each ml. medium 30 units of 'Mycostatin' (Squibb) were added. The cells were grown in suspension at 37° C and with 5 per cent CO_2. The antiserum with activities directed against *H*-2 alloantigenic specificities 4, 10, 13 and 31 was produced in (C57Bl × C3H)F_1 hybrids ($H2^b/H2^k$) by repeated weekly subcutaneous inoculation of spleen, liver and kidney tissues from DBA/2 mice ($H2^d$) (ref. 2). Sera from several mice were pooled and stored at $-20°$ C in aliquots of 0·06 ml. Anti-Moloney serum was produced in (DBA/2 × A.BY)F_1 hybrids by inoculation of irradiated (6,000 r) lymph node cells from syngeneic mice bearing the solid Moloney lymphoma YDYA.

Cytotoxicity tests were performed with 10^5 cells and 0·05 ml. serum of appropriate dilution. All dilutions were made in MEM without foetal calf serum. The cells were incubated with serum for 20 min at 37° C, washed once in MEM free of foetal calf serum, and incubated with complement (diluted 1 : 2) for 45 min at 37° C. The source of complement was fresh guinea-pig serum absorbed with mouse tumour cells 1 : 20, and stored at $-20°$ C. The viability of target cells was assessed by the trypan-blue exclusion test (0·025 per cent in balanced salts solution). During procedures other than incubations the cells were kept in cold. The absorptions of the (C57Bl × C3H)F_1 anti-DBA/2 and anti-Moloney sera were performed with 0·05 ml. serum on 10^6 YCAB cells at 6° C for 30 min with shaking. The (C57Bl × C3H)F_1 anti-DBA/2 serum was absorbed in 1 : 2 dilution; anti-Moloney serum was absorbed undiluted. Both absorbed sera were frozen and later tested against standard YCAB cells (see below).

To determine the modal cell volume during growth *in vitro*, cells were harvested every day and the cell volume was measured in a Coulter counter, model B. The population doubling time[3] was calculated according to the formula[4]

$$\log N = \log N_0 + kt \log 2$$

where N is the number of cells at time t, N_0 the number of cells at time 0, and k is the regression constant. The population doubling time is the reciprocal of k. The cytotoxicity index was calculated as described elsewhere[5].

Fig. 1 shows the growth curves and changes of the cytotoxin sensitivity, as well as the population doubling time of YCAB cells cultured in two different conditions: cells from a 3-day culture (in 400 ml. bottles with 100 ml. medium and 10^5 cells as initial inoculum) were put in 10 ml. of medium in 25 ml. screw-cap bottles at a concentration of either 2×10^5 cells/ml. (*A* and *B* in Fig. 1) or 6×10^5 cells/ml. (*C* and *D*). With the lower initial inoculum the cytotoxic sensitivity to the (C57Bl × C3H)F_1 anti-DBA/2 serum and complement decreased to very low values 48 h after seeding, remained low during the next 24 h, and rose within 48 h to 0·90. The sensitivity to the anti-Moloney serum followed the same pattern.

A striking correlation between the cytotoxic sensitivity and the population doubling time is observed in these (Fig. 1) and various other experiments (Table 1). With the initial cell inoculum of 6×10^5 cells/ml., in otherwise identical conditions, the changes in cytotoxic sensitivity occurred much more rapidly and again corresponded with the changes in population doubling time. An inverse relationship between the modal cell volume and cytotoxic sensitivity was observed in all experiments (see, for example, Fig. 2).

The absorption experiments (Fig. 3) indicate that the cytotoxic sensitivity of the cells is indeed reflecting the amount of detectable antigens present on the cell surface. The serum absorbed with the cells harvested two days after seeding (Fig. 1), when the cytotoxic sensitivity was low, and that absorbed on the cells harvested five days after

Table 1. CHANGES OF THE POPULATION DOUBLING TIME AND CYTOTOXIC SENSITIVITY OF THE YCAB CELLS DURING A PERIOD OF 4 DAYS IN CULTURE

	Dilution	Days after seeding 0	1	2	3	4
Cells/ml. $\times 1^5$		1·0	1·5	10·4	13·6	16·6
Population doubling time (h)		—	40	8·5	62	83·7
C.I. of (C57Bl × C3H)F_1 anti-DBA/2 serum	1 : 2	0·54	0·46	0·01	0·45	0·49
	1 : 4	0·44	0·15	0	0·19	0·27
C.I. of the anti-Moloney serum	1 : 1	0·41	0·35	0	0·19	0·26
	1 : 2	0·37	0·13	0	0·16	0·22

10^5 cells/ml. were seeded in 400 ml. bottles in 100 ml. medium. *C.I.* = cytotoxicity index. The population doubling time data refer to the period between two subsequent days (24 h).

seeding (in the same experiment), when it was high, are compared with the unabsorbed sera. All sera were tested simultaneously on standard YCAB cells grown in conditions favouring the expression of a relatively large amount of antigen on the cell surface; this can be achieved by manipulating the size of the bottles, the amount of medium, and the initial cell inoculum, as well as the growth phase of the seeded cells (to be published). The sera absorbed on the cells grown for two days in culture in the conditions of the experiment of Fig. 1*A* have only slightly decreased activity compared with the unabsorbed sera (Fig. 3). On the other hand, when the sera were absorbed in the same experiment on the cells grown for five days in culture, they almost completely lost the activity against the standard cells.

Large cells exhibited low cytotoxic sensitivity and low absorbing capacity, whereas small cells had high cytotoxic sensitivity and high absorbing capacity, so it follows that the number of expressed antigenic receptors per cell is directly proportional to the cytotoxic sensitivity. If the number of expressed antigenic receptors on a single cell were to remain constant during growth of a cell population in culture, the absorbing capacity of a constant number of cells should not vary with the cell volume.

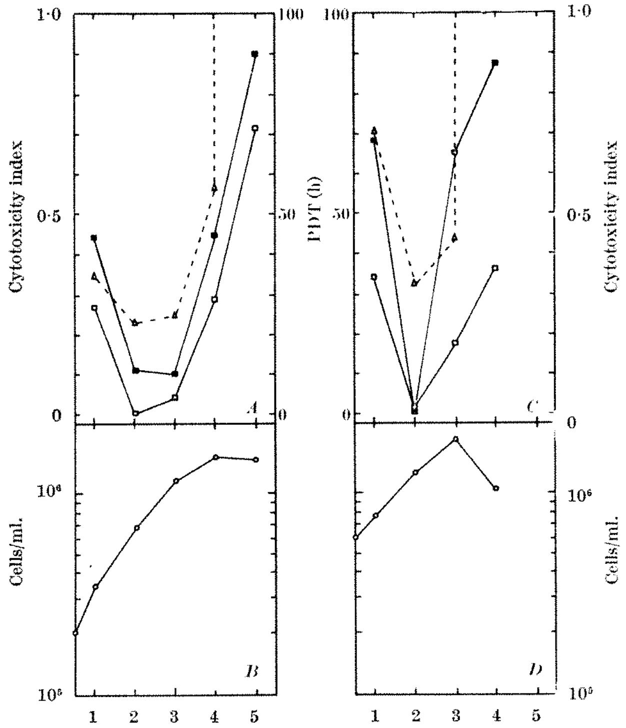

Fig. 1. Cytotoxic sensitivity, population doubling time (PDT), and growth curves of MV-induced lymphoma YCAB during 5 days in culture; two different experiments. *A* and *B* represent experiments with an initial inoculum of 2×10^5 cells/ml. in 25 ml. bottles and 10 ml. medium. *C* and *D* represent experiments with an initial inoculum of 6×10^5 cells/ml. but otherwise in the same conditions. *B* and *D* are the growth curves of the respective cell populations. *A* and *C* depict the cytotoxicity index for (C57Bl × C3H)F_1 anti-DBA/2 serum in 1 : 2 dilution (■—■), and for the undiluted anti-Moloney serum (□—□), as well as population doubling time (△ - - - △).

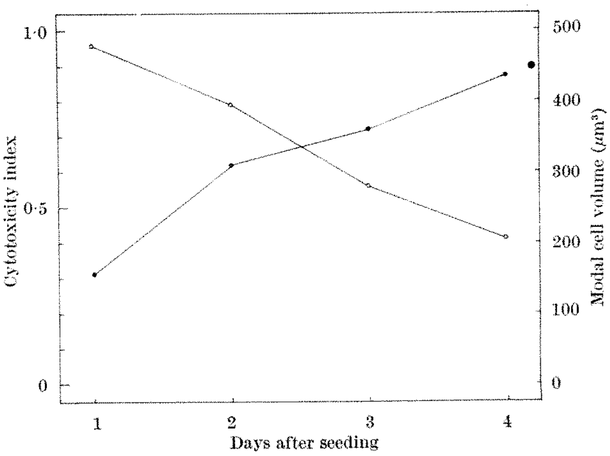

Fig. 2. Changes of the modal cell volume (○—○) and cytotoxic sensitivity (●—●) at various times.

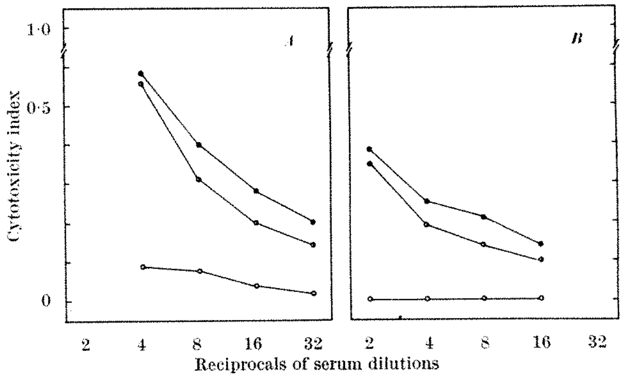

Fig. 3. Results of the absorption tests. *A*, Tests performed with (C57Bl × C3H)F_1 anti-DBA/2 serum; *B*, tests with anti-Moloney serum. ●—●, Unabsorbed sera; ◑—◑, sera absorbed on day 2 after seeding; ○—○, sera absorbed on day 5 after seeding. All sera were tested simultaneously against the same standard cells.

The experiments demonstrate that the expression of antigenic characteristics of YCAB cells during growth *in vitro* is directly proportional to the population doubling time and that an inverse relationship exists between cell volume and the concentration of antigenic receptors on the cell surface. The data do not determine, however, whether the changing pattern of expression of antigenic characteristics is the result of the coating of antigenic receptors[6], or of a restricted period of gene transcription during growth *in vitro*. Experiments are in progress to relate antigenic expression to different phases of the cell cycle. At this state no more than indirect conclusions can be drawn, namely, that the antigenic characteristics of the YCAB cells are fully expressed during *G*1 phase, and that at saturation density YCAB cells are arrested in this phase. These conclusions are based on the inverse relationship of cytotoxic sensitivity and population doubling time, on the one hand, and cell volume on the other[7,8]. It would be of interest to know whether similar events take place *in vivo*, and also whether other phenotypic characteristics of cells are dependent on growth phases.

Transplantation Antigens in the Central Nervous System

INVESTIGATIONS into the presence of histocompatibility antigens in mouse brain have given apparently conflicting results. Haemagglutinin[1,2] and cytotoxin[3] inhibition studies have revealed that the brain has an extremely small capacity for absorbing H-2 antibodies, compared with lymphoid tissues. Brain tissue, however, induces transplantation immunity[4] and histocompatibility antigens are detected in neurones of the cerebral cortex by immunofluorescence[5]. The selective localization of the specific fluorescence to the neurones can explain these conflicting results, for the number of stained cells represents only a small proportion of the total brain tissue. This will be reflected by a very low absorptive capacity in quantitative inhibition studies.

I report here the detection of transplantation antigens in the cerebellum of three inbred strains—C3H, CBA and C57Bl—and further confirmation of their selective distribution in the central nervous system.

Table 1. EXPERIMENTAL DESIGN

Tissue donor strain	Control antisera	Antisera to tissue donor
C3H (H-2^k)	C3H anti-E.L.4*	C57Bl-anti-B.P.8† Balb/C anti-B.P.8 129 anti-B.P.8
CBA (H-2^k)	CBA anti-E.L.4	C57Bl anti-B.P.8 Balb/C anti-B.P.8 129 anti-B.P.8
C57Bl (H-2^b)	C57Bl anti-B.P.8	C3H anti-E.L.4 CBA anti-E.L.4 Balb/C anti-E.L.4 A anti-E.L.4

* E.L.4 is an H-2^b leukaemia originating in C57Bl mice.
† B.P.8 is an H-2^k ascitic sarcoma originating in C3H mice.

H-2 antigens were detected with an indirect fluorescent antibody technique. Acetone-fixed or unfixed cryostat sections of mouse cerebellum were incubated with an alloantiserum known to contain H-2 antibodies, washed and treated with fluoresceinated rabbit antibodies to mouse gamma globulins. The experimental design, materials and methods were the same as those previously reported in detail[5]. Table 1 summarizes the experimental design. All antisera were used undiluted and had comparable haemagglutination and cytotoxic titres. The conjugate consisted of a preparation of IgG from a rabbit antiserum to mouse IgG coupled with fluorescein isothiocyanate. The purification of this conjugate and other technical factors were found to be of critical importance and have been fully described[5]. Five controls were performed in each test to assess the specificity of the fluorescent staining. These included incubation with only the conjugate, the "blocking test", absorption of the positive antiserum with tissue donor cells before use, and substitution of the positive antiserum with normal mouse serum. The most reliable control, however, was provided by the genetic system used in which the same antiserum was employed as a control with syngeneic tissues and as a positive antiserum with allogeneic cells (Table 1).

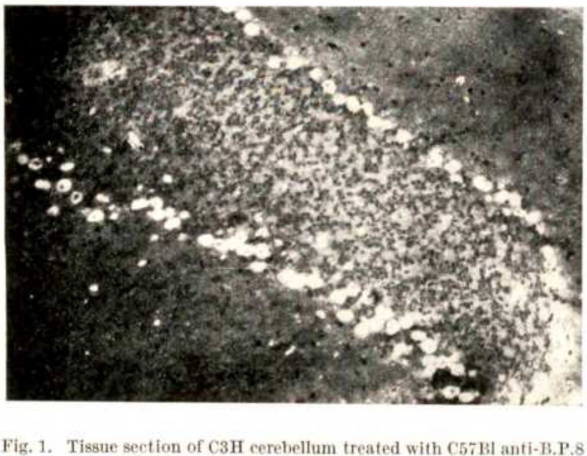

Fig. 1. Tissue section of C3H cerebellum treated with C57Bl anti-B.P.8 and the conjugate. Acetone-fixation. × 50.

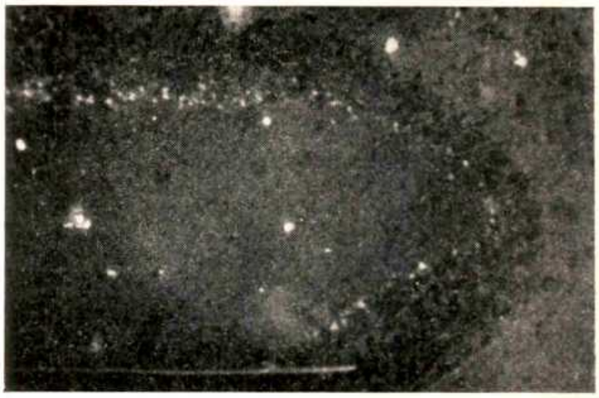

Fig. 2. Tissue section of C3H cerebellum treated with C3H anti-E.L.4 and the conjugate. Acetone-fixation. × 50.

The results showed that the localization of specific green fluorescence was better defined after acetone fixation. Tissue sections treated with positive antisera displayed bright cytoplasmic staining of the Purkinje cells, the nucleus remaining unstained. The cytoplasm of cells of the inner granular layer was also stained, but the fluorescence was not so intense (Fig. 1). In the "blocking test", there was moderate inhibition of the staining. In all other controls, with or without acetone fixation, specific fluorescence was absent (Fig. 2). Bright yellow autofluorescent granules were observed in all tissue sections. This has been attributed to autofluorescence of lysozymes[6].

My results show that the cerebellum, as well as the cerebral cortex, contains H-2 antigenic material and that these antigens are restricted to certain types of cell in the central nervous system. The cells of the granulosa have little cytoplasm and this may explain why their fluorescence appeared less intense than that of the Purkinje cells with abundant cytoplasm. These findings are consistent with the reported ability of cerebellar tissue to induce transplantation immunity[4].

Induction of Hepatic Tyrosine Aminotransferase mediated by a Cholinergic Agent

TYROSINE aminotransferase in the rat liver is subject to regulation by a number of hormones and amino-acids[1-3]. Recent work has indicated that the sympathetic neurotransmitter norepinephrine suppresses the synthesis of tyrosine aminotransferase by forming a complex with the pyridoxal 5′-phosphate cofactor (refs. 4–6 and I. B. B., manuscript submitted for publication). Evidence suggesting mediation of this effect by peripheral autonomic nerves has been presented[7]. Because many of the physiological consequences of sympathetic stimulation are antagonized by parasympathetic discharge with acetylcholine release, the effect of cholinergic agents on enzyme regulation was examined. I report here that the cholinergic agent carbachol (carbamylcholine) induces hepatic tyrosine aminotransferase and that this induction is antagonized by the cholinergic blocking agent atropine.

Adrenalectomized, female, Sprague–Dawley rats (160–180 g) were subjected to a diurnal lighting schedule previously described[4] and offered one per cent NaCl solution *ad libitum*. Animals were used 4 to 6 days after adrenalectomy and were fasted from the onset to the termination of each experiment. All studies were performed between 0800 h and 1200 h.

The effects of administered acetylcholine are evanescent, presumably because of the rapid hydrolysis by acetylcholinesterase and non-specific cholinesterases. The choline ester carbachol, which is resistant to these enzymes, was therefore used to mimic acetylcholine. After treatment, rats were killed by a blow to the head and livers were rapidly removed and frozen. Livers were homogenized in isotonic KCl solution and tyrosine aminotransferase activity was assayed by a modification of the method of Diamondstone[8].

Carbachol administration resulted in a two-fold rise in tyrosine aminotransferase activity within 2 h (Fig. 1). Bethanecol, another cholinergic agent, caused a similar increase in enzyme activity. To determine whether the increased enzyme activity was the result of cholinergic receptor stimulation, additional groups of rats were also treated with atropine. This compound, which competitively antagonizes the effects of cholinergic agents, blocked the rise in tyrosine aminotransferase activity after carbachol. Atropine alone, in the doses used, did not alter enzyme activity (Fig. 1).

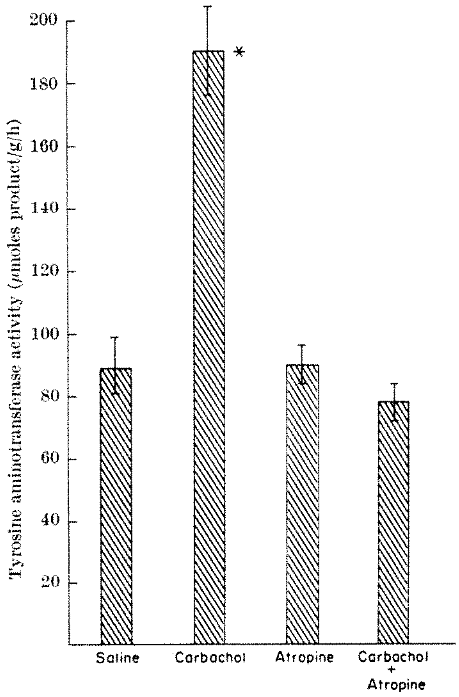

Fig. 1. Specificity of tyrosine aminotransferase activity elevation after carbachol. Rats were injected with carbachol 0·75 mg/kg at 0900 h and/or with atropine 10·0 mg/kg at 0845 h. Controls were treated with saline at appropriate times. All injections were intraperitoneal in a volume of 1 ml. All rats were killed at 1100 h. Results are expressed as mean ± *S.E.* (brackets). * Differs from all other groups at $P < 0\cdot001$.

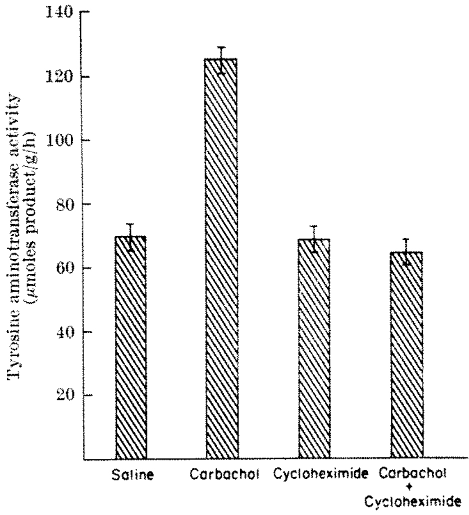

Fig. 2. Induction of tyrosine aminotransferase by carbachol. Rats were treated with carbachol as in Fig. 1, and/or with cycloheximide 20 mg/kg intraperitoneally 15 min earlier. Controls were treated with saline. Animals were killed 2 h after carbachol administration. Results are expressed as mean ± *S.E.* (brackets). The group treated with carbachol above differs from all other groups at $P < 0\cdot001$.

Enzyme activity may increase either through activation of existing molecules or as a result of an increase in the amount of enzyme protein. To distinguish between these alternatives, rats were treated with the inhibitor of protein synthesis, cycloheximide, before receiving carbachol. Cycloheximide prevented elevation of tyrosine aminotransferase by carbachol (Fig. 2), indicating that on-going protein synthesis is necessary for this rise in enzyme activity.

Induction of tyrosine aminotransferase by carbachol and blockage of this effect by atropine suggests that this induction is mediated by a cholinergic receptor. The effect of this cholinergic agent is opposite to that previously described for the sympathetic neuromediator, norepinephrine. Norepinephrine suppresses tyrosine aminotransferase synthesis by binding pyridoxal 5′-phosphate, whereas carbachol induces the enzyme. Thus, although these two neuromediators may be operating at different sites, this enzyme system provides a molecular model for the recognized antagonism of the sympathetic and parasympathetic nervous systems.

The locus of action of carbachol has not been determined. Because acetylcholine has been associated with the release of pancreatic insulin[9] (a known inducer of tyrosine aminotransferase[10]), the drug may be acting through hormonal mediation.

Actinomycin-*D*: Effects on Memory at Different Times after Training

INHIBITORS of macromolecular synthesis have been used extensively for studies of memory storage. The amnesic effects of two inhibitors of protein synthesis, acetoxycycloheximide and cycloheximide, have been attributed to specific interference with the synthesis of protein required for formation of long-term memory[1-4]. The effects of actinomycin-*D*, an inhibitor of DNA-dependent RNA synthesis, have been particularly difficult to interpret because doses sufficient to produce marked inhibition of cerebral RNA synthesis produce fairly rapid onset of irreversible systemic toxicity[5,6]. Even much smaller doses produce localized chromatolysis[7] and may lead to death. Studies with rodents injected before learning show that marked inhibition of RNA synthesis does not interfere with retention for a few hours after injection[5,6,8], but the marked toxicity of this drug has limited its usefulness in studies of the participation of cerebral RNA synthesis in long term memory.

In goldfish, intracerebral injection of actinomycin immediately after training has produced impairment of memory tested 3 days later, but injections 1 h after training had no effect[9]. These results were interpreted as supporting the view that participation of cerebral RNA synthesis is involved in the formation of long-term memory. Because of this report, we have investigated further the effects of actinomycin-*D* on memory in mice.

We trained mice in a shock-escape (0·4 mA) position discrimination to a criterion of only two correct responses. Mice learned this discrimination in an average of 3·4 trials (including the two correct trials) and showed good savings as long as 7 days later. Distributions of trials to criterion for learning and retention tests are shown in Fig. 1.

Male Swiss albino mice (25–50 per group) were injected intracerebrally in both temporal or frontal regions of the brain with a total of 30 µl. of mannitol (40 mg/ml.) containing either 30 µg (high dose) or 1 µg (low dose) of actinomycin-*D*. Injections were given 3 h before, 1 day after, or 7 days after training. Control animals were injected with mannitol. All mice were tested for retention 27 h after injection. In contrast to the substantial inhibition of cerebral RNA synthesis found previously[5,6] with high doses of actinomycin-*D*, we found that whole cerebral RNA synthesis was inhibited only 14 per cent or 18 per cent 3 h or 27 h after injection of the low dose.

Uninjected mice and mice injected with mannitol or actinomycin-*D* 3 h before training needed an identical number of trials to learn the position discrimination.

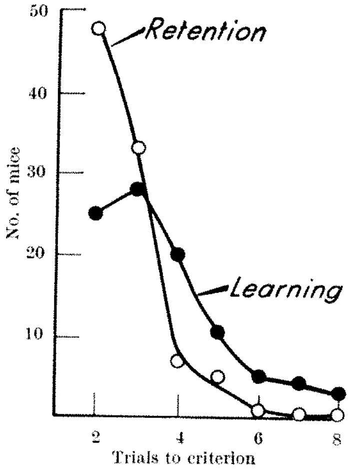

Fig. 1. Distributions of trials needed to reach a criterion of two correct during original learning and retention tests. These distributions represent the pooled results of all ninety-six control (mannitol-injected) mice in the study.

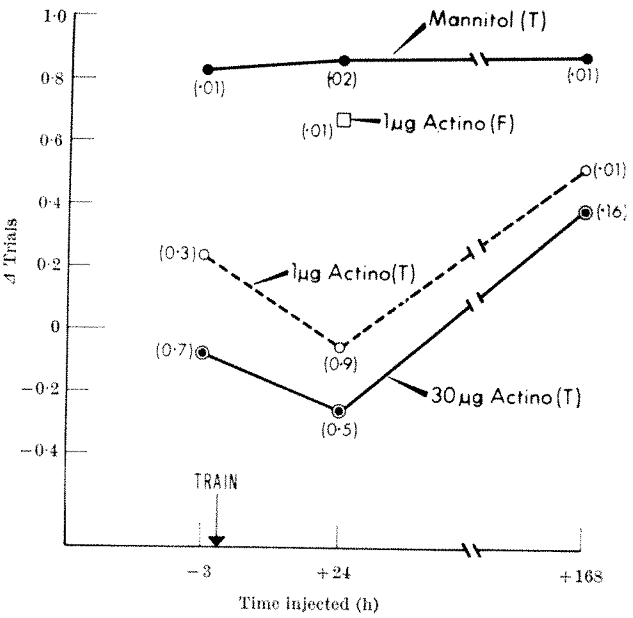

Fig. 2. Effect of injection of actinomycin-*D* or mannitol on retention. Mice were injected (25–50 per group) before or 1 or 7 days after training. Retention was always tested 27 h after injection. Five mice failed to reach criterion within eight trials and were eliminated. Mice ($N = 8$) requiring more than eight trials to relearn the task were assigned a relearning score of 8. T denotes bitemporal injection (1 mm rostral to the caudal sutures, 1 mm lateral to the sagittal suture, and 4 mm below the skull surface). F denotes bifrontal injections (6 mm rostral to the caudal sutures, 1 mm lateral to the sagittal suture and 2 mm below the skull surface). Δ Trials was computed by subtracting the mean number of trials needed to reach criterion on retest from the mean number needed for original learning. For each group, the probability that Δ trials was due to chance is shown in parentheses. The distributions of the difference scores (trials to learn—trials to relearn) for each group closely approximated a normal distribution. Accordingly, two-tailed *t* tests were used to evaluate differences between independent groups. Paired *t* tests, two-tailed, were used to evaluate the significance of savings within groups. Differences between the mannitol group and the group given a high dose of actinomycin-*D* at −3 h, $P < 0{\cdot}02$; at +1 day, $P < 0{\cdot}03$; at +7 days, $P > 0{\cdot}3$. Differences between the mannitol group and the group given the low dose of actinomycin-*D* at −3 h, $P < 0{\cdot}13$; at +1 day, $P < 0{\cdot}04$; at +7 days, $P > 0{\cdot}4$. Differences between the low dose (F) group and the low dose (T) group at +1 day, $P < 0{\cdot}06$. Differences between the 7 day actinomycin-*D* (high and low dose) group and the 1 day actinomycin-*D* (high and low dose) group, $P < 0{\cdot}03$.

Mannitol-treated mice showed significant retention when injected 3 h before, 1 day after or 7 days after training (Fig. 2). In contrast, mice injected bitemporally with actinomycin-*D* 3 h before or 1 day after training gave no evidence of retention. Mice given the high or the low dose of actinomycin-*D* at these times needed as many trials to relearn the task as they required to learn it originally. When injections were given 7 days after learning, there were no significant differences between mice injected with mannitol and mice injected with a high or a low dose of actinomycin-*D*. Mice given the high or low dose of actinomycin-*D* at this time showed, as a group, significantly better retention than mice given the high or low dose of actinomycin-*D* 1 day after learning ($P < 0{\cdot}03$). Further, frontal injections with the low dose of actinomycin-*D* 1 day after training had no effect on retention.

We also found that inhibition of protein synthesis by bitemporal injection of 20 µg acetoxycycloheximide, 1 day after learning this task, had no effect on retention 27 h later (savings significant, $P < 0{\cdot}01$), although substantial prolonged inhibition is known to result from such a dose[1-3]. Both the high and low doses of actinomycin-*D* did impair retention 1 day after training, so it seems that the drug is not acting by inhibiting RNA synthesis specifically needed to direct the synthesis of protein needed for long-term memory storage. Furthermore, the low dose (1 µg) of actinomycin-*D* has relatively little effect on cerebral RNA synthesis, although it is enough to produce hippocampal cellular damage and abnormalities in electrical activity[7]. We believe that these results have no direct bearing on the hypothesis that cerebral RNA is specifically required for long-term memory. Rather, these effects may result from non-specific (toxic) actions of the drug.

The report that actinomycin-*D* produces a brief temporal gradient of retrograde amnesia in goldfish[9] is in sharp contrast to the long gradient that we find. Differences in length of retrograde amnesia gradients are found with a variety of treatments[10], and may result from differences in motivation, task or species. It is possible that the necrosis and electrical abnormality known[7] to be produced by actinomycin-*D* may be responsible not only for the long gradient of retrograde amnesia which we found, but for shorter gradients as well. Results with goldfish and mice, however, have often been different[11-13]. Accordingly, in the absence of evidence that actinomycin-*D* produces neuronal abnormalities in the goldfish, care should be taken in generalizing this interpretation from one species to another.

Although they do not seem to be relevant to the possible participation of cerebral RNA synthesis in memory storage, our results are interesting in another respect. The fact that bitemporal actinomycin-*D* injections impaired retention if given 1 day but not 7 days after training suggests that some aspect of the memory formation process is changing during the interval. The effects of bitemporal injections of puromycin or of anticholinergic or anticholinesterase drugs suggest that the memory storage process changes for several days after training[13-17]. Our study thus neither supports nor falsifies the hypothesis that cerebral RNA synthesis participates in memory storage. Actinomycin-*D* seems to have limited usefulness for investigating the role of specific macromolecules in memory formation. The results do, however, support the suggestion that, at least in the case of undertrained habits, intact hippocampal function is needed for 1 or more days after training, but not 7 days after training. This suggestion may also apply to more overtrained tasks[13,14].

Effects of an Imprinting Procedure on Regional Incorporation of Tritiated Uracil into Chick Brain RNA

WE have demonstrated previously that an imprinting procedure influences the rate of incorporation of amino-acid into acid insoluble substances in the upper part of the chick's forebrain[1]. In so far as changes in incorporation rate reflect changes in the rate of protein synthesis, these should be reflected also in an altered rate of RNA production. In addition, the time sequence of events at the biochemical level within the brain should be one in which an increase in RNA production should precede the increase in protein. We describe here the effects of varying amounts of exposure to an imprinting stimulus on the incorporation of tritiated uracil into RNA of different regions of chick brain.

Eight batches of Chunky chicks were hatched and kept in a dark incubator until the start of the experiment. All the birds hatched 6–12 h before the peak period of hatching. Experiments were begun at a mean post-hatch age of 17·03 ± 0·25 h. Chicks from each of the batches were distributed into three groups (experimental, light control, dark control).

The experimental group was exposed to a flashing light, previously shown to be a highly effective imprinting stimulus[2], and the light control group was exposed to an overhead light as described earlier. A total of thirty-five chicks (dark control) were kept in darkness from hatching to death. The period of exposure of the experimentals and light controls was varied; twelve experimentals and twelve light controls received 38 min of exposure, nineteen experimentals and nineteen light controls received 76 min, and eighteen experimentals and eighteen light controls received 160 min. Each chick in the experimental group exposed for 160 min was placed in a testing alley for 10 min during which the speed of approach to a flashing light was measured.

Meanwhile the light control was kept in a lit pen at the same temperature (23·5°–26·5° C) as the testing alley. Immediately after the initial exposure each chick was weighed and given an intracardiac injection of 0·1 ml. Locke solution containing 20 μCi 5-^{3}H-uracil (1,000 mCi/mmole). For 150 min after injection the experimental group was exposed to the flashing light and each light control was isolated in a pen illuminated by a 60 W bulb. Both groups were kept at 28°–31° C. None of the chicks exposed to light for shorter periods of time was tested before injection; initially, after injection they were all placed singly in dark compartments at 28°–31° C. The 76 min groups were kept in the dark for 37 min before and after their period of exposure to light and the 38 min groups for 56 min before and after. All handling of chicks was done in the dark or under dim green light.

Each chick was placed in the testing alley 150 min after injection and its speed of approaching the flashing light was measured. It was then decapitated. The brain was removed and three regions dissected out (midbrain, forebrain roof and forebrain base). The brain samples and a piece of liver tissue were placed in individual pots and kept frozen on solid CO_2 until analysis. The samples were treated essentially as described previously[3]. They were homogenized in 5 ml. of ice-cold 0·9 per cent NaCl and portions of the homogenate taken for (*a*) protein assay, (*b*) determination of total (pool) radioactivity and (*c*) radioactivity associated with nucleic acid. Acid insoluble radioactivity was determined following precipitation and three washes with 10 per cent trichloroacetic acid containing 0·1 per cent uracil. Radioactivity in the samples was counted and specific activity calculated as described previously[1,3]. The figures were corrected to a standard body weight of 50 g. Preliminary experiments showed that incorporation of radioactivity from uracil was linear over 3 h from the injection of precursor, and amounted at the end of that period to some 4 per cent of pool radioactivity. Entry into the pool was thus not rate-limiting in these conditions.

To eliminate variability between batches, the specific activity of each sample of tissue in a batch was divided by the mean for all brain samples from the dark control group in that batch. The results are therefore standardized and expressed as percentages of the mean for the dark

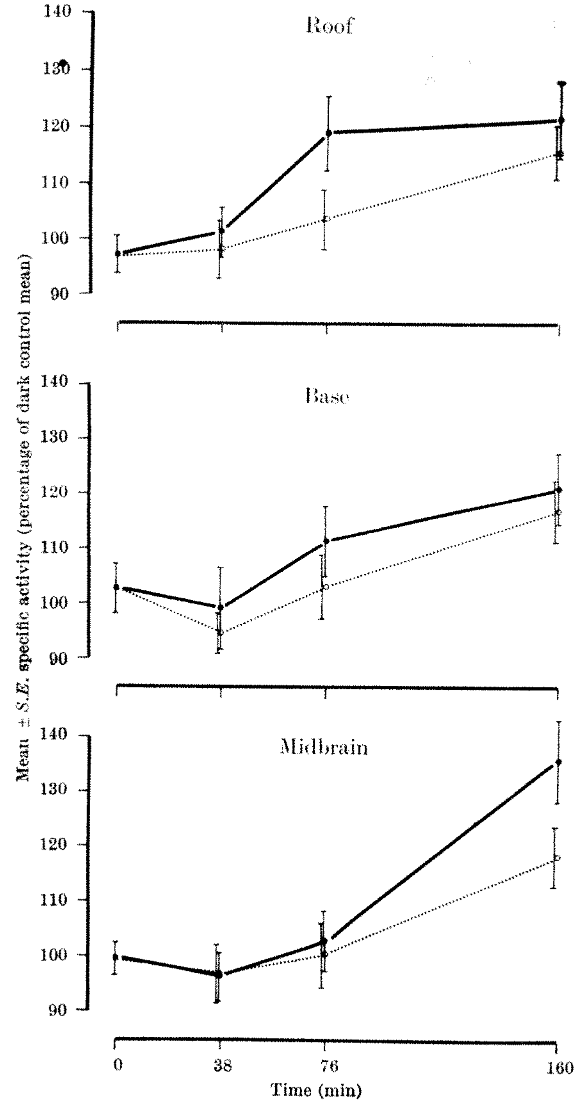

Fig. 1. Means and standard errors of standardized specific activities of RNA from the forebrain roofs, forebrain bases and midbrains of differently treated chicks. All chicks were injected with tritiated uracil and the time from injection to killing was kept constant. The experimental birds (———) were exposed to a flashing light and the light controls (. . .) to a continuous light.

controls. Fig. 1 gives the mean values and standard errors of the standardized specific activities (s.s.a.) for different regions of the brain after each treatment.

No change in the mean values of s.s.a. could be detected after 38 min of exposure in either the experimental or light control group. After 76 min exposure, a highly significant increase had occurred in the s.s.a. of the forebrain roofs of the experimental group (Table 1). No other differences between the dark controls (0 min exposure) and the experimental and light control groups exposed for 76 min are statistically significant. But after 160 min of exposure, the mean s.s.a. in all three brain regions in both experimental and light control groups are significantly greater than those in the dark controls (Table 1). The experimental group differs significantly from the light control in the forebrain roof after 76 min of exposure ($d = 1{\cdot}81$, $P < 0{\cdot}05$ 1-t) and in the midbrain after 160 min of exposure ($d = 1{\cdot}93$, $P < 0{\cdot}05$ 1-t). No significant differences were found in the liver at any time.

Table 1. VALUES OF d and PROBABILITY LEVELS FOR STATISTICAL COMPARISONS BETWEEN THE DARK CONTROL GROUP (0 MIN) AND (a) EXPERIMENTAL AND (b) LIGHT CONTROL GROUPS EXPOSED FOR 76 AND 160 MIN

Time of exposure (min)	Group	Roof	Base	Midbrain
76	Experimental	3·00†	1·13	0·48
	Light control	1·07	0·03	0·08
160	Experimental	3·23†	2·38*	4·70‡
	Light control	3·14†	2·05*	3·08†

* $P < 0{\cdot}05$. † $P < 0{\cdot}01$. ‡ $P < 0{\cdot}001$.

Clearly RNA synthesis in the brains of day-old chicks is very sensitive to visual stimulation. By varying the time of exposure to such stimulation while keeping the time from injection to killing constant, the effects of different treatments on different brain regions can be distinguished. Particularly striking is the rapid increase in RNA synthesis in the forebrain roof of experimental birds. This is the region where we previously detected an increase in protein synthesis after early hatching chicks had been exposed to an imprinting stimulus[1]. We should point out that because mere exposure to a continuously illuminated environment eventually affects RNA synthesis in all brain regions, the causes of the more rapidly occurring change in the forebrain roof of experimental birds are not clear. On the one hand, the difference between experimental and light control groups at 76 min might have arisen because the experimental birds merely received more visual stimulation. On the other hand, the difference might have been related in a more direct way to the imprinting process.

Investigation of *p*-Methoxyamphetamine Excretion in Amphetamine Induced Psychosis

Many differences exist between the symptoms of schizophrenia and those of drug-induced states caused by agents like LSD or mescaline[1]. Amphetamine psychosis, by contrast, can in some cases replicate virtually all of the manifestations of natural schizophrenic illness[2–5]. Such a correspondence justifies a study of the biochemical basis of this condition.

A provocative hypothesis about the genesis of amphetamine psychosis has been proposed[6]. Smythies *et al.* suggest that *p*-methoxyamphetamine (PMA) may be formed from amphetamine in patients who develop psychotic symptoms. In an animal test system utilizing a conditioned avoidance response and analysis of reaction time which is designed to correlate with human psychotogenicity[6,7], Smythies has found PMA to be highly potent as a disruptor of behaviour—second only, in this respect, to LSD of all the compounds tested[6]. Shulgin *et al.* have established that PMA is psychotogenic in humans and also that it has an order of potency of approximately five times that of mescaline[8]. The doses of amphetamine required to induce a psychosis in humans are such that pharmacologically active amounts of this metabolite could be produced. We therefore examined the urine of subjects who were receiving amphetamine in psychotogenic doses to ascertain the presence or absence of PMA.

The subjects were four physically healthy non-schizophrenic volunteers to whom amphetamine was administered orally in doses of 5–50 mg/h for as long as was tolerated. A mean total cumulative dose of 629 mg was administered over an average period of 51 h. The method of administration and behavioural effects have been reported[5].

Urine was collected continuously in 6–12 h pooled specimens throughout amphetamine administration. The specimens representing hours before and immediately after amphetamine was last administered were examined. Urinary amphetamine was assayed by a method in which an internal standard, phenethylamine, is added to a 5 ml. aliquot of each urine sample, in duplicate. The amines, extracted with chloroform at *p*H 10, are acetylated directly with acetic anhydride. The residue on evaporation is dissolved in dioxane and a portion is injected into an F and M 'Biomedical 400' gas chromatograph fitted with a six foot U tube packed with 8 per cent ethylene glycol adipate on 'Chromosorb W'. For 8 inches at the two ends the packing was 3 per cent 'SE–30' on 'Diatoport S'. The column temperature was 215°.

The amount of amphetamine present can be calculated by comparing the height of its chromatographic peak with that of the internal standard[9]. PMA was assayed with the same method. Retention times for N-acetylamphetamine and N-acetyl-PMA were, respectively, 4 and 15 min. From peak height measurements of standard amounts (0·1–1·0 μg) of N-acetyl-PMA and, independently, from recovery studies of PMA added to urine, it is estimated that the limit of detectability of PMA in these urines is about 70–80 μg/l. of urine. In none of the nine studies was PMA detected even though large amounts of amphetamine were present in these urine samples (Table 1).

Table 1. SCHEDULE OF TESTING FOR PMA EXCRETION

Subject and trial	Cumulative dose (mg)	Duration of administration (h)	Urine volume (ml.)	Amphetamine excreted (mg)	Psychotic symptoms
1 A	325	28·75	95	10·0	Present
B	745	64·25	36·5	14·2	Present
C(+R)	950	54	735	123	Absent
2 A	390	45·75	485	18·3	Minimal
B	590	74·75	325	23·4	Minimal
3 A	955	71·5	245	21·4	Absent
B(+R)	465	26	405	9·20	Absent
4 A	595	46	79	9·05	Present
B(+R)	645	47	490	14·9	Absent

PMA was not detected in any of the trials. R indicates pretreatment with reserpine, which seemed to prevent the occurrence of psychotic symptoms[5].

Our study does not support the suggested formation of PMA from ingested amphetamine as a mechanism for the genesis of amphetamine psychosis, but the distinct possibility remains that amphetamine could undergo such transformation within the central nervous system and not peripherally, and then subsequently be further transformed before being excreted in the urine. Even the transient production of such a substance, should it occur at critical sites in the central nervous system, could cause significant behavioural effects. In partial support of this alternative, we have found that N-^{3}H-acetyl-PMA is almost entirely O-demethylated in rats *in vivo*.

We thank Dr Alexander Shulgin for the *p*-methoxyamphetamine used as a chromatographic standard for preliminary studies. The standards were synthesized in our laboratory.

Inhibition of ^{3}H-Thymidine Incorporation into Rat Liver Nuclei by *E. coli* L-Asparaginase

THERE have been numerous reports dealing with the antitumour activity of *Escherichia coli* L-asparaginase in the therapy of human leukaemia. It has been postulated that the agent is without toxic action on normal tissues and that it is specific for asparagine dependent tumour cells, but neither of these assumptions has been proved[1,2]. When L-asparaginase was used in the treatment of human cancer, a satisfactory effect could be seen only with acute lymphoblastic leukaemia[3–5], but many investigators emphasized the toxicity of L-asparaginase. An alteration of liver function[2,5–7] has been demonstrated by the finding of hepatic lipoidosis; a marked increase in bromsulphthalein retention, and in serum levels of cholesterol, triglycerides and phospholipid; a decrease in human serum proteins and the demonstration of various clotting disorders in the course of therapy. Other authors[8] observed the total inhibition of the early wave of mitotic activity in regenerating rat liver approximately 30 h after partial hepatectomy. We decided to study the effect of L-asparaginase preparations of high specific activity on DNA synthesis in rat liver nuclei, and to determine nuclear DNA and RNA polymerase activity in rat liver under the influence of L-asparaginase.

The methods used in this study—with a few modifications—have been described[9–11]. Female Wistar rats with an average initial weight of 90 g have been used throughout this study. *E. coli* L-asparaginase (220 IU/mg protein, crystal suspension in 3·5 M $(NH_4)_2SO_4$) was a gift from Boehringer, Mannheim. The enzyme was injected intraperitoneally in an adjusted dilution of the crystal suspension which contained the administered doses in a solution volume of 0·5 ml. In all experiments control animals were injected with the same volume of an equimolar solution of $(NH_4)_2SO_4$. Labelling of nuclear DNA was achieved by means of a 1 h pulse of ^{3}H-thymidine (20 μCi/animal; 5 Ci/mmole) given intraperitoneally in 0·5 ml. 0·9 per cent NaCl. The nuclei were isolated using the procedures described elsewhere[11–13]. DNA as well as RNA polymerase assay followed the description in previous studies[9–11]. Nuclear DNA was estimated essentially as described by Burton[14]. To determine the incorporation of ^{3}H-thymidine into nuclear DNA, aliquot suspensions of liver nuclei were precipitated and washed with 2 per cent perchloric acid and radioactivity was counted in a toluene scintillator[15]. The results are presented in Tables 1–3.

Table 1. ^{3}H-THYMIDINE INCORPORATION INTO NUCLEAR DNA OF RAT LIVER FOLLOWING INTRAPERITONEAL INJECTION OF L-ASPARAGINASE

Group No.	Time of L-asparaginase injection before death (h)	Dose L-asparaginase (IU/kg)	Radioactivity (c.p.m./mg DNA)	Per cent inhibition
1	—	—	2,194 ± 1,313	—
2	1	780	478 ± 191	78 $P < 0.02$
3	4	780	912 ± 468	58 $P < 0.02$

Four animals were used in each group.

Perkin-Elmer offers you the most complete range of U.V. Spectrophotometers in the world!

One of them is ideal for your application. For instance, the new Model 402 scans from 190 to 850 nm in only two minutes and gives you built-in ordinate scale expansion, selectable wavelength limit switches, time drive and repetitive scanning, Flowchart recording, plus automatic multiple sampling to follow enzyme reactions. The Model 124 is a double-beam instrument with manual or recording operation, whilst the Model 139 has an extensive range of accessories for unsurpassed versatility. The Model 6/20 is robust and reliable, ideal for routine clinical use. The Model 356 is a dual wavelength instrument which can record single-beam, double-beam or derivative spectra and give accurate measurements on turbid samples.

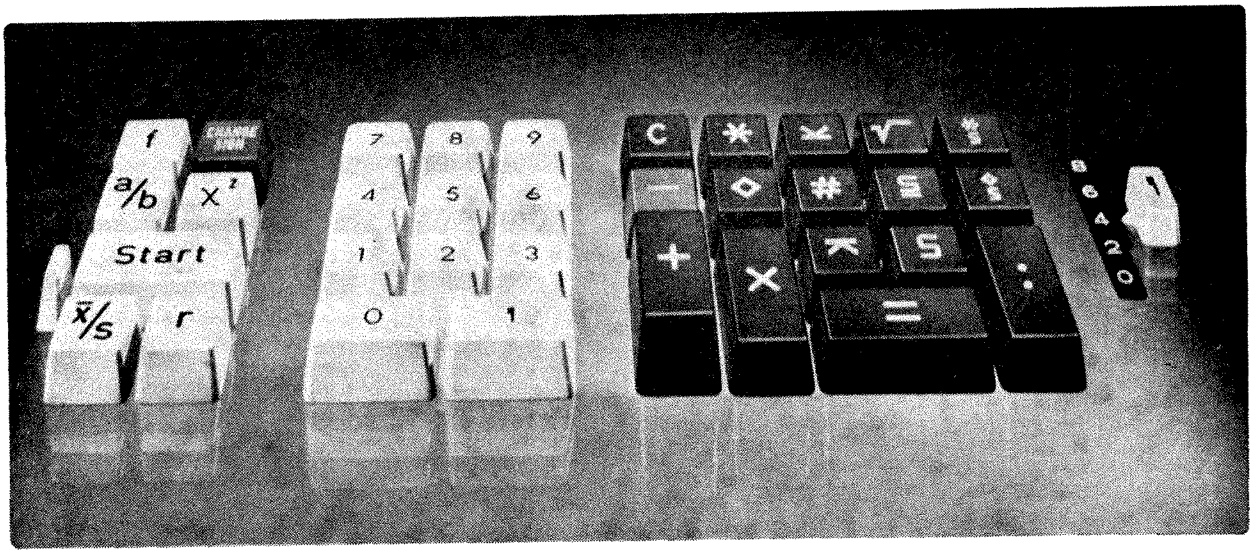
PERKIN-ELMER

DIEHL sigmatron

Electronic Calculating System with Pre-programmed Statistical functions



DIEHL sigmatron is the first calculating system specifically designed for Statistical calculations. By pre-programmed functions, Statistical calculations are reduced to one key operations. For instance, to obtain the Arithmetic Mean and Standard Deviation enter data on the keyboard and touch the pre-programmed key. After entry of the data is completed you need only touch the same pre-programmed key to obtain the results immediately. Linear Regression, Chi Square, Coefficient of Correlation are all reduced to the simplicity of one key operation. DIEHL sigmatron also gives you a powerful and effective calculating performance with ten separate memories, automatic square root, automatic decimal selection up to 8 places and a complete check of each figure, each step and each result.

If you prefer to make your own programs, DIEHL combitron S has 10 Program/Memory registers providing a capacity of 120 steps with branching and looping.

For external input of data, DIEHL dilector – punched tape reader – is available.

Table 2. DNA POLYMERASE ACTIVITY OF RAT LIVER NUCLEI

	c.p.m./mg DNA 0 min	10 min	20 min
Controls	461 ± 60	14,475 ± 1,990	22,400 ± 3,505
+ L-Asparaginase	640 ± 74	14,600 ± 1,410	22,800 ± 1,617

Four rats received 780 IU/kg L-asparaginase 2 h before being killed. Four control animals received 0·5 ml. 0·43 M $(NH_4)_2SO_4$. The incubation mixture contained 80 μM each of dATP, dGTP, dCTP; 1 μCi dTTP (5 Ci/mmole); 0·5 ml. nuclear suspension (corresponding to 0·8 mg nuclear DNA); 21·1 mM N-2-hydroxyethylpiperazine-N′-2-ethanesulphonic acid (Hepes) buffer; 16·5 mM $MgCl_2$; 0·312 M sucrose. The *p*H was 8·1 and the total volume 0·8 ml.

Table 3. RNA POLYMERASE ACTIVITY OF ISOLATED RAT LIVER NUCLEI IN THE PRESENCE OF L-ASPARAGINASE

Group No. (3 tests/group)	Radioactivity (c.p.m./mg DNA) 0 min	10 min	20 min
1 (control)	400 ± 50	10,720 ± 400	16,030 ± 1,250
2 (+1·5 IU/sample)		12,500 ± 1,800	16,640 ± 2,100
3 (+7·5 IU/sample)		11,680 ± 390	16,280 ± 160
4 (+15 IU/sample)		11,380 ± 1,400	15,870 ± 110

L-Asparaginase was added directly to the incubation mixture which contained, in a final volume of 0·8 ml.: 50 mM Tris (*p*H 8·5); 5·6 mM spermidine · 3 HCl; 8 mM NaF; 2·5 mM phosphoenolpyruvate; 1·875 mM $MgCl_2$; 45 μM each of ATP, CTP and GTP; 0·45 μM ^{3}H-UTP (1 μCi); 1–2 IU pyruvate kinase; nuclear suspension corresponding to 0·6 mg nuclear DNA; 0·094 M sucrose. L-Asparaginase (Boehringer) was dissolved in 0·1 ml. H_2O; controls were dissolved in 0·1 ml. 0·43 M $(NH_4)_2SO_4$.

In another experiment, four rats were given 900 IU/kg L-asparaginase 90 min before being killed. In these conditions, the average labelling of nuclear DNA in the control group (four animals) was found to be 1,262 ± 220 c.p.m./mg DNA and that of the L-asparaginase treated group only 510 ± 158 c.p.m./mg DNA. This difference was highly significant ($P < 0.002$). There is no influence of the enzyme on nuclear DNA and RNA polymerase even when pre-injected *in vivo* (Tables 2 and 3). When L-asparaginase (15 IU/sample) was added to the incubation mixture directly, no effect was detectable either.

Although a satisfactory explanation for the rapid and remarkable inhibition of ^{3}H-thymidine uptake into rat liver cell nuclei caused by L-asparaginase cannot yet be given, these data constitute further evidence for the hepatotoxicity of the enzyme. A similar effect has been shown with leukaemic lymphocytes[2,16]. Using a highly purified preparation (specific activity 220 IU/mg protein), any toxic effects of contaminating *E. coli* endotoxins should have been excluded.

We thank Miss Margot Ickelsheimer for technical assistance. The study was aided by grants from the Deutsche Forschungsgemeinschaft.

Changes underlying Halothane-induced Malignant Hyperpyrexia in Landrace Pigs

MALIGNANT hyperpyrexia is a rare but often fatal complication of inhalation anaesthesia in man[1]. The fluorinated hydrocarbon halothane, $CF_3CHBrCl$, is among the many anaesthetic agents which have been implicated[2]. A similar syndrome has been described in a pure Landrace strain of pig[3]. The onset of this phenomenon is rapid (10–15 min after administration of halothane) and there is extreme rigidity of skeletal muscles, a rapid rise in body temperature to 42°–45° C, severe acidosis and a fatal outcome in spite of cooling, muscle relaxants and intravenous alkalis. Once initiated, the process seems independent of the tissue concentration of halothane, which appears to act as a trigger. A few animals have recovered after brief exposure to halothane.

Wilson *et al.* have suggested uncoupling of oxidative phosphorylation as a possible mechanism[2]. The process is augmented by dinitrophenol and halothane is known to uncouple oxidative phosphorylation in normal rat liver mitochondria *in vitro*[4].

All animals studied were of pure Landrace or Landrace–Large White cross strains. No untoward effects of thiopentone were observed in susceptible pigs over periods of up to 150 min. Monitoring was accordingly established under controlled steady state conditions of thiopentone anaesthesia with pigs breathing oxygen. Observations made during thiopentone anaesthesia were compared with those following halothane. Arterial blood samples and pressure readings were taken from a femoral catheter. Venous blood was withdrawn from an indwelling right atrial catheter. Temperatures of the core (oesophagus and rectum), liver, muscle and skin were recorded by thermistor probes. Oxygen uptake was measured with a Benedict–Roth spirometer and respiration was assisted during apnoeic periods by manual chest compression. Carbon dioxide output was determined gravimetrically after absorption in $CaCl_2$/soda-lime. The acid-base status of the blood was measured by the Astrup technique[5]. Total CO_2 content, serum concentrations of Na^+, K^+, Ca^{2+}, Mg^{2+}, total protein and inorganic phosphate (P_i) were determined by standard clinical laboratory techniques. Blood lactate[6] and pyruvate[7] were determined enzymatically. Blood oxygen tensions were measured with a Clarke electrode. Biopsies of muscle were assayed for glycogen[8] and ATP[9].

Anaesthesia with thiopentone for up to 150 min had no effect on organ temperatures. Within 10 min (usually 3–4 min) of introducing halothane, the temperature of all organs rose, except skin (Fig. 1). Cooling of the latter and cyanotic blotchiness indicated decreased circulation. After discontinuing halothane, the temperature continued to rise and maximum core temperature (oesophagus) was reached at 30–45 min.

O_2 consumption and CO_2 output after giving halothane were compared with control periods of isothermia on thiopentone anaesthesia. The results (Fig. 2) reveal augmented uptake of oxygen, but the disproportionate rise in CO_2 output resulted in high respiratory quotients (1·69 in one experiment). Oxygen consumption rose 20–40 per cent per °C rise in core temperature. Between 38° and 39° C, passive heating raises O_2 consumption 18 per cent in rats[10] and 12–15 per cent in normal human adults[11]. Increased oxygen consumption appeared therefore to be slightly greater than that expected from elevated temperature alone.

Table 1 presents some metabolic changes observed during the development of malignant hyperpyrexia. These changes, initiated by halothane, were: (*a*) Shift of water into the intracellular space; serum Na^+ and total protein concentrations both increased. (*b*) Shift of Ca^{2+} and Mg^{2+} into the extracellular space.

Concentrations of these two cations rose disproportionately with respect to serum protein concentration assuming 50 and 30 per cent, respectively, to be protein bound. (*c*) Release of P_i into plasma. (*d*) Increase in blood glucose. In control animals blood glucose tended to fall from values of 60 to 80 to below 50 mg/100 ml. after 2 to 3 h of anaesthesia. (*e*) Uncompensated metabolic acidosis resulting from a rise in plasma lactate. The base deficit was equivalent to the increase in plasma lactate and reflected a pure lactic acid acidosis. A respiratory defect, denoted by lowered arterial pO_2 in spite of administering 100 per cent oxygen, could be partly responsible for elevated pCO_2. In spite of diminished respiratory gaseous exchange, however, raised CO_2 output, measured gravimetrically (Fig. 2), doubtless arose from the reaction: $H^+ + HCO_3^- \rightarrow H_2O + CO_2$. Although both plasma lactate and pyruvate concentrations increased, "excess lactate", calculated according to Huckabee's formula[12], indicated a net shift in the equilibrium $NADH + H^+ + pyruvate \rightleftharpoons lactate + NAD^+$, in favour of lactate; presumably the result of accumulation of NADH.

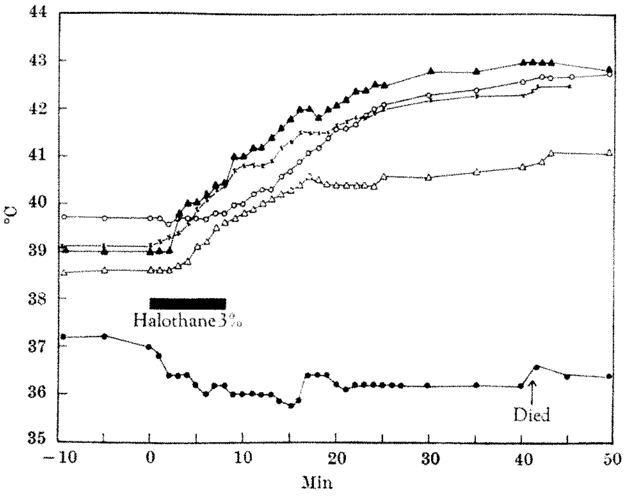

Fig. 1. Temperature changes in organs of pig 82A induced by halothane. While anaesthetized with thiopentone alone, no significant changes took place in those portions of the curves from −150 to −10 min. Halothane, 3 per cent (v/v) in O_2, was commenced at 0 min. and discontinued at 8 min. ▲, Liver; ○, rectum; ×, oesophagus; △, muscle (gluteus); ●, abdominal skin.

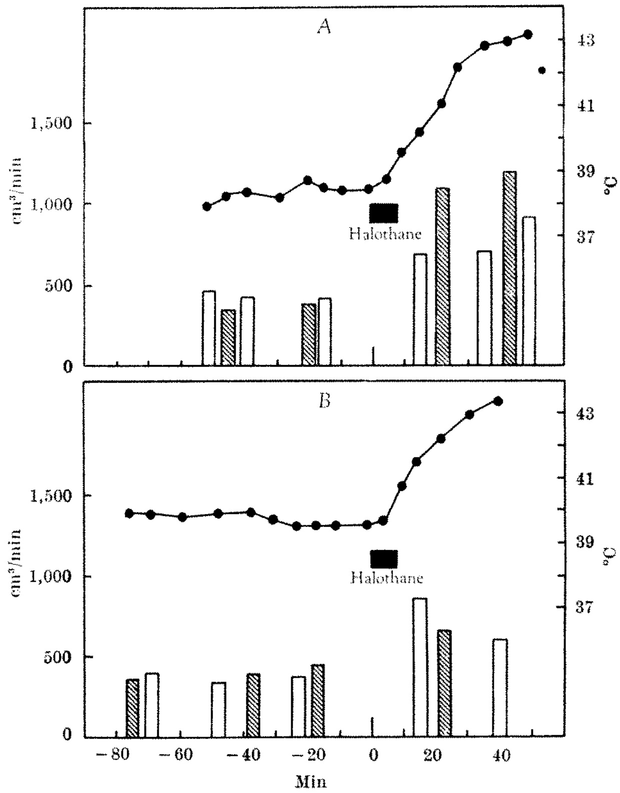

Fig. 2. *A*, Pig 39A, weight 80 kg; *B*, pig 82A, weight 56·1 kg. Effect of halothane on O_2 consumption and CO_2 output. O_2/CO_2 exchange was measured over timed 4 min periods. Halothane, 3 per cent (v/v, in O_2), was given from 0 to 8 min. White columns, O_2; hatched columns, CO_2. ●, Oesophageal temperature.

To establish more precisely the interrelation between the observed biochemical and temperature changes, these were carefully timed in a separate experiment on a susceptible pig (82A) in the first 10 min after halothane induction. During this period, oesophageal temperature rose from 39·5° to 40·8° C. All the expected changes had occurred within 4 min and Ca^{2+} and Mg^{2+} shifts and P_i and lactate production were apparent at 2 min. It was therefore clear that biochemical changes preceded the onset of pyrexia and were not secondary to heat injury to tissues. The sequence of metabolic changes that we have encountered in pigs sensitive to halothane seems to be completely different from that associated with heat injury[13], in which rise in blood lactate is a late manifestation.

Halothane, in susceptible pigs, initiates massive and uncontrolled glycogenolysis with production of "excess lactate" and a rise in blood glucose. The mechanism responsible for this is not immediately clear, because the usual anaerobic causes of lactate accumulation can be excluded. The animals breathed pure oxygen throughout the experiment and arterial oxygen tensions were maintained above 100 mm Hg in all cases. Blood pressure was over 100 mm systolic, but did fall terminally after lactacidosis had become well established. Cyanotic blotchiness and decline in temperature of the skin, however, provided evidence of a local perfusion defect, but its contribution to the stimulation of glycogenolysis in this and other tissues, for example, muscle, cannot be evaluated. Skin anoxia is considered unlikely to be responsible for the lactacidosis, for it appeared after 8–10 min on halothane (after serum lactate had risen) and was transient. The magnitude of the lactacidosis, moreover, continued to increase after the skin had returned to a healthy pink

Table 1. PIG 39A. EFFECT OF HALOTHANE ON BLOOD COMPOSITION

Experimental details are as in Fig. 2*A*.
* Calculated from total blood CO_2 and pH.

colour. The possibility remains that muscle rigor resulted in occlusion of blood vessels causing an anaerobic state in muscle. The concentrations of muscle glycogen after halothane fell in two animals from 0·56 and 0·35 to 0·28 and 0·20 g/100 ml., respectively. In one instance muscle ATP fell from 2·7 to 2·2 mg/100 ml., concentrations above those at which fully developed rigor mortis is to be expected[14]. In the pigs we studied, the mechanism of muscle rigor seemed to be intrinsic, for the relaxant, tubocurarine, was ineffective in dispelling the rigidity. Impairment of blood supply to a limb consistently delayed onset of rigidity, suggesting that the effect of halothane on muscle is humoral rather than neural.

For the purpose of discussion of the origin of heat, we may consider pig 82A (weight 56·1 kg). Assuming a water content in the body of 67 per cent by weight and disregarding body solids (whose specific heat is not easily measured), the rise in temperature observed (3·9° C) represents extra heat of 147 kcalories, which—averaged over 40 min—is equivalent to 3·68 kcalories/min. Initially, however (5–10 min), the rate was 10·5 kcalories/min. If this extra heat were strictly related to increased O_2 utilization, 2·18 l./min additional O_2 consumption should have resulted (assuming that 1 l. O_2 consumed generates 4·825 kcalories[15]) whereas the measured increment at 15 min ($T = 41{\cdot}5°$ C) was 0·38 l./min and by 40 min ($T = 43{\cdot}4°$ C) the increment had fallen to 0·22 l./min. Non-oxidative mechanisms seem to be at least partly responsible for the excess heat production. Possibly anaerobic sources of heat include: (*a*) Glycolysis:

$$(\text{Glucose})_n + H_2O \longrightarrow (\text{glucose})_{n-1} + 2\ \text{lactate} + 2H^+$$

for which $\Delta F^{\circ\prime} = -52{\cdot}4$ kcalories/mole[16]. In pig 82A, heat from this source = 21·7 kcalories. (*b*) Neutralization of lactic acid:

$$H^+ + OH^- \longrightarrow H_2O;\ \Delta H = -13{\cdot}6\ \text{kcalories/g equivalent}$$

In the experimental animal this process provided 11·3 kcalories. These calculations are based on the rise in serum lactate concentration and are minimal because the quantity of lactate oxidized was unknown. (*c*) Hydrolysis of high energy phosphate esters.

During anaerobiasis, fall of creatine phosphate in frog sartorius muscle corresponds to rise in its P_i content[17]. Assuming that the released extracellular P_i was derived from compounds possessing high phosphate bond energy, for example creatine phosphate, ATP or phosphoenal pyruvate, capable of yielding 10 kcalories/mole, the rise in serum phosphate from 10 to 30 mg/100 ml. represents 2·4 kcalories in this animal. The sum of accountable anaerobic heat sources amounted to 35·4 kcalories or about 25 per cent of that actually evolved. We are investigating other potential heat sources which could be activated by halothane.

The mechanism by which halothane stimulates excess heat production in susceptible pigs is still obscure. Certain conclusions can, however, be reached which will influence further investigations and possibly management of the similar condition occurring in man.

(1) Excessive heat production is not accountable in terms of oxidative mechanisms and uncoupling of oxidative phosphorylation. Halothane induced an anaerobic state favouring breakdown of glycogen and organic phosphate esters. Anaerobic mechanisms have not previously been considered as possible sources of physiological or pathological heat.

(2) Alterations in the distribution of water and electrolytes and lactic acid production preceded significant rise in temperature and must be regarded as primary and not secondary to non-specific heat damage. They were apparently closely related to the development of muscle rigor. The lactate acidosis was uncompensated and blood pCO_2 rose to levels which could cause narcosis. Immediate treatment with intravenous HCO_3^- is contraindicated because death could ensue from CO_2 poisoning rather than H^+ accumulation.

(3) Known causes of defective tissue oxygenation could not account for the extent of lactate production. Future studies will aim at localizing a possible defect in mitochondrial electron transport.

We thank Misses P. du Toit and A. Munro for technical assistance. Dr R. Hickman selected the susceptible animals. We acknowledge financial support from Anglo-American and De Beers Anaesthetic Research Fund.

Transformation of Hamster Macrophages into Giant Cells with Antimacrophage Serum

THE sequence of cellular changes leading from monocyte to macrophage, epithelioid cell and finally multinucleated giant cell is now well documented both *in vitro* and *in vivo*. These changes, however, occur only in prolonged culture and in normal conditions only a small number of cultured macrophages have a tendency to undergo such transformation[1,2]. It is known that antimacrophage serum (AMS) has a marked influence on the physiology of the macrophage, the target structure probably being the cell membrane[3]. Agglutination of macrophages and decrease in the rate of phagocytosis have been described by several authors[3,4]. Moreover, Unanue[4] found macrophages showing aberrant nuclear changes in the peritoneal cavity of AMS-treated mice. This report concerns the influence of the protracted action of AMS on the development of giant cells in the cultures of mouse and hamster peritoneal macrophages.

AMS was produced in rabbits by four intravenous injections of 10^7 cultured mouse (Porton strain) or Syrian hamster macrophages at weekly intervals. Thioglycollate stimulated macrophages, for immunization, were cultured for 3 days in Eagle's basal medium supplemented with 40 per cent of inactivated horse serum. Ten days after the last injection the animals were exsanguinated and the sera, after heat inactivation, were absorbed twice with an equal volume of packed mouse or hamster red blood cells. For our experiments, sera with cytotoxic titres of at least 1/160 were used. Mouse or hamster antilymphocyte serum (ALS) was prepared in rabbits by the schedule used for AMS and absorbed twice with mouse erythrocytes. For immunization, peripheral lymph node cells were used. The unstimulated mouse or hamster macrophages were obtained by washing the peritoneal cavity with Eagle's basal medium. The fluid containing peritoneal cells was withdrawn and transferred to Leighton tubes with flying coverslips. The medium was changed every second day. Between 2 and 5 days later (sometimes even longer) AMS or ALS in different concentrations was added to the fresh medium. To the control tubes inactivated normal rabbit serum was added in similar dilutions. Each culture was observed daily in the light microscope. At different times the coverslips were removed and the cells examined, unfixed, by phase contrast and interference microscopy or by staining with haematoxylin-eosin. In 5 day cultures, macrophages form about 97 per cent of the total cell count, the remaining cells being classified as fibroblasts. In these conditions the number of hamster macrophages containing two or three nuclei does not exceed 5·5 per cent; the number of multinucleated giant cells is less than 0·5 per cent. These numbers do not alter significantly in older cultures.

Hamster macrophages after 2–5 days of culture (Fig. 1*A* and *B*), and after the addition of AMS—even at the final dilution of 1/50—exhibit the following sequence of changes in the course of several hours. Initially, because of the disappearance of cell extensions, the macrophages become round and then stick together to form aggregates containing two to four cells (Fig. 1*E*). After 3–4 h the aggregation of macrophages is more pronounced and many cells are arranged in coral-bead structures (Fig. 1*C* and *D*). The degree of agglomeration of cells exceeds 96 per cent, whereas in untreated controls it is 3–5 per cent. At this stage only a slight increase in the number of cells containing two or three nuclei is visible. At 24 h nearly all the macrophages fuse (96 per cent) and form multinucleated cells containing from a few up to several scores of nuclei (Fig. 1*F*). The fusion is preceded by a stage of strong cyto-adherence with pronounced duplication of the cell membrane (Fig. 1*C* and *E*). The possibility that some of the giant cells arise as a result of cell division cannot be entirely excluded, although the mitotic index of AMS-

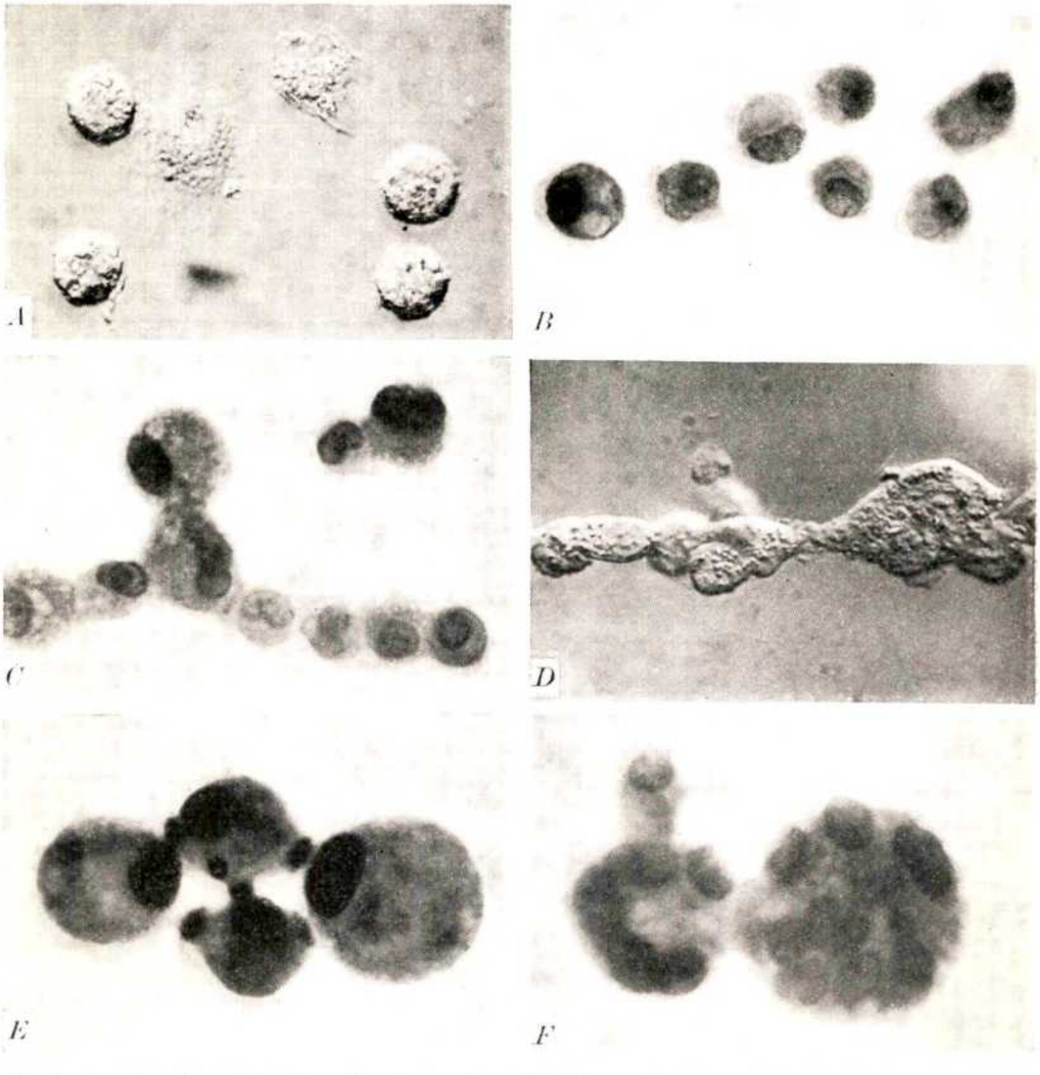

Fig. 1. *A*, 5 day culture of hamster peritoneal macrophages; interference microscope, × 300; *B*, the same, stained with haematoxylin-eosin, × 300; *C*, bead-like arrangement of macrophages exposed to antimacrophage serum, stained with haematoxylin-eosin, × 300; *D*, bead-like arrangement of macrophages and giant cell formation; 24 h exposure to AMS; interference microscope, × 150. *E*, Early stage of macrophage fusion and giant cell formation; note the duplication of cell membranes; stained with haematoxylin-eosin, × 900; *F*, giant multinuclear cells, 36 h exposure to AMS, stained with haematoxylin-eosin, × 300.

treated macrophages is lower (0·2 per cent) than that of untreated cells (0·4 per cent). Measurements in the interference microscope revealed a distinct increase in the dry mass of giant cells as compared with macrophages. The macrophage cultures treated with ALS—even at the final dilution of 1/5—showed no such changes, nor were they visible in control cultures. Higher concentrations of ALS or normal rabbit serum exert a cytotoxic effect on macrophages. The effect of AMS can therefore be attributed to its specific action on hamster macrophages. In none of the many experiments with macrophages from various strains of mice were similar changes observed, following the action of specific AMS, except for cell aggregation.

It has been shown that antibody against the surface antigens of Krebs ascites tumour cells can have a stimulating effect on the surface activity of these cells appearing in the interdigitations of the cell membranes of adjacent cells[5]. The differing reactions of hamster and mouse macrophages after treatment of AMS may be related to the different degree of maturity of these cells. The mononuclear phagocytes in the unstimulated peritoneal cavity of the hamster, by contrast with those in the mouse, more closely resemble blood monocytes than macrophages. During their cultivation, however, typical macrophages develop. We have observed that monocyte-like macrophages from 2–5 day cultures react more readily to AMS than mature macrophages from later phases of cultivation. It can therefore be assumed that during the differentiation of macrophages substantial changes in the structure of the cell membrane take place. The factors influencing the development of giant cells from macrophages are not fully understood. The origin of these cells has frequently been attributed to the increased rate of phagocytosis by macrophages[6,7]. It seems, however, that AMS, acting specifically on the surface of the macrophage, promotes cell development in the same direction. This assumption is substantiated further by the fact that the cultured macrophages can be fused by means of Sendai virus acting on the cell membrane[8].

Stimulation of Mitosis in Amphibian Kidney by Organ Specific Antiserum

IT has been shown that the rate of mitosis in the pronephric kidney of larval *Xenopus* is inhibited by factors present in soluble fractions of homogenized adult *Xenopus* kidney (mesonephros) or rat kidney (metanephros)[3,10] and it was suggested that the rate of cell division in the kidney may be controlled by a tissue-specific mitotic inhibitor or chalone such as has been described in other tissues[1,9,11,13]. Although the rate of mitosis in the larval pronephros is sensitive to the "kidney chalone" we do not know whether it is controlled by the chalone in natural conditions, because this would imply that the pronephros already produces the chalone at this early stage in development. Extraction of the chalone from such a small organ would be difficult and we have therefore sought a different way of demonstrating its presence.

An antiserum can be produced to the epidermal chalone[6] and if this is also true for the kidney we should expect that the immediate effect of a kidney chalone antiserum on the pronephros would be to neutralize any endogenous chalone and hence to stimulate mitosis. This hypothesis has been examined.

The effect of test substances on the mitotic rate in the pronephros was measured in the way previously described[3,10]. Trunk regions containing the pronephros and epidermis and variable amounts of skeletal muscle, spinal cord and in some cases heart, were dissected from stages thirty-two to thirty-three (post-tailbud) *Xenopus laevis* larvae. These pronephric explants were cultured in groups of five for two days in Niu and Twitty balanced saline solution (BSS) with 250 µg/ml. of streptomycin at 25° C. Four hours before fixation, test substances were added together with colcemid (0·025 mg/ml.) to accumulate mitoses at metaphase. The number of arrested metaphases was counted in a sample of 1,000 pronephric or epidermal cells from each explant (5,000 cells per group of five) and the mean mitotic incidence (*MI*) expressed as the proportion of arrested metaphases per 10^5 cells.

An extract of rat kidney was prepared in the manner described earlier for *Xenopus* kidney[3,10]. The perfused kidneys were homogenized in 3·5 times their volume of BSS using a teflon pestle. The homogenate was centrifuged at approximately 100,000*g* and the clear supernatant freeze-dried and stored at –70° C. Extracts of rat liver and lung were made in the same way.

The specific inhibitory activity of this extract preparation was assessed by adding it to pronephric explants at a concentration of 25 mg dry weight equivalent/ml.[3,10]. The *MI* of pronephros in control explants was $1,771/10^5$, compared with $262/10^5$ for kidney extract. The kidney extract thus depressed mitosis by 85 per cent ($P < 0\cdot001$). No significant alteration in *MI* was achieved by the addition of rat lung ($1,721/10^5$) or liver ($1836/10^5$) extracts to the medium at the same concentration. These results are very similar to those obtained with *Xenopus* organ extracts and it thus seems that the inhibitory factor present in the kidney is tissue specific but not species specific.

An adult rabbit was immunized with the inhibitory kidney extract following a schedule described in detail elsewhere[14]. A total of four series of injections was given at intervals of fifteen days. For the first series a quantity of extract equivalent to 0·3 mg of protein was made up to 3 ml., emulsified with an equal volume of Freund's complete adjuvant, and injected intramuscularly at four different sites. For the second and third series of injections the dose was increased to 3 mg protein emulsified with Freund's adjuvant, and for the fourth series of injections 3 mg protein suspended in normal saline was given. Seven days after the final injection a sample of 20 ml. of blood was taken from the marginal vein of the ear. This was stirred to remove fibrinogen, incubated at 37° C for 3 h and centrifuged at 4,500 r.p.m. for 30 min. The clear supernatant serum ("kidney antiserum") was stored at –70° C. Normal rabbit serum was prepared in the same way using a sample of blood taken from a non-immunized animal.

Kidney antiserum or normal serum was added to the culture medium to give a final concentration of 5 per cent and the effects of these two treatments on the *MI* of pronephros and epidermis are compared in Figs. 1 and 2. In explants treated with kidney antiserum the *MI* of the pronephros was increased by 42 per cent ($P < 0\cdot02$) but that of the epidermis was decreased by 42 per cent

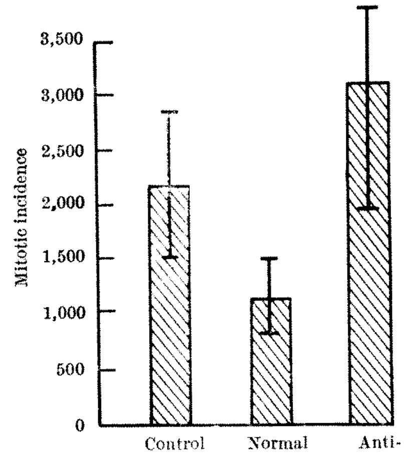

Fig. 1. Effect of normal serum (5 per cent) and kidney antiserum (5 per cent) on mitotic incidence in the pronephros of larval explants of *Xenopus laevis*.

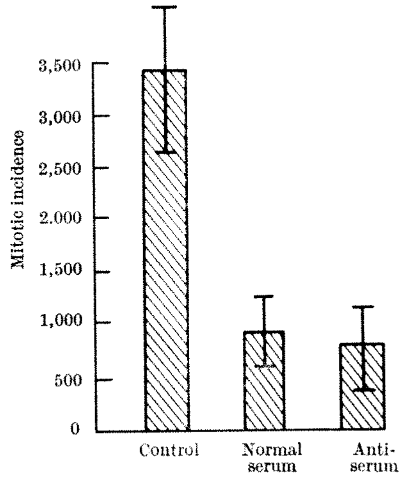

Fig. 2. Effect of normal serum (5 per cent) and kidney antiserum (5 per cent) on mitotic incidence in the epidermis of larval explants of *Xenopus laevis*.

($P < 0{\cdot}001$) compared with untreated control explants. In explants treated with normal serum the *MI* in both pronephros and epidermis was decreased ($P < 0{\cdot}001$) by approximately the same amount as in the epidermis of antiserum-treated explants.

Preparations of serum from adult non-immunized animals are frequently found to be toxic to cells in culture[12] probably because they contain antibodies to common tissue antigens[4]. This is the probable explanation for the mitotic depression in pronephros treated with normal serum and that in epidermis treated with either normal serum or kidney antiserum. The probable explanation for the increased rate of mitosis in pronephros treated with kidney antiserum is that the pronephros contains a growth inhibitor identical to that contained in adult kidney extracts and that this inhibitor is neutralized by the antiserum. Our results therefore support the view[2] that synthesis of the "kidney chalone" begins during the development of the larval pronephros.

The observation that kidney antiserum stimulates cell division in the pronephros of cultured explants may have a bearing on the aetiology of autoimmune glomerulonephritis. In some forms of this disease proliferative changes occur in a number of cell types[5,7] including the glomerular epithelium[8], and we propose that these localized increases in the rate of cell production may in some cases be caused by circulatory antibodies against tissue specific mitotic inhibitors present in the kidney.

Absolute, Unambiguous Ultramicroanalysis of Metabolites present in Complex Biological Extracts

The analysis of substances of biogenic interest is usually difficult and often ambiguous because the metabolite of interest is usually present at low concentration in a complex mixture. Quantitation usually proceeds via prefractionation (organic solvent extraction, ion exchange or absorption), chromatographic separation and then a relatively specific chromogenic or fluorogenic reaction either directly on the chromatogram or, after elution, in solution. The certainty of identification using these, or variants of these, procedures is limited. This is particularly so in the field of biochemical psychiatry where over the past few years there have been numerous examples of chromatographically separated chromogenic factors which have meant different things to different people (further details in ref. 1). We present here preliminary data on the use of a new technique—the so-called "integrated ion current (IIC) technique"—involving the high resolution double focusing mass spectrometer (in our case, the MS9 manufactured by Associated Electrical Industries).

When the mass spectrometer is used conventionally in the quantitative analysis of sample mixtures, a large reservoir of sample vapour is usually kept at a constant low pressure while allowing a very small fraction to flow into the instrument through a constriction such as a sinter. The ion currents recorded on ionization of the sample in the instrument are proportional to the partial pressures of the respective components of the sample mixtures in the reservoir. The ratio of the ion current at any appropriate m/e value to the partial pressure of the component responsible is substantially constant during times which are long compared with the duration of the recording. This ratio, which is called the sensitivity of the instrument for that particular component, may be determined by calibration with a standard sample of the component.

This technique is inappropriate when only small samples in the nanogram range of mixtures of materials of biological origin having a comparatively low vapour pressure are available. It is possible, however, to use an alternative technique in which the ion current at a significant m/e value for each component is recorded separately while small samples of the solid mixture are evaporated from a probe. This probe is inserted into the vacuum system and sample evaporation takes place close to the ionizing beam. It is then possible to relate the integrated ion current at the selected m/e value to the weight of pure component evaporated and so calibrate the instrument. This technique enables samples in the subnanogram range to be estimated[2]. In order to compensate for any instrumental instability, it is convenient to make a series of measurements of ion current at intervals of 1 s using the peak matching facilities.

This technique has been applied to the analysis of *p*-tyramine in human urine and in various anatomical regions of the rat brain. *p*-Tyramine was selected in this first instance because it has been positively identified in human urine[3], but its concentration is different from normal in some patients suffering from Parkinson's disease, migraine and schizophrenia[3,4]. It has not hitherto been positively identified in brain material. Furthermore, two relatively specific chromatographic analytical procedures, one macro[5] the other semi-micro (A. A. B. and L. Quan, paper presented at the second International Neurochemistry meeting, Milan, September 1969), were available for comparative purposes.

A record of the evaporation of a 1 ng sample of *p*-tyramine at a temperature of 200° C is shown in Fig. 1. Each vertical line represents a single determination of the ion current at m/e 108. It is the area under the envelope which is proportional to the integrated ion current and hence to the weight of *p*-tyramine evaporated. A calibration curve for *p*-tyramine in the 10–100 ng region is shown in Fig. 2.

Co-evaporation of any compounds which do not have peaks in their mass spectra at m/e 108 has no effect on the sensitivity of the instrument for *p*-tyramine provided that the source pressure does not reach so high a value that ionization is suppressed. If, however, a compound is co-evaporated which can produce an ion with an m/e value of 108, then the integrated ion current is the sum of the individual contributions and interference takes place. The possibility that two compounds will evaporate at the same temperature and provide an identical ion is a slight one and it has been demonstrated that even in the case of geometrical isomers such as, for example, cis- and trans-stilbene the integrated ion current curve shows fine structure caused by the differential evaporation of the isomers (J. R. M., unpublished work).

There remains the possibility that two such substances may co-evaporate, each providing an ion at the integral m/e value of 108 but with ions having a different atomic constitution. As a result, the precise mass of these ions may differ by a few hundred parts per million. A high resolution mass spectrometer can record ion currents due to ions differing by this slight mass interval as two separate peaks. Such an effect is observed when the phenolic amine extract[6], containing *p*-tyramine, isolated from rat brain is examined by the integrated ion current technique. Each determination of the ion current at m/e 108 is represented by two lines each corresponding to a different ion. The two ions responsible are $C_7H_8O^+$ (from *p*-tyramine) with a precise mass of 108·0575 and $C_8H_{12}^+$ with a precise mass of 108·0939. The envelopes of these two separate ion peaks can readily be identified and so the amount of *p*-tyramine in the mixture may still be estimated using the calibration graph. In cases where double envelopes appear at one m/e value, it may sometimes be possible to find an alternative m/e value where only one ion current is registered or alternatively modify the substance of interest by deuterium exchange labelling or by the formation of a simple derivative.

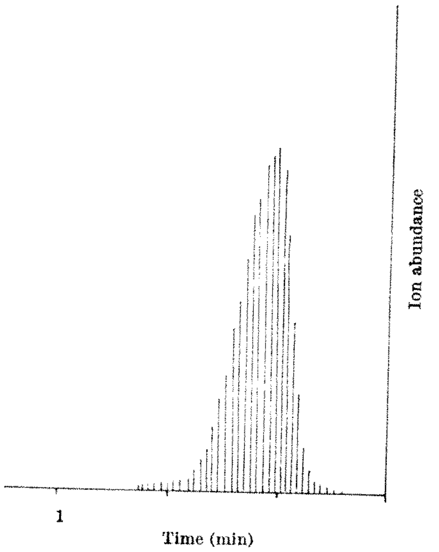

Fig. 1. Record of the ion current at m/e value 108 during evaporation at 200° C of 1 ng of *p*-tyramine.

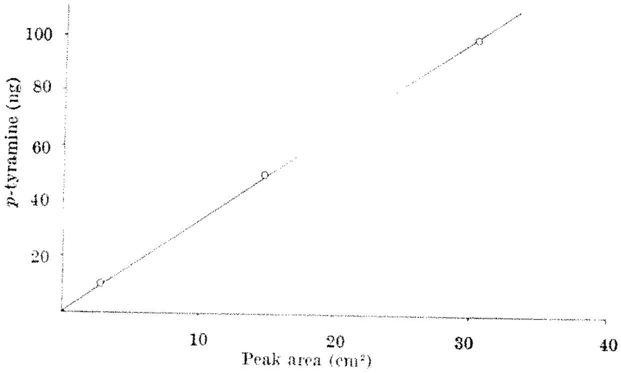

Fig. 2. Calibration curve for *p*-tyramine using the integrated ion current technique.

Table 1. REGIONAL DISTRIBUTION OF *p*-TYRAMINE IN RAT BRAIN

Sample No.	Brain area	IIC technique		Chromatographic technique
		ng *p*-tyramine	ng *p*-tyramine per g tissue	ng *p*-tyramine per g tissue
1	Whole brain	43	200	192 ± 24 (8 estimations)
2	Whole brain	43	224	
3	Whole brain + 500 ng	91	478	—
4	Whole brain + 500 ng	97	483	—
5	Caudate nucleus	11·3	587	—
6	Hypothalamus	14	1,690	—
7	Cerebellum	14	229	—
8	Stem	10	201	—
9	Rest	15·5	54·7	—
10	Blank	Nil	—	—

Rats were stunned, decapitated and their brains removed. The various areas were then dissected out. Whole brains or the dissected areas from two brains were washed in ice cold saline solution and then homogenized at 2° in 0·4 N $HClO_4$. After centrifugation, the supernatant was neutralized with 1 N NaOH and the phenolic amine fraction isolated by ion exchange chromatography as described by Kakimoto and Armstrong[6]. For IIC (see text) estimations the extract was triturated in 50 µl. ethanol : ammonia, 70 : 30 (v/v) and a 5 µl. sample placed directly into the mass spectrometer. Recovery of added *p*-tyramine is effectively 100 per cent. Quantitative chromatographic analysis was achieved following separation of the total phenolic amine extract on Kodak (silica gel) TLC plates in the solvent system butanol : acetic acid : water, 4 : 1 : 1 (v/v). The *p*-tyramine zone was eluted, danyslated and separated twice more on Kodak (silica gel) TLC plates in the solvent systems chloroform : butyl acetate, 5 : 1 (v/v) and ethyl acetate : cyclohexane, 3 : 2 (v/v)[7]. The fluorophore was then finally eluted in benzene : acetic acid, 99 : 1 (v/v)[7], and measured in the spectrophotofluorometer. The overall recovery of added *p*-tyramine by this procedure is 54 ± 10 per cent Further details were given in a paper presented by A. A. B. and L. Quan at the second International Neurochemistry Meeting, Milan, September 1969.

In this present case, the alternative m/e value of 137 also showed a double envelope caused by the ions $C_8H_{11}ON^+$ (from *p*-tyramine) with a precise mass of 137·0841 and $C_{10}H_{17}^+$ with a precise mass of 137·1330. The precise origin of the hydrocarbon ions is uncertain, but they may be fragments of lipid originating in the homogenization procedure (A. A. B. and L. Quan, paper presented at the second International Neurochemistry Meeting, Milan, September 1969) and carrying through in the subsequent aqueous operations. They were not present in urinary phenolic amine extracts. Using this new technique, however, their presence does not interfere with the estimation of *p*-tyramine in the samples and, further, it is possible that if they could be identified their concentration could be determined at the same time as that of *p*-tyramine in a single evaporation, a result which has not previously been possible.

The results of *p*-tyramine determination on extracts of various areas of rat brain using this technique are compared with those obtained by a fluorimetric procedure based on the chromatographic separation of the 1-dimethlyaminonaphthalene-5-sulphonyl (Dansyl) derivative.

The further development of this technique towards analysis at the picrogram level and its use in the analysis of other amines and their respective metabolites in various neurochemical specimens is currently in progress.

We thank Miss L. Quan for making available her chromatographic data and for help in obtaining the various brain areas, and Miss M. J. A. Reade for carrying out the mass spectrometric determinations. Flying Speed of the Largest Aerial Vertebrate

THE Cretaceous pterosaur *Pteranodon* was the largest flying animal known to exist in vertebrate history (see Fig. 1). Its wing-span reached 25 feet, far exceeding in size the largest modern bird, the albatross, which has a wing span of only 12 feet[1,2]. Although *Pteranodon* was so large, its weight was surprisingly low. This has been estimated as a maximum of 55 pounds or a minimum of 25 pounds[1,3]. About 40 pounds may be taken as a reasonable weight. In any case, *Pteranodon* was an animal of great size and fragility. Its weight had become reduced during the course of its evolution in many different ways; for example, the heavy hind legs and pelvic region of the earlier pterosaurs had been much reduced, the teeth had been lost, and the bone itself was no thicker than blotting-paper, the wing bones being strengthened internally by crosswise struts.

Hankin and Watson[4] have studied the flight of *Pteranodon* in detail, and they have suggested that *Pteranodon* was primarily a glider and that it was not constructed for continuous flapping flight. This is shown by the long, narrow wing shape and the relative smallness of the pectoral musculature.

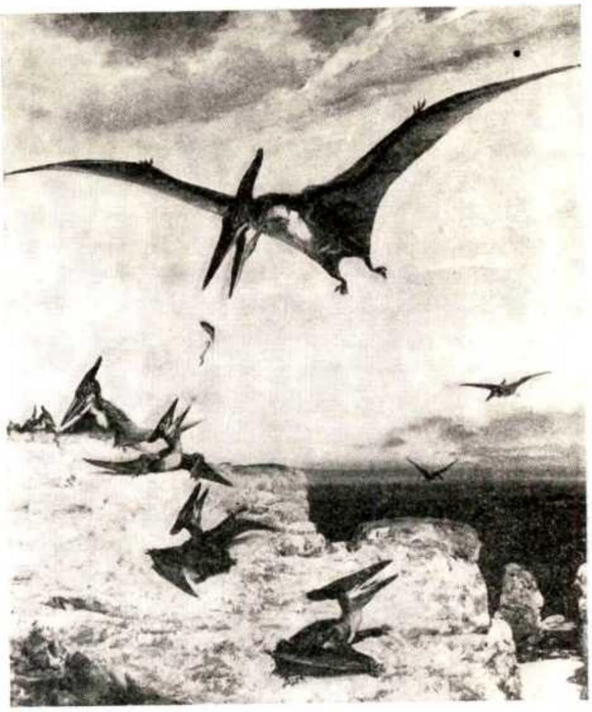

Fig. 1. *Pteranodon* feeding its young (after J. Burian).

Take-off in pterosaurs has always been considered a problem, because it has been assumed that the animals had to obtain a considerable velocity before becoming airborne. Most authors suggest that *Pteranodon* must have obtained sufficient speed for taking off by jumping from cliffs rather than trying to get up speed from ground level: Bellairs[5] states that "*Pteranodon* had great difficulty in taking off from flat surfaces", while Romer[6] comments "how this animal could get itself into the air from level ground is difficult to understand". Several authors have also observed that *Pteranodon* must have landed very gently, because its delicate body could not have stood the force of a sudden impact[9].

These difficulties are resolved when the flying speed is calculated. Using the standard formula[7], weight = $\frac{1}{2}C_L \rho v^2 S$, and assuming a maximum lift coefficient, C_L, of 1, and a body weight of 40 pounds, the minimum flying speed of *Pteranodon* is 22 feet/s (or 15 m.p.h.). Even at the upper limit of weight, 55 pounds, the minimum flying speed is only 17 m.p.h.

These speeds are so low that take-off and landing (into wind, of course, like modern birds and aeroplanes) would have been easy. In fact, in winds above 15 m.p.h. *Pteranodon* would only have needed to spread its wings to become airborne, with negligible effort. It is still probable that *Pteranodon* took off more frequently from cliffs than from level ground because it was an oceanic animal and was likely to have nested on cliff sites; but if it landed on the water it could have easily taken off from the crest of a wave.

After take-off, *Pteranodon* would have had to rely largely on soaring. Its low wing loading would have ensured a low sinking speed, facilitating slope soaring even in light winds, the best slopes being cliffs, but at sea large waves would have sufficed, as they do for the albatross[8].

Thus many of the problems envisaged by palaeontologists for the pterosaurs did not exist for the pterosaurs themselves.

Absence of Antimicrobial Substances in the Egg Capsules of Millipedes

MILLIPEDES lay their eggs in hollow capsules of their own construction, within which the emerged young spend the early part of their existence. The capsules are moulded primarily of soil and vegetable debris, and are built with the apparent addition of maternal enteric constituents, both oral and aboral in origin[1,2], which suggests that they might be impregnated chemically for defence against microorganisms. Here we present evidence indicating that for at least two species of millipede this hypothesis does not apply, because neither antibacterial nor antifungal substances could be detected in the walls of their capsules.

The millipedes studied were *Glomeris marginata* (order Glomerida) and *Narceus annularis* (order Spirobolida), from Europe and Ithaca, New York, respectively. They produced their capsules in laboratory cages, which were set up with soil and leaf litter, simulating their natural habitat. In the case of *Narceus*, the contents in the cage came from the actual collection sites. Several hundred *Narceus* capsules were obtained and several dozen of *Glomeris*. Extracts were prepared by separating the eggs from the capsules, homogenizing the capsules in water (ratio of capsule to water = 1 : 2 for antibacterial tests; 3 : 10 for antifungal tests), and sterilizing the homogenates by membrane filtration.

The bacteria tested included *Pseudomonas fluorescens*, *Escherichia coli*, *Aerobacter aerogenes*, *Sarcina lutea*, *Bacillus megaterium* and *B. subtilis*, as well as several Gram-negative cocci and bacilli and Gram-positive spore-forming rods isolated from the soil in which the capsules had been deposited. The tests were carried out by addition of capsule extract (droplets or soaked filter paper disks) to tryptose blood agar base (Difco) plates on the surface of which were spread standardized bacterial suspensions. The plates were incubated at 30° C for 18 h and examined for antibiotic effects at a magnification of 12. Even at maximal concentrations, the extracts had no inhibitory effect.

The fungi tested were *Candida albicans*, *Histoplasma capsulatum*, *Cryptococcus neoformans*, *Coccidioides immitis* and—with the *Glomeris* extract only—*Paecilomyces varioti*. Growing cultures of the fungi, in suitable defined media, were uninhibited by the addition of extract to medium in the ratio of 1 : 5. Moreover, capsules of *Narceus* placed directly on peptone glucose agar were quickly overgrown with saprophytic moulds.

It seems probable that the principal function of the capsules is to offer concealment and mechanical protection from predators. A single negative finding of this sort should not be taken to indicate that antimicrobial agents are likely to be generally absent from soil-inhabiting arthropods and other animals. Clues to the occurrence of such agents are not numerous (probably because biologists are not generally alert to their possible significance), but they do occur. In some centipedes, for example, the eggs are tended by the mother, and when unattended become overgrown with mould[3,4]. Comparable brooding behaviour has been reported for crickets[5], earwigs[6] and ants[7]. In our opinion, a systematic pursuit of such leads is likely to pay off, particularly with regard to the eventual discovery of new antifungal agents.

This work was supported in part by grants from the US Public Health Service. The *Glomeris* were supplied by Dr W. Dohle (Berlin) and Dr R. H. Cobben (Wageningen).

Sterol Metabolism as a Basis for a Mutualistic Symbiosis

MUTUALISM makes it possible for certain organisms with unusual nutritional requirements to survive and reproduce[1]. Species of this kind may be invaluable in studies of metabolism if the aposymbiotic (symbiote-free) organisms can ultimately be raised easily on defined substrates in sterile conditions[2]. During efforts to develop such a laboratory culture of the beetle *Xyleborus ferruguineus*, fungus-free females feeding on media containing cholesterol as the sterol source produced second-generation larvae that did not pupate[3]. Here we report evidence that the mutualistic fungus *Fusarium solani* associated with the beetle produced ergosterol as its only sterol in pure culture on a chemically defined substrate in sterile conditions. Ergosterol proved to be adequate as the sole sterol source for continued growth, development and reproduction of the fungus-free beetle. Subsequent tests of other sterols showed that 7-dehydrocholesterol was similarly adequate.

The fungal sterol fraction was isolated from *F. solani* grown on Neutral-Dox-Yeast medium[4]. Batches of fungus harvested after five, ten or fifteen days' growth were washed, freeze-dried, weighed and analysed for sterols. For each analysis, 15 g of freeze-dried fungus of a given age was homogenized in and extracted with a 2 : 1 mixture of chloroform–methanol. The total lipid extract was chromatographed on a silicic acid column and the sterol-containing fraction was eluted with chloroform. Thin-layer chromatography of this fraction using several solvent systems showed that significant amounts of sterol esters were not present. Free sterols were precipitated by digitonin treatment[5].

Preliminary identification of the sole sterol, ergosterol, in the fungus was based on its retention time as the free form and as the trimethylsilyl derivative on 1 per cent 'QF-1' on 'Gas-Chrom Q' at two temperature programmes using dual-hydrogen gas–liquid chromatography. Retention times of the isolated ergosterol were compared with recrystallized commercial ergosterol. This identification was confirmed by mass spectrometry. Gas–liquid chromatography quantitation of the ergosterol per 15 g dry fungus was based on a standard curve derived from gas–liquid chromatography of known concentrations of authentic ergosterol.

Ergosterol content increased with the age of the fungus, and ranged from 0·17 to 0·24 per cent on a dry weight basis. Because insects generally require 0·01 to 0·1 per cent sterol in their diets[6], the fungus, irrespective of age, should be an adequate source of this nutrient.

For studying the nutritional adequacy of various sterols or related compounds for the growth, development and reproduction of the fungus-free beetle, the basic diet was: sucrose (10 g), vitamin-free casein (10 g), Wesson salt mixture (2·5 g), linolenic acid as methyl ester (0·1 g), sorbic acid (0·4 g), streptomycin (0·1 g), powdered cellulose (15 g), fibrous cellulose (4 g), Bacto-agar (10 g), 95 per cent ethanol (2·5 ml.), 20 ml. of a vitamin solution[3], and de-ionized water (230 ml.). One of the following sterols was added at 0·4 g (0·13 per cent) per batch of diet: cholesterol, 7-dehydrocholesterol, ergosterol, lanosterol or lumisterol. Vitamin D_2, D_3 or squalene was also tested at 0·4 g in place of a sterol. The purity of all treatment chemicals was affirmed by gas–liquid chromatography and/or thin layer chromatography. Twenty fungus-free female beetles were originally placed on each test diet.

In the first fungus-free generation, viable progenies, including at least pupae, were present at 6 weeks in diets with each treatment except sterol-free (control), lumisterol, vitamin D_2 or D_3. Even though one pupa was found in the diet with squalene, it is considered equivalent to the no-sterol control. In the second generation (or brood), pupation had only occurred at 6 weeks in diets containing ergosterol or 7-dehydrocholesterol. Diets with cholesterol or lanosterol did support egg production and larval growth in the second generation.

The only structural characteristic present in both ergosterol and 7-dehydrocholesterol but absent in both cholesterol and lanosterol is the Δ^7 bond. Pupation of *X. ferrugineus* therefore required this double bond. Structural differences at C_{10} between variously useful sterols and the deleterious lumisterol and two vitamins apparently caused the latter compounds to inhibit larval growth even in the first generation.

In summary, *X. ferrugineus* is apparently unique among studied insects in its use of cholesterol for egg production and larval growth, but not for pupation. Cholesterol as a sole sterol was reportedly[7] inadequate for both larval growth and pupation of *Drosophila pachea*. With the development[8] of a completely chemically defined diet for the sterile culture of fungus-free *X. ferrugineus*, investigations of steroid and hormone metabolism with the beetle should bring about significant developments in insect endocrinology.

This study was supported in part by the Institute of Allergy and Infectious Diseases, US National Institutes of Health.

Inheritance of Sex Ratio in the Butterfly *Acraea encedon*

IN equatorial Africa, the butterfly *Acraea encedon* occurs chiefly in disturbed habitats in populations that are ecologically and genetically isolated from each other. Many of these populations are composed mainly of females, with males making up as little as 2 per cent[1,2]. In other parts of Africa, mainly in relatively dry or undisturbed habitats, the sex ratio is normal. There is no evidence of parthenogenesis[2]. In at least one population (Lubya, Uganda) the very low frequency of males seems to regulate the size of the population; many females remain unmated and contribute nothing to succeeding generations[1,2].

At Newton, Sierra Leone, a population of *Acraea encedon* is established in a small area of irrigated rice fields. The larvae feed on a weed, *Commelina* sp., associated with the cultivation of rice and other crops. In the period September 1968–August 1969 the sex ratio fluctuated from 1–2 per cent male to just over 30 per cent male, with an overall frequency of 15·6 per cent ($n = 1307$, obtained by marking and releasing the butterflies once a week over 44 consecutive weeks). In October 1968–March 1969, twenty-eight clusters of eggs, each from a different female and each comprising 50–100 eggs, were brought into the laboratory and the butterflies reared. Twenty-six clusters produced only female butterflies and two clusters males and females in ratios that do not depart significantly from the expected 1 : 1. There was no conspicuous mortality of larvae or pupae during the rearing. From this stock four successive generations of butterflies were obtained in the laboratory. Three kinds of mating were made: brother × sister, male × female from all-female broods, and male × female from male/female broods that were not sisters of the males. The results are summarized in Table 1. Males mated to females from all-female broods produced only female offspring. Brother × sister matings and males × females from male/female broods that were not sisters of the male produced males and females. In the twenty-nine broods that produced males and females there was no overall significant departure from the expected 1 : 1 sex ratio. One male was mated successively with three different females: two were its sisters and one a female from an all-female brood. The matings with its sisters produced male and female offspring, but the mating with the female from the all-female brood produced only females. There are thus two kinds of female, one producing males and females and one producing females only.

Table 1. SEXES APPEARING FROM DIFFERENT KINDS OF MATINGS IN *Acraea encedon*

Mating	Broods obtained	Sexes present in broods obtained
Brother × sister	24	Males and females
Male × female from male/female brood	5	Males and females
Male × female from all-female brood	17	Females only

The larvae of *Acraea encedon* are gregarious until the last instar and pupation takes place on or near the foodplant. Adult butterflies from a brood emerge from pupae over a period of several days, the males tending to appear slightly earlier than the females. Females are able to mate on the day they emerge. Because of this and because of the overall scarcity of males in a predominantly female population most matings that eventually produce males and females must be brother × sister.

It is possible that the predominantly female populations of *Acraea encedon* are of relatively recent origin[3], and that the sex ratio phenomenon is the result of hybridization of formerly isolated populations caused by human disturbance of the environment. Hamilton[4] has suggested that the phenomenon could be caused by a driving *Y* chromosome. If he is correct it is likely that there are populations in which the effects of a driving *Y* chromosome are covered up by the selection of epistatic suppressors on other chromosomes. But when a female from such a population enters a new population (perhaps as the result of human alteration of the environment) the trait could spread very rapidly as the new population may not have evolved a suppressing system. In these conditions a population could become predominantly female in quite a short time, but the sex ratio should return to normal again once suppressors have been evolved. If suppressors are not evolved the population could become extinct, although there are other possible ways of avoiding extinction, such as increased fitness of normal females, multiple matings by males (which are known to occur[1]) and non-random mating. In Uganda, one predominantly female population did become extinct, while another population seemed to become extinct but was apparently revived by butterflies arriving from elsewhere[1].

Acraea encedon is not a pest of crops—indeed, it is capable of defoliating an important agricultural weed—but the sex ratio phenomenon described here could have implications in the control of insect pests. Females that produce only females could be introduced into pest populations and numbers would then be regulated. Provisional sampling suggests that similar distortions of the sex ratio, always in favour of the females, occur in other African butterflies. All the species so far examined are characteristic of disturbed agricultural areas.

My results will be published in full elsewhere as part of a wider investigation.

Alkaloids of an *Ipomoea* Seed known as *Kaladana* in Pakistan

Ipomoea muricata Jacq. (*Calonyction muricatum* G. Don) has now been confirmed as the biological origin of the *Ipomoea* seed mentioned in a previous communication[1]. Seeds of Indian origin (obtained by courtesy of Dr O. Fervidi, Simes Servizi Scientifici, Milan), identical to those from Pakistan, showed on germination in Beirut the typical shape and size of the cotyledonary and first leaves of *Ipomoea muricata* Jacq. described by Kassner[2]. The identity was further confirmed by the characteristically tubercled stem[3] and the aristate sepals[4]. *Kaladana* seeds, obtained from Pakistan (Gohar and Co., Karachi) in 1965 and 1967, differed from the original seeds (and those from India) in being hairy and greyish-black but otherwise identical to the original seeds in size and shape. All the seeds, however, had identical alkaloid chromatograms. A few of the 1967 seeds were grown in Lafayette in 1968 (by courtesy of Dr J. E. Robbers, Purdue University, Lafayette). Seeds obtained from these plants and grown in Beirut produced plants identical to those obtained from the Indian seeds. Strangely enough, the seeds obtained from Lafayette were devoid of alkaloids. In this connexion it is interesting to note that Der Marderossian[5] reports no indole alkaloids from "*I. muricata*". Besides lysergol and chanoclavine-I, reported[1] as present in *Kaladana* seed, other alkaloids were also found but in much smaller amounts[6].

Achene Spacing of Strawberries as an Aid to calculating Potential Yield

THERE have been attempts to determine potential biological yield on the basis of the size and efficiency of the photosynthetic apparatus. Economic yield, however, depends on the successful partition of assimilates to useful parts of the plant and, in the case of fruit crops, to the reproductive organs[1,2]. In the strawberry, one component of yield is fruit size, which we have shown to be determined by the number of fertilized ovules (achenes) on the surface and the degree of receptacle expansion associated with each achene. Berry weight is highly correlated with achene spacing and achene number, so that for each value of achene spacing there is a linear relation between berry weight and achene number (Table 1).

Table 1. LINEAR REGRESSION RELATING BERRY WEIGHT, NUMBER OF ACHENES AND ACHENE SPACING FOR REDGAUNTLET BERRIES

No. achenes/cm²	6	7	8	9	10
Slope of line	0·109	0·093	0·081	0·073	0·072
Constant	82	78	48	67	87
Correlation coeff. *r*	0·98	0·92	0·95	0·91	0·96
Achene spacing × slope	0·654	0·655	0·645	0·660	0·657
Percentage shortfall in berry weight	0	14·3	25·0	33·3	40·0

A general formula for berry weight has been developed:

$$\text{Berry fresh weight (g)} = \frac{(\text{Total No. achenes} - C)F}{\text{No. achenes/cm}^2}$$

where C is the mean constant of the regression lines and F is the mean value for achene spacing × slope. It follows that for an individual berry where the total number of achenes is unalterable and constant, fresh weight × achenes/cm² is constant[3]. For the variety Redgauntlet, C and F have the values 67 and 0·653 respectively.

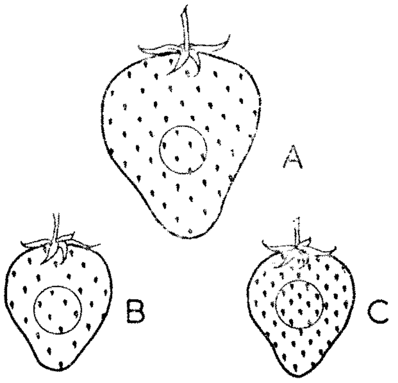

Fig. 1. Diagram showing relation of achene spacing to strawberry fruit size. Circles represent 1 cm².

All the data so far available to us show that a limit to surface expansion is reached at about 6 achenes/cm², so that it is now possible to calculate the potential maximum weight of a berry. In Fig. 1, berries A and B have both reached their potential size with six achenes/cm², and their weights are proportional to the total number of achenes on each. If berry C, with twelve achenes/cm², had expanded to the same extent as *A* it would have been of equal size because it has the same total number of achenes.

It is thus possible, using achene spacing measurements, to calculate the shortfall in yield resulting from submaximal receptacle development. The percentage shortfall in berry weight has been determined for achene spacings in the range 6–10 achenes/cm² (Table 1). Other experimental plants, yielding well by accepted standards, appear to have been capable of producing a 50–100 per cent greater yield of berries; and yields from a local commercial strawberry holding suggest that the crop could have been doubled if conditions had been more favourable to berry expansion. A large gap thus clearly exists between present yields and what could be achieved by manipulation of the environment (for example, irrigation, or better nutrition) during the final phase of development alone. A similar approach to the calculation of potential yield and the theoretical shortfall it reveals may be possible for other fruits, such as the raspberry, pineapple, blackcurrant and gooseberry.

Non-biological Reduction of Nitrite in Soil

CHEMICAL decomposition of nitrite in soil[1-7] resembles microbial denitrification by producing gaseous end-products, N_2 and N_2O (refs. 8–11). NO and N_2 are formed in sterile soil over a wide *p*H range[12], and N_2 is also formed in sterile aqueous solutions containing nitrite and iron[13,14]. We show here that NO, N_2 and N_2O are products of non-biological nitrite decomposition in soil.

Soil was sterilized by autoclaving, brought to 60 per cent water-holding capacity with sterilized distilled water, and equal amounts of membrane-filtered $Na^{15}NO_2$ (60·019 atom per cent ^{15}N) and $Na^{14}NO_2$ were added. Final concentration was 250 μg N/g dry soil. The soil was incubated in respirometer flasks[15] at 25° C in an oxygen-free helium atmosphere for 168 h. Flask atmospheres were analysed by mass spectrometry. Atom per cent of ^{15}N in excess of normal was determined from isotope beam ratios. Quantitative analysis of respirometer gases was done by gas chromatography, using commercially available columns. Soil *p*H was measured at the sticky point with a glass electrode.

Table 1. ^{15}N ENRICHED GASES EVOLVED FROM SOILS AMENDED WITH NITRITE-^{15}N*

Soil	Per cent ^{15}N excess† NO	N_2	N_2O
Amity silty clay loam	29·40	4·10	5·22
Cove clay	14·70	3·13	11·70
Chehalis silty clay loam	19·40	2·94	14·20
Cloquato silt loam	14·60	2·48	9·70
Willamette silty clay loam	14·80	2·09	11·80

* Equal amounts of $Na^{15}NO_2$ (60·019 atom per cent ^{15}N) and $Na^{14}NO_2$ added to soil respirometer flasks to give a final concentration of 250 μg N/g dry soil.

† Excess ^{15}N in normal abundance determined from isotope beam ratios obtained by mass spectrometric analysis of flask atmospheres.

Soil containing added nitrite–^{15}N produced NO and N_2O heavily enriched with ^{15}N (Table 1). No microbial growth occurred in soil extracts incubated for 3 weeks in a variety of media and environmental conditions. The relative proportion of gases evolved from Amity, Cove and Cloquato soils was $NO > N_2 > N_2O$; whereas, for Chehalis and Willamette soils the order was $N_2 > NO > N_2O$. Gas analyses of many other soil systems in similar conditions revealed NO, N_2 and occasional small quantities of N_2O. Formation of N_2 and N_2O in sterile soil together with NO, a gas which is not usually associated with microbial denitrification, provides strong evidence for non-biological mechanism(s).

Table 2. PATTERN OF GAS PRODUCTION IN SEVERAL SOIL TYPES AMENDED WITH NITRITE*

Soil	*p*H	Per cent nitrite–nitrogen converted to gas† Autoclaved N_2	N_2O	NO	Non-autoclaved N_2	N_2O	NO
Astoria silt loam	4·8	7	0	71	9	0	68
Cove clay	5·8	14	0	37	17	0	41
Chalis silty clay loam	6·1	23	0	33	25	0	34
Willamette silty clay loam	6·2	26	0	63	28	0	60
Walla Walla silt loam	7·3	14	0	7	17	0	7
Corvallis sandy loam	8·9	1	0	11	1	0	10

* Nitrite-nitrogen added as $Na^{14}NO_2$ to give a final concentration of 200 μg N/g dry soil.

† Quantitative analysis of gases in respirometer atmospheres by gas chromatography.

The pattern of gas production in several soil types with added $Na^{14}NO_2$ is presented in Table 2. Evolution of N_2 and NO from both alkaline and acid soil indicates that *p*H is not the only factor involved in converting nitrite–N to gases[16]. Additional evidence, not presented here, suggests that organic matter and clay also affect the stability of nitrite in sterile soil systems. Autoclaving did not alter those soil properties which affect nitrite decomposition.

Copper, iron, manganese and certain aluminium salts may promote non-enzymatic decomposition of nitrite[13,14]. Metal ions can be reduced by metabolic intermediates and end-products of anaerobiosis[17] and then combine with nitrite, organic matter and colloidal clay. Such a complex could become reactive and liberate N_2 and other gases which are significant in soil denitrifying systems[11].

We thank Dr F. E. Broadbent, University of California, for assistance and interpretation of the ^{15}N analyses.

Book Reviews

EVOLUTION OF AN INDUSTRY

A History of Coal Mining in Great Britain

By Robert L. Galloway. Introduction, Bibliography and Index by Baron F. Duckham. Pp. xi + 273. (David and Charles: Newton Abbot, April 1969. First published in 1882.) 63*s*.

THIS book is a reprint of Galloway's original text, first published in 1882, to which has been added an introduction, bibliography and index by Baron F. Duckham. It is difficult to imagine Galloway's historical synopsis of the British coal mining industry being superseded, for he and his family were contemporary to so much of what is now one of the most fascinating periods in the evolution of the industry. Written by a mining engineer as well as scholar and coalfield tourist, Galloway's book invites, and indeed enjoys among those who know it, approval as an accurate and well-balanced account of technical and scientific development of coal mining art and practice. He locates, as accurately as we are ever likely to define, an industrial embryo and traces its emergence from obscure beginnings, through periods of quiescence and vigorous growth, to a gigantic industrial activity gathering in economic momentum as it approaches the twentieth century. The story is simply told and is easy to read. It makes compelling reading not only for those associated with the industry but for anybody remotely interested in Britain as an industrial power either ancient or modern.

Baron F. Duckham has provided a historical supplement to the main text extending from 1880 to 1914. His treatment of the period is necessarily brief and claims to be no more. Fortunately, he resists what must have been a compelling temptation for an economic historian to comment on the social and political activity associated with the industry at that time. In this respect, Duckham keeps faith with his "co-author", thereby presenting a readable, stylish and accurate contiguity albeit chronologically misplaced. Rather than précis the events of 1880 to 1914 in his introduction, it might have been more meaningful to the reader to find the updating as an epilogue to Galloway's text.

Although undeniably accurate in his unfolding of events, Duckham fails to impress the importance of certain inventions and ideas to the development of the industry. For example, the invention of the face conveyor and the concept of conveyor transport has had a greater impact on technical progress in coal mining than any other single factor. Its introduction at the turn of the century completely changed the development of working methods. Indeed, the highly sophisticated mining systems of today are direct descendants of this invention. It is a pity that he was unable to find the time to tell more of the weird and wonderful inventions of the day in the field of mining machinery. These were mostly abortive but none the less fascinating. "Burnett's Patent Roller Wedge and Nicking Machine", for example, would excite the imagination of any engineer.

The publication of this book is opportune, coming at a time when today's coal mining industry is suffering the pains of rejuvenation. The reader is made aware that such tribulations are not new to this industry and our perspective of modern coal mining may be improved on learning that a mere 90 years ago, 4,231 collieries were needed to produce a gross output similar to that of today. Logically, one is at liberty to conclude that we have been averaging a net annual closure rate of forty mines for almost a century.

The book will provide interesting and informative weekend reading for anybody. But more particularly, the many college students who choose, as a study project, the history of coal mining in their region will find it an invaluable aid. There is an excellent bibliography which provides selected references appropriate to all the major coalfields. Engineers, be they mining or mechanical, civil or electrical, would do well to give the book more than a glance. For there is no industry in Britain that has not been either spawned or significantly influenced by the coal mining industry.

Duckham concludes his introduction with the comment ". . . The history of modernization since 1918, and particularly since nationalization, is a stirring one. It deserves another Galloway to do it justice". Indeed it is and indeed it does. Perhaps Duckham should look no further than the nib of his own pen.

F. F. ROXBOROUGH

SUNDIAL CONSTRUCTION

Sundials

A Simplified Approach by Means of the Equatorial Dial. By Frank W. Cousins. Illustrations by Malcolm Chandler. Pp. 247. (Baker: London, December 1969.) 126*s*.

MR COUSINS's book is the first major work on sundials in the English language to be published in the past 20 years (although one must not entirely overlook another recent work in a slightly lighter vein). It therefore deserves serious consideration, and it must be said at once that it fills a gap in the scientific literature and is to be welcomed.

The introduction is a little discursive, but the chief part of the work is mathematical and technical in content. Cousins sets out to describe the astronomical and mathematical foundations of the theory and practice of the construction and use of sundials, and shows in considerable detail how dials of many types, with their hour-lines inscribed on surfaces of a great variety of shapes and aspects, may be constructed by an intelligent layman. For each chief type of dial he illustrates three constructional methods for laying out the dial lines: one involving three dimensions and using the equatorial dial as described in the title to the work; a second involving two-dimensional drawing; and a third using simple trigonometry with the aid of tables. About one fifth of the book consists of a series of illustrations showing a large variety of existing sundials, both fixed and portable, with very brief descriptions; then comes the principal part of the book, consisting of about half of the total, in which the author gives full details for the construction of most of the chief types as described above. The work is rounded off with sections devoted to the layout of zodiacal lines, the use of dialling scales, a useful bibliography, and appendices including comprehensive tables of atmospheric refraction, the Sun's declination and the equation of time.

The author has been well served by his collaborators: Dr J. G. Porter, to whom is due much of the mathematical and astronomical detail; and Mr Malcolm Chandler, who has struggled manfully with the difficult task of representing in two dimensions diagrams involving three-dimensional geometry, and has been in most instances highly successful, although his upper illustration of a cone dial on page 31 could be misleading.

Cousins's own technical descriptions are well conceived but in some instances a little too brief for maximum clarity. There are a few errors here and there and some rather surprising omissions. The author touches only lightly on the large subject of portable and pocket sundials. He makes no mention of the important fact that there are

Mechanical equinoctial dial by Wm. Deane of London, c. 1690 (from *Sundials*, by F. W. Cousins, p. 65). (Photo by courtesy of the National Maritime Museum.)

two chief classes of such sundials—compass and altitude dials—nor does he draw attention to the defects of altitude dials, and he omits any description of ring, disk and quadrant dials. His historical series starts with the dial of Ahaz of about 700 BC and he omits the important Egyptian dials of about 1500 and 900 BC in the Berlin Museum. A minor point of criticism is that in dealing with the Equation of Time on page 74 he makes no attempt to dissect this into its two principal harmonic components. The only specific errors I wish to quote are the name of Hepslow for Henslow at the top of page 74, and in the photograph of a proposed Noon Mark on page 203, where the lower XI should be IX, and the month-end dots in the same region have a strange spacing.

Summing up, the book (apart from the blemishes I have mentioned) is an excellent compendium, attractively presented, of essential facts and figures relating to the theory and practice of the construction of sundials; and the fact that three alternative methods of layout are given for most of the principal types of dial should make it useful to a wide range of potential users. F. A. B. WARD

LANDMARK IN GEODESY

Mathematical Geodesy

By Martin Hotine. (ESSA Monograph No. 2.) Pp. xvi+416. (US Department of Commerce, Environmental Science Services Administration: Washington, DC, October 1969.) $5.50.

THIS book is indeed a new book on geodesy in that it treats the whole subject from a completely new standpoint and with the powerful technique of tensor calculus which is also completely new to most geodesists. The basic premise is that all geodetic measurements and concepts can be expressed as geometrical properties of a three-dimensional manifold, and a Euclidean metric suffices. Tensor calculus then enables geodetic and physical properties to be expressed in general form, particularly those which are invariant with the coordinate system, and they may be transformed very simply from one system to another.

The following illustrates the power of Hotine's use of tensor calculus. It is shown that the geometry of the Newtonian gravitational field can be treated as a special case of a (ω, φ, N) coordinate system, in which ω is longitude, φ latitude and N potential. Using Fermat's principle of least action, a light ray becomes a geodesic of the curved space obtained by conformally transforming the space in question to a curved space with scale factor n, the index of refraction. The whole of the theory of dynamic satellite geodesy is derived from Newton's second law of motion, which is first expressed in a general coordinate system. Then, although the whole concept of least action is Newtonian and the equations of motion referred to accelerating (rotating) axes are not Newtonian, the geodesic principle, the principle of least action and Newton's second law of motion are all shown to be equivalent.

Parts one and two of the book explain tensor notation and discuss the geometric properties of three-space expressed in this notation. Part one derives, or indicates the derivation of, formulae which will be used later. Part two derives coordinate systems of special interest in geodesy, and transformations between them, from a general class of three-dimensional systems. Part three applies the results of the first two to geodetic problems —to atmospheric refraction, computation and adjustment of control frameworks, potential and gravity anomalies, and to geometric and dynamic satellite geodesy. Finally, there is an index of symbols and a complete summary of formulae.

I disagree with some of the strictures made on current "classical" geodetic theory, in particular those on the classical use of the Laplace azimuth equation (paragraphs 14 and 15 of chapter 19). The tenor of the book could be considered to be given by the opening sentence of the preface: "This book is an attempt to free geodesy from its centuries-long bondage in two dimensions". When one comes to chapter 26, entitled "Internal Adjustment of Networks", it is, however, stated that, in adjustment by the widely used method of "Variation of Coordinates", the β (geodetic zenith distance) equations should properly be given less weight than the α (geodetic azimuth) equations because of uncertainties in angular refraction and, as their interaction is so limited, "the two sets of equations might be solved separately". This is indeed what is done in "classical" theory and practice, for the very reasons stated. Recent research, however, gives hope that it may soon be possible to measure angular refraction in the field with relatively simple field equipment to an accuracy commensurate with other measurements. When this day dawns, geodesy will indeed be freed from "its centuries-long bondage in two dimensions".

The real tenor of the book, however, is the unification of the whole of geodetic theory with complete mathematical rigour and elegance. In concept and in execution it is a beautiful piece of work and a fitting finale to the lifetime's work of the author. It is indeed a book which appears once in a generation and it is tragic that the author did not live to see the fruits of his labours. A. R. ROBBINS

STRUCTURES REVEALED

Methods for the Study of Sedimentary Structures

By Arnold H. Bouma. Pp. xvi+458. (Wiley (Interscience): New York and London, October 1969.) 190*s*.

THE interest shown by geologists in sedimentary structure has fluctuated over the years. Sir Charles Lyell and James Hall, working early in the past century, gave for the first time detailed descriptions of many structures, and Henry Clifton Sorby, in the 1850s, showed how such structures as ripple marks and cross-bedding could be understood physically and used for environmental interpretation.

In the 80 years following Sorby's work, there was little interest in sedimentary structures on account of the overwhelming need to solve purely stratigraphical problems, in which features indicative of sedimentary environment were widely thought to be irrelevant.

The wheel has turned once more, and geologists now realize the importance of a knowledge of sedimentary structures to an appreciation of both stratigraphy and sedimentary environments. But first, one must find the structures and then develop them to reveal as much as possible about themselves. Dr Bouma's important book is concerned with the techniques available to reveal sedimentary structures in the greatest possible detail according to circumstances. In studies of modern sediments, the field worker is faced with two problems which must be solved together: how to consolidate the sedimentary material and how to pick out with clarity the structures present in the deposit. The worker on consolidated sediments, on the other hand, is often faced with rocks showing structures only obscurely or not at all, and techniques are therefore needed to reveal any structures which, by reason of diagenetic processes, have become obscured or hidden in the rock.

Solutions to these and many related problems are to be found in Bouma's thorough and detailed account. The making of sedimentary peels is described together with the impregnation of sediments, either dried out or in a wet or moist state. Radiography, with application to unconsolidated as well as to lithified sediments, is discussed in detail and many useful practical hints on this relatively troublesome and expensive technique are given. Bouma also describes a variety of minor techniques such as staining, sand-blasting (also useful in fossil preparation), and moulding. The book has an exhaustive list of references, helpful appendices containing conversion tables and receipts, and a particularly useful list of manufacturers and suppliers of materials and apparatus.

This book will be an essential reference for all whose work involves sedimentary structures. It is unfortunate that its length and therefore price could not have been kept smaller by the rigorous exclusion of unnecessary detail and illustration for its own sake. For example, there are twenty-three full pages of costly half-tone illustrations that do little more than show that radiography will reveal the (not always unobvious) fabrics and structures present in rocks of different kinds. It is a pity that readers should be burdened in this way.

J. R. L. ALLEN

ENGINEER'S VIEW OF GEOLOGY

Engineering Geology and Rock Mechanics

By Neil Duncan. Vol. 1: Pp. xxii + 252 with 37 plates. Vol. 2: Pp. xxiv + 270 with 68 plates. (Leonard Hill: London, 1969.) Vol. 1, 55*s*; Vol. 2, 60*s*.

THE recent appearance of several new books on engineering geology suggests that new ideas and techniques have made it an opportune time for a re-statement of the subject for students. This two-volume work is related to the author's own experience of the ground covered in the first and second years of a civil engineering degree course. The approach is a creditable one because it is a new attempt to look at geology for engineers from the viewpoint of the engineer. Yet it does seem to fall short in the amount of real geology that it contains.

Volume one deals with the properties of "rock materials" and begins with the properties of minerals. (A short introductory chapter giving the nature and scope of engineering geology in relation to pure geology and engineering would perhaps have been appropriate here.) The structure of the Earth is briefly described and then there is a discussion of igneous, metamorphic and sedimentary rocks. The content of this discussion, however, is perfunctory, and the use of the now obsolete silica-percentage classification for igneous rocks is unfortunate. The nature and occurrence, structure and texture of each rock group are described together with a brief classification. The author then goes on to erect an engineering classification of rocks based on texture, structure, composition, colour and grain size, in which rocks fall into six groups. Such an approach may be of value to an engineer but might also tend to absolve him from making any geological identification at all, besides involving him in descriptions of texture, and the like, not catered for in earlier chapters. Presumably this is where a thorough course of practical work is essential—as indeed the author implies in his preface.

There is then a very detailed and lengthy consideration of the physical, mechanical and dynamic properties of rocks and the ways in which these properties may be measured. The volume ends with a description of soils (in the engineering and not the geological sense)—in what is a particularly comprehensive introduction to soil mechanics.

The second volume is concerned with rock masses and the application of geology to engineering problems. Because the reading lists in this and the first volume are quite adequate, it might have been better to omit the structural and stratigraphical chapter of this volume altogether rather than give it so brusque a treatment. The greater part of the section, however, is concerned with the methods by which joints may be studied in rock masses, the effects of groundwater, and the overall description of forces acting on the masses and their significance. The second part of this volume describes all types of engineering problems and practice, and provides a good practical demonstration of what has gone before. It also stresses by implication that field-work is an integral part of the course.

The text is very well illustrated with diagrams and graphs, but the choice and reproduction of some of the photographic plates make their interpretation almost meaningless (for example, plate 6, vol. 1, and plate 62, vol. 2). Any understanding of the graphs is also marred by the absence of any mention of the number of samples, and frequency and geographical location of the samples taken.

The approach of this work is very interesting and it can be recommended to teachers in the subject because it is different. Those that find sympathy with the approach will no doubt recommend the book to their students. It can also be recommended to geologists, particuarly those who are reluctant to quantify, for whom the chapters relating to rock–soil mechanics might prove particularly useful. But because it was written with students in mind, it would doubtless be better received if the volumes were combined in a paperback—perhaps without so many plates—at a reduced price.

JOHN R. V. BROOKS

SOLID STATE TUNNELLING

Tunneling in Solids

By C. B. Duke. (Solid State Physics: Advances in Research and Applications, Supplement 10.) Pp. x + 353. (Academic Press: London and New York, September 1969.) 149*s*.

TUNNELLING has enjoyed a golden age for the past decade, when it developed from a "good example in wave mechanics" to a major study and tool in solid state research. The publication of the first book on the subject probably indicates that this era is over and that both theoretical and experimental techniques will have to be refined to discover small deviations from the behaviour that can now be understood.

Duke has undertaken to tell the whole story of tunnelling. He considers electrons tunnelling through barriers with and without excitation states, between electrodes which are combinations of semiconductors, metals and superconductors. The achievements of both theory and experiment are critically examined, but the author's own interest has led to a greater emphasis on theory and rather less understanding is shown towards experiments. For example, he says that all systems claimed to be tunnelling should be proved to be so by the observation of the gap characteristic if one of the electrodes becomes superconducting, whereas this, of course, only indicates tunnelling over a small fraction of the energy range that is of interest.

The book is divided into two. The first half is concerned with independent electron effects which are usually large and can be understood quite well with relatively simple theory. The theory is presented first and then the measurements are critically compared with it. The second half deals with many body effects, and the author adopts the more cautious approach of describing the experiments and their interpretation before the detailed theory.

An admirable attempt has been made throughout the book to unify the diverse studies in tunnelling. The treatment and emphasis throughout are clearly personal, but this is the price of coherence. An honest effort has been made to present the arguments clearly and failures are emphasized as much as successes. I am sure people will find parts controversial, but on the whole it is, nevertheless, a very useful review. A. F. G. Wyatt

PHYSICS OF SCATTERING

Scattering Theory

New Methods and Problems in Atomic, Nuclear and Particle Physics. Edited by A. O. Barut. Pp. viii + 431. (Gordon and Breach: New York and London, 1969.) n.p.

This book consists of a collection of articles presented by theoretical physicists well known in their respective fields on aspects of quantum scattering theory and its applications to atomic, nuclear and elementary particle physics. Because quantum scattering theory is the chief underlying theme in the description of the various processes in atomic, nuclear and particle physics, an exposition of certain of its basic ideas and their relevance and use in these branches of physics could hopefully serve to bring out the unifying features of these different physical processes. This, together with a hope that such an effort may lead to a cross-fertilization of ideas between atomic, nuclear and particle physicists, forms, as the editor points out in the introduction, the chief objectives of this book. Given the enormous growth in these branches of physics in the past decade or so and their ever continuing expansion at an even faster pace, any significant accomplishment of these objectives is, in my opinion, quite impossible within the confines of a modest sized volume. Even a small contribution towards these objectives is, however, a praiseworthy venture and I think that this book does indeed make such a contribution.

The book consists of five parts. Most of the first part consists of a lucid article by F. Calogero on the variable phase approach to potential scattering. There is also a useful section by A. Degasperis on the inverse problem—that of obtaining the potential from the experimental scattering data.

The second part, which has the slightly misleading title of "General Scattering Theory", consists of three topics in quantum scattering theory. The first, written by G. C. Ghirardi, deals with the evaluation of upper and lower bounds for the number of bound states of a physical system. An elementary knowledge of the spectral theory of linear operators in a Hilbert space should prove useful in acquiring a deeper understanding of this material. The second topic, presented by J. Werle, is on relativistic polarization and angular correlation which is essentially a small portion of our up to date knowledge of the non-dynamical theory of relativistic particle reactions. Finally, the third topic, by L. Fonda, is on many-channel collision processes. Its relevance to the theory of nuclear reactions is obvious.

Parts three, four and five deal with the applications of scattering theory to atomic, nuclear and particle physics respectively. M. H. Choudhury

CRITICAL PATH CALCULATIONS

The Critical Path Method

Application of the PERT Method and its Variants to Production and Study Programs. By A. Kaufman and G. Desbazeille. Pp. x + 167. (Gordon and Breach: New York and London, August 1969.) 195*s*.

This book should be entitled "Theory of the PERT Method and its Variants". It is an account of the mathematical theory of critical path calculations, starting from an assumed knowledge of set theory, and extending to methods of parametric linear programming in the optimization of cost functions. It is well printed and laid out, with a consistent scheme of chapter, paragraph, table and figure numbers. As a result, it is possible to treat with amusement the occasionally quaint wording resulting from its translation from the French. But care is needed in following the terminology, as, for example, "float" becomes "margin", and "precedence diagrams" are variously called "method of potentials" or "tasks and constraints". Although the authors do take care to define all their terms as they come to them, there is no glossary or index to facilitate subsequent reference to definitions.

According to the foreword, this book is aimed at engineers, organizers, entrepreneurs and all who are responsible for the elaboration and control of programs. The first half of the first sentence reads "Without stretching the theoretical aspects relative to the search for ordinal relations in a graph, this concept, as will be seen, being nothing else but a set of elements among which oriented relations exist . . . ". If the reader survives the first chapter, which is a revision of the theory of graphs, he will find an impressive and well illustrated mathematical text, but one into which any really practical examples seem to have been introduced very grudgingly. The two mapping examples in section two are both borrowed from other authors, and Fig. 11.1, which is intended to explain the first of these, seems to be both irrelevant and inconsistent. The example in section thirty used to illustrate the Fulkerson algorithm is commended to the reader in the preface, where it is admitted that the algorithm itself is somewhat forbidding. But to work through the example requires the reader to have studied most of the rest of the book in any case.

For a dedicated operational research specialist who cares about the theory of critical path calculations, this book might well prove valuable. P. L. Cloot

POISONS INTRODUCED

Essays in Toxicology

Vol. 1. Edited by Frank R. Blood. Pp. xi + 169. (Academic Press: New York and London, September 1969.) 70*s*.

The increased use of chemical substances such as drugs, food additives, pesticides, fertilizers, and the like, and the fear of environmental pollution have stimulated the development of toxicology in its widest sense. Toxicology, the study of poisons, is today a multidisciplinary system of knowledge which acquires and interrelates information from many sciences including chemistry, physics, biochemistry, physiology, pharmacology, pathology, entomology, industrial and forensic medicine and food technology. The aim of *Essays in Toxicology*, of which this is the first volume, is to provide a publication which is scientifically accurate and at the same time sufficiently general to be read with profit by the "non-toxicologist". This is an ambitious aim in a world of increasing specialization, but the four essays in this volume illustrate the wide range of what may be regarded as toxicology. The titles of the four essays in this volume illustrate this point. They are "Poisons as tools in studying the nervous system", "Teratology", "The significance of methemoglobinemia in toxicology" and "Lead poisoning. An old problem in a new dimension".

The first essay, by R. D. O'Brien, occupies a third of the book and is an account of how poisons are used to study various forms of nervous transmission, namely axonic, excitatory synaptic and inhibitory synaptic transmission. The essay is an excellent introduction to nerve physiology with a brief account of the history and chemistry of each of the poisons used. It describes how natural and synthetic poisons have been used to study and differentiate the various forms of nerve transmission, the natural tetrodotoxin and synthetic DDT for axonic transmission, the plant poisons atropine, physostigmine, and the like, and the synthetic carbamate and organophosphate insecticides for excitatory synaptic transmission, and strychnine and picrotoxin for inhibitory synaptic transmission. The author suggests that whilst these poisons have served and will serve as tools for the nerve physiologist, they also represent one of the very few available starting points for biochemical work in this field in which our knowledge of biochemical mechanisms is as yet poor apart from the work on GABA (γ-aminobutyric acid), a transmitter substance in invertebrates. This could be regarded as an essay on nerve physiology rather than toxicology, but it illustrates admirably how the information from other sciences can be used to explain certain toxic actions.

The second essay, on teratology, by R. S. McCutcheon, is relatively short but with an extensive and useful bibliography. Although abnormal development and foetal malformations have been studied for more than a century, the author regards teratology as a new science stimulated by the thalidomide episode. The widespread occurrence of thalidomide malformations has led to the need for careful assessment of new and old drugs from the point of view of their action upon the foetus. The terms such as embryo and foetus and conceptus are defined, then the essay covers briefly placental physiology and the part of nutrition, genetic factors, drugs and infectious diseases in teratogenesis. The chief emphasis is on the need for increased basic and analytical research in teratology to replace much of the empirical animal work being done.

The third essay, on aspects of methaemoglobinaemia, by Roger P. Smith, discusses the concept of using a toxic response as a therapeutic measure, namely the generation of methaemoglobin by sodium nitrite in cyanide and sulphide poisoning. The other points which are interestingly discussed are toxic methaemoglobinaemia and its treatment and the contradictory reports concerning the effect of methylene blue in cyanide and carbon monoxide poisoning.

In the fourth essay, on lead poisoning, by P. B. Hammond, attention is drawn to the general problem of environmental pollution, lead being taken as an example. The author surveys lead poisoning in infants, industry and domesticated and wild animals, the metabolism of lead and the mechanism of its toxicity especially through the inhibition of haem synthesis. The new dimension mentioned in the title is that of foresight regarding general environmental pollution. In the case of lead, the author shows that, in the United States in 1966, 1,277,000 tons of lead were consumed, 573,000 tons were recovered, leaving 704,000 tons in the environment. About 20 per cent of the US lead consumption is in the form of the petrol additive, tetraethyl lead (TEL), and 70–80 per cent of the TEL used is released into the atmosphere to be inhaled or deposited on vegetation, soil and water.

These essays show the wide scope of toxicology, which is really a combination of many sciences. The "non-toxicologist" should therefore have no great difficulty in assimilating their content.

Obituaries

Professor Max Born

THE account that follows is a translation of the main part of a memorial address by Professor Werner Heisenberg. The address was given on January 12 at a meeting in Göttingen, where Max Born had died a week before at the age of 87.

Göttingen was Born's true scientific home. By the time he was 22, he was reading mathematics under Felix Klein and David Hilbert; he was introduced by Minkowski to problems in the electrodynamics of moving bodies, and it was here that he heard of the very beginnings of Einstein's theory of relativity and Einstein's light-quantum hypothesis, both of which made a very deep impression on him. Born's own thesis brought him into contact with questions of the elastic oscillations of rigid bodies, and in 1912, together with Theodore von Karman, he published his first scientific work of great significance; this dealt with the oscillations of crystal lattices. At that time the concept of a crystal as a regular ordering of atoms in a three dimensional lattice was generally accepted in principle; but it became a true physical statement only when it was possible to obtain concrete measurable results from the concept of a lattice. Born and von Karman applied the lattice model to the specific heat of the crystals at low temperatures for which Einstein had given a preliminary, although not entirely satisfactory, explanation in terms of Planck's quantum theory. Born and von Karman were able to demonstrate that the specific heat could be expressed even better if instead of considering the individual atoms as vibrating oscillators (as Einstein did), one considers the fundamental oscillations of the crystal lattice as the carriers of the oscillation-quanta. Henceforth much attention was to be paid to the lattice-structure of the crystal. In the same year, X-ray diffraction in crystals was discovered, providing a tool to throw light on the interior of crystals and to test the speculations of theoreticians. In the years that followed, Born continued to publish research on the lattice theory of crystals and assigned to his students doctoral theses connected with this sphere of problems. As late as 1954, when he was 72, he wrote in collaboration with a Chinese colleague a definitive report on this subject.

In 1915, Born was invited to Berlin as professor-extraordinary, where he entered into close association with Planck and Einstein. The four years in Berlin founded, first and foremost, the close friendship of Max Born and his wife Hedwig with Albert Einstein, which endured with undiminished cordiality until Einstein's death in 1955. A great part of Born's scientific deliberations was set down in his extensive correspondence with Einstein. After a brief period as professor in the University of Frankfurt, Born succeeded in 1921 to the professorship of theoretical physics at the University of Göttingen, and he was successful in obtaining at the same time the position of experimental physicist at Göttingen for his friend James Franck. Thus began the decisive new chapter in the history of the Mathematical Scientific Faculty at Göttingen. Up to this time, Göttingen had been a stronghold of mathematics; the tradition of Gauss, Riemann and Weber was consolidated by Felix Klein and Hilbert. And now, through Born and Franck, Göttingen also became a focus of atomic physics. Through his close cooperation with Franck, Born's interest was turned towards quantum theory, which he already knew very well from his contacts with Planck but which had originally repelled him somewhat by its obscurity, since he was so steeped in mathematical precision. With Niels Bohr's invitation to Göttingen in the summer of 1922 there began for Born a period of great activity on Bohr's theory of atomic structure, which found its expression in numerous lectures, seminars and colloquia.

Max Born proved to be an excellent teacher. Very soon he had attracted to his institute a number of gifted young theoreticians from various countries whom he inspired to take part in the study of the difficult problems of quantum theory. Together with Copenhagen, where Niels Bohr founded the new atomic theory, and Munich, where Sommerfeld with his work on atomic structure and spectral lines had founded a school for the new atomic science, Göttingen became a centre of the emerging discipline.

When I look back and compare the two schools of Munich and Göttingen where I was educated, and the teachers Sommerfeld and Born who headed them, I would say that Born bound his young colleagues to him first and foremost by making them still more sceptical of the contemporary state of the Bohr–Sommerfeld theory of atomic structure, and by awakening in his students the conviction that the most important work still remained to be done. In Munich there was still a widely held opinion that the atom could be approached by the old Newtonian mechanics provided that it was supplemented by the quantum conditions as formulated by Planck, Bohr and Sommerfeld. We at Göttingen had already more or less lost faith in this approach as a result of Bohr's lectures at Göttingen in 1922, and in his seminars Born expounded systematically his conviction that ultimately the problem was not one of working out complicated models of atoms and molecules, but rather of creating an entirely new mechanics. In spite of that fact—or rather, because of it—he required his students and colleagues to make a thorough study of the mathematical methods of the older mechanics and to consider them in seminars and discussions. For he rightly expected that only from a mastery of the older mechanics in all its details could there be awakened a consciousness of the scope which could perhaps be found for a new formulation of mechanics.

The seminars often took place in the evenings in a very small circle in the living room of the Borns' villa in an atmosphere of personal contact to which Frau Born, too, made a not inconsiderable contribution. I recall that at the time when I took part in these seminars, the participants very often included Pauli, Fermi, Hund, Jordan, the later Frau Goppert-Mayer and Delbrück. At that time most of them were still young students and only a few of them were over 25 years old. It was only later that they became known as co-founders of a new science, but it was here that they received their training for their future roles.

While speaking of personal contact, it should be mentioned that Born's home provided a good deal of social life for the young people, in which music played a great part. Born often played sonatas with Einstein, and as there were two grand pianos in Born's living room, I was occasionally able to play Mozart or Bach concertos with him. In the discussions at Born's seminars the ground was certainly prepared for the new atomic physics. As early as 1924 the word quantum mechanics was among those concepts which were obvious subjects of study. Born succeeded in producing among his young collaborators a sense of enthusiasm which meant that in the refectory or in the ski-lifts of the Harz mountains, quantum mechanics and the theory of astronomical perturbation were discussed far more than the notable events of the day.

If Born's school is to be compared with Bohr's school in Copenhagen, it should perhaps be said in favour of the Göttingen school that Born had a stronger conviction than Bohr that ultimately there must be a quantum mechanics that is closed and strictly formulated mathematically, and that quantum theory could not long remain in a state of contradiction between Newtonian mechanics, quantum conditions and the light quantum hypothesis. For Bohr, who had picked up the pragmatic tradition from his studies in England, this idea was not of such compelling importance as it was for Born with his mathematical training.

In 1925 and 1926, as a result of the joint work of Born's school, the final form of the new atomic theory was evolved. From his exceptional mathematical knowledge, Born was able to provide the methods of modern linear algebra, matrix calculus and theory of mappings for the representation of the new-found physical relationships. In the spring of 1926, when Schrödinger published his first researches in wave mechanics and proved the mathematical equivalence of quantum mechanics and wave mechanics, Born showed that the Schrödinger waves should be interpreted statistically so that their intensity is taken as a measure of the probability of finding a particle at a given point. The statistical character of natural law was for a long time the great stumbling-block to acceptance of the new theory; even Born and Einstein themselves could not agree on this, although their long-standing friendship was not, of course, affected. Later developments, however, proved that Born's views were the right ones.

In the years that followed, Born, together with his younger colleagues and students, applied the new quantum mechanics to problems of atomic structure, molecular physics and solid state physics. During this period a number of people destined to become the leading minds in physics, including Heitler, Fock, Oppenheimer, Teller, Weisskopf, Wigner and von Weizsäcker, belonged to the Göttingen circle. The intensive work they achieved is too far-reaching in its implications to be discussed here. The University of Göttingen at that time contributed far more to the prestige of German science abroad than most other German universities.

In the spring of 1933, the work came to a sudden halt with the devastation inflicted by the Nazis on Göttingen and all the other German universities. Born and Franck had to leave Göttingen. First of all, Born obtained a lectureship in Cambridge—the Stokes lectureship in applied mathematics, a position far lower than he had held in Göttingen. In 1936 he was offered the Tait professorship in natural philosophy at Edinburgh, and here he remained until his retirement in 1953. In Edinburgh too, Born gathered colleagues and students around him for a combined assault on physics. A series of works appeared on the statistical mechanics of condensed systems, the theory of fluids and associated problems. But the great activity of the Göttingen years could not be repeated in the Scottish university city, if only because in the meantime the interest of many physicists had turned to other problems. Nuclear physics was now the chief point of discussion. But Born did not take part in these developments. The possibility of the technical application of nuclear physics and the use of atomic energy became, at the end of the thirties, with Otto Hahn's discovery of uranium fission, the most exciting topic for atomic physicists. Born observed this development with great concern; he was dismayed at the possible consequences of these significant scientific advances and strove to minimize the danger.

Correspondence

X-Ray Stars and Infrared Excess

SIR,—In the course of his article on January 3, your Astronomy Correspondent says that Cowsik and Pal[1] are credited with the observation that " . . . the infrared flux might also be the cause of the X-ray background in the galactic plane which the Leicester group reported in October. . . . "

The fact is that the first article suggesting this mechanism for X-rays is the *Phys. Rev. Lett.*[2] article of the undersigned. Furthermore, when the Leicester results were reported in *Nature*, we published a further article (in *Nature*[3])—which also pre-dated the Cowsik–Pal article—discussing the anisotropy of the X-rays.

Yours faithfully,

Diffusion in Embryogenesis

SIR,—As an embryologist who started work during the heyday of "fields" and "gradients", I suppose I ought to be grateful to Dr Francis Crick for allowing me a nostalgic look back at these long-discredited concepts which he has now resurrected—or should I say, canonized—with the double halo of his own reputation and some elegant mathematics (*Nature*, **225**, 420; 1970). There is, however, one point that he appears to overlook: the extreme rarity with which sheer diffusion processes occur in living systems. Twenty years ago my better-informed colleagues told me about active transport and permeases. Ever since then, if materials have diffused in and out of my experimental embryos, I have regarded it as a sign that they are dying or dead. A sheet of frozen-dried tissue, extended between source and sink, might fit Dr Crick's formulae, but—alas—it would not differentiate !

Yours faithfully,

ELIZABETH M. DEUCHAR

University of Bristol.

British Diary

Monday, February 16

Contention or Polling Techniques for Data–Computer Systems (5.30 p.m. discussion) Institution of Electronic and Radio Engineers. Joint IEE/IERE Computer Group, at the Institution of Electrical Engineers, Savoy Place, London WC2.

Insect Hormones and Insect Control (5 p.m.) Dr K. C. Highnam, Society of Chemical Industry, at 14 Belgrave Square, London SW1.

Recent Advances in Medicine, Surgery and Therapy (6 p.m.) Sir Brian Windeyer, Royal Society of Arts, at John Adam Street, London WC2. (First of three Cantor Lectures. Further lectures on February 23 and March 2).

The Treatment and Disposal of Industrial Effluent (all-day symposium) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

Tuesday, February 17

Acrylates, Their Production and Use (6 p.m.) Dr H. Willersinn, Society of Chemical Industry, at 14 Belgrave Square, London SW1.

Amplification Reactions and their Applications (4.30 p.m.) Professor R. Belcher, Society for Analytical Chemistry; and the Edinburgh University Chemical Society, in the Chemistry Department, University of Edinburgh, West Mains Road, Edinburgh 9.

Casting of Polyurethanes (2.30 p.m.) Plastics Institute, Processing Discussion Circle, at 11 Hobart Place, London SW1.

Cereal Growing in Britain (10 a.m.) Society of Chemical Industry, Agriculture Group, at 14 Belgrave Square, London SW1.

Discriminators for Broadcast FM Transmission (6.30 p.m.) Mr Hugh Mayo, Institution of Electronic and Radio Engineers, at Brighton College of Technology, Brighton.

Experimental Gallstones (5.30 p.m.) Dr I. A. D. Bouchier, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1. (Twelfth of fifteen lectures on "The Scientific Basis of Medicine".)

Ionisation by Coordination (2.30 p.m.) Professor V. Gutmann (Vienna), University of London, in the New Chemistry Theatre, University College London, Gower Street, London WC1. (Further lecture on February 18).

Ocean Resources—Boom or Bubble? (1.20 p.m.) Professor L. J. Rydill and Dr A. J. Smith, University of London, in the Botany Theatre, University College London, Gower Street, London WC1.

System Identification with special reference to Respiration (5.30 p.m.) Dr I. Priban, Institution of Electrical Engineers; the Institute of Measurement and Control; and the Automatic Control Group of the I.Mech.E., at Savoy Place, London WC2.

The Management of Climatic Resources (5.30 p.m.) Professor T. J. Chandler, in the Chemistry Auditorium, University College London, Gower Street, London WC1.

The Volcano at Santorini and the Destruction of Minoan Crete (5.30 p.m.) Professor D. L. Page, University College London, in the Collegiate Theatre, 15 Gordon Street, London WC1. (Further lectures on February 19 and 24).

Wednesday, February 18

Cybernetics (7.30 p.m.) Dr A. M. Andrew, Institution of Electronic and Radio Engineers, at the University of Reading, Whiteknights Park, Reading.

Development and Marketing of New Chemical Engineering Equipment (2 p.m. symposium) Institution of Chemical Engineers, at the Royal Society, Carlton House Terrace, London SW1.

Factors Limiting the Application of Food Science and Technology in Developing Countries (2 p.m.) UK Coordinating Committee for Food Science and Technology, at the Society of Chemical Industry, 14 Belgrave Square, London SW1.

Gravitation and Geometry (5.30 p.m.) Professor P. C. Vaidya (Gijarat), University of London, at Queen Elizabeth College, Campden Hill Road, London W8.

Mass Communication (6 p.m.) Mr Stanhope Shelton, Royal Society of Arts, at John Adam Street, London WC2.

Microscopical Illustration (1 p.m.) Mr G. L'E. Turner, Royal Institution, History of Science Discussion Group, at 21 Albemarle Street, London W1.

Recent Advances in Radar Anti-Clutter Techniques (5.30 p.m.) Dr W. S. Whitlock, Institution of Electrical Engineers, at Savoy Place, London WC2.

Solute-Solvent Interactions (5.30 p.m.) Professor Viktor Gutmann, University of London, at King's College, Strand, London WC2.

Street Lighting (5.30 p.m. discussion) Institution of Electrical Engineers, at Savoy Place, London WC2.

The Measurement of Ships' Velocity (5 p.m.) Mr B. W. Oakley, Institute of Navigation, at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London SW1.

The Presentation of Data from a Process Control Computer (7.30 p.m.) Institution of Chemical Engineers, in Room G44 Royal Fort, University of Bristol.

The Professional Engineer as an Industrial Tutor (6 p.m. discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

The Role of The City University (1.10 p.m.) Sir James Tait, City University, at the Graduate Business Centre, Gresham College, Basinghall Street, London EC2.

Use of Computers in Designing Automatic Process Controllers (6 p.m.) Mr D. J. Norton, Institution of Electronic and Radio Engineers; and the Institution of Electrical Engineers, at the University of Bristol.

Thursday, February 19

Amino-Acids and Peptides in Gut and Kidney (5.30 p.m.) Professor M. D. Milne, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1.

Bridging the Gap—an Open Discussion of the Problems of Manufacturers and Users in the Field of Automatic Instrumentation (6.30 p.m. discussion) Society for Analytical Chemistry, Automatic Methods Group, at the Leicester Lounge, Glasshouse Street, London W1.

Carbon Fibres (7 p.m.) Mr R. Morgan, Plastics Institute, at Imperial Chemical Industries, Ltd., Britannia House, 50 Great Charles Street, Birmingham 3.

Gene Action and Its Control (10 a.m. two-day meeting) Royal Society, at 6 Carlton House Terrace, London SW1.

Fragrances for the Paper Industry (7.30 p.m.) Mr A. F. Morris, British Society of Perfumers, at "The Havelock", Gray's Inn Road, London WC1.

How to Find a New Herbicide (7 p.m.) Dr J. A. Farrington, Society for Analytical Chemistry; and the Royal Institute of Chemistry, in the Department of Chemistry, University College of Swansea.

Manufacture of Small Electronic Components (6 p.m. discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

People, Communications and Engineering (5.30 p.m.) Mr J. H. H. Merriman, OBE, Institution of Electrical Engineers, at the Central Hall, London SW1.

Phlebotomine Sandflies and Leishmaniasis in British Honduras (Belize) (7.30 p.m.) Dr Paul Williams, Royal Society of Tropical Medicine and Hygiene, at Manson House, 26 Portland Place, London W1.

Placental Localization Studies (5.45 p.m. discussion); **Plain Film Changes in Heart Disease** (7.15 p.m.) Dr R. G. Grainger, Dr K. E. Jefferson and Dr I. Kerr, British Institute of Radiology, at 32 Welbeck Street, London W1.

Polishes (7 p.m.) Mr E. M. Clough, Oil and Colour Chemists' Association, at the Manor Hotel, Dachet, Bucks.

The Oxford Biological Films Unit. Films and the Techniques of Scientific Film Production (5 p.m.) Linnean Society of London, at Burlington House, Piccadilly, London W1.

The Problems of Specifying Road Materials Mr J. H. Nicholas, Society of Chemical Industry, Road and Building Materials Group: and the Institute of Highway Engineers, in the Mechanical Engineering Department, Imperial College, Exhibition Road, London SW7.

The Use of Grease as an Engineering Component (two-day symposium) Institution of Mechanical Engineers, at 1 Birdcage Walk London SW1.

Your Environment at Stake (8.15 p.m.) Mr Dunstan Skillbeck, University of London, at Witheradane Hall, Wye College, near Ashford, Kent.

Friday, February 20

A Review of Image Intensification (10 a.m.) Dr F. H. Doyle, Dr T. H. Hills, Mr E. J. Steadman *et al.*, British Institute of Radiology, at 32 Welbeck Street, London W1.

Communications in the Pacific (1.15 p.m.) Mr E. Clunies-Ross, Institute of Rural Life at Home and Overseas, at Friends International Centre, Courtauld House, Byng Place, London WC1.

Corrosion Problems in Highway Research (6.30 p.m.) Dr R. R. Bishop, Oil and Colour Chemists' Association, at the Chamber of Commerce House, 75 Harbourne Road, Birmingham 15.

Field Store Standards Conversion (5.30 p.m.) Mr S. M. Edwardson, Institution of Electrical Engineers, at Savoy Place, London WC2.

Forensic Science (7.45 p.m.) Dr Hamish Walls, H. G. Wells Society, in the Electrical Engineering Department, Imperial College, Exhibition Road, London SW7.

Moon Dust (9 p.m.) Professor S. Tolansky, FRS, Royal Institution, at 21 Albemarle Street, London W1.

Some Recent Studies of Excited States by Pulse Radiolysis (1 p.m.) Dr E. J. Land, Royal Institution, Photochemistry Discussion Group, at 21 Albemarle Street, London W1.

The Chemistry and Biological Activity of 1,4-Benzodiazepines (6.30 p.m.) Dr L. H. Sternbach, Society of Chemical Industry, at 14 Belgrave Square, London SW1.

The Core-Mantle Interface (2.30 p.m. geophysical discussion) Royal Astronomical Society, at Burlington House, Piccadilly, London W1.

The Relative Importance of Heredity and Environment in the Growth and Physique of Children in Sub-Saharan Africa (5.30 p.m.) Professor Jean Hiernaux (Brussels), University of London, at the Institute of Child Health, 30 Guilford Street, London WC1.

Saturday, February 21

Rapture of the Deep (3.30 p.m.) Mr Ley Kenyon, Inner London Education Authority, at the Horniman Museum, London Road, Forest Hill, London SE23.

HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one copy of NATURE each week is:

12 MONTHS (52 issues and 4 indexes)

Great Britain and Eire	**£14.0.0** each
United States of America (by air freight)	**$48** each
Canada (by air freight)	**$52** each
Elsewhere overseas by surface mail	**£14.0.0** each

(Charge for delivery by air mail on application)

•Shorter periods *pro rata*. (Minimum three months.)

Monday, February 23

Terminal Units and Transmission in Electronic Telephone Exchanges (5.30 p.m.) Mr T. H. Flowers, Institution of Electrical Engineers, at Savoy Place, London WC2.

The Mechanical Equipment for the Construction of the Victoria Line (6 p.m. discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

Thermoplastics in the Cable Industry (7.30 p.m.) Mr R. H. Greenhalgh, Plastics Institute, at the Stork Hotel, Queen Square, Liverpool.

STAINS & REAGENTS FOR BIOLOGY

Acridine orange, Aquamount, Fluormount, Lipid crimson, Matamount, May-Grünwald, Leishman, Giemsa Toluidine blue, Cresyl fast violet, Papanicolaou stains, Thioflavine S, Brilliant cresyl blue, Nile blue, Pyronin Y, Trifalgic acid, Rhodanile blue, Haplo, etc.

CATALOGUE AVAILABLE ON REQUEST

DYES FOR USE IN ALL INDUSTRIES

RESEARCH & PRODUCTION CHEMISTS: if you are seeking dyes with specific chemical and physical properties suitable for particular manufacturing and/or testing processes you are invited to contact us for supplies.

We hold stocks of an enormous variety of dyes, ready for immediate despatch, including:

Cyanine, Dicyanine, Fast Bordeaux O, Aurantia, Crystal violet, BPC-Scarlet R, BPC, Diazonium salts, Neutral violet, Lacmoid, Nile blue, Janus green, Brilliant green BPC, Rosolic acid, Methyl green, p-Ethoxy-chrysoidin, Methyl red, Nitrazine yellow, Pinacryptol green, etc.

INDUSTRIAL RESEARCH ESTABLISHMENTS

are invited to make use of our professional services as consultants on the selection and use of dyes as research and production tools.

QUALITY — RELIABILITY — SERVICE
PROMPT DELIVERY

wright ACRYLIC chromatography columns

versatile inexpensive laboratory columns for chromatographic and gel filtration procedures employing aqueous solvents

Simple to use—unique patented design in acrylic and nylon with sintered plastics bed support.
Minimal dead space with low-volume connections. Diameters selected to produce cross-sectional area of 2, 4, 8, & 16 sq. cms.
Fixed or adjustable columns with or without jackets.
Standard lengths of 30, 60 and 90 cms.
Columns easily lengthened by joining.
Prompt delivery of standard columns from stock.
Preparative columns with bed volumes up to 50 litres are available to special order

Prices from £5

MONASH UNIVERSITY

Graduate Research Scholarship for Research into Engineering Properties of Plastics (Civil Engineering)

Applications are invited from suitably qualified graduates for a graduate research scholarship which has been established by the State Rivers and Water Supply Commission for an investigation into the long term behaviour of plastics components in the field. The work involves both an examination of the materials involved and the conditions to which they will be subjected in service.

BENEFITS:

Stipend £2,500 p.a., plus dependants allowance £500 p.a. for a scholar with one or more dependent children; tuition fees covered by grant attached to scholarship. The scholarship is initially for 2 years and would enable a candidate to complete the requirements for the degree of Master of Engineering Science; a possible extension for a third year is envisaged to enable the scholar to transfer to Ph.D. candidature.

Further details may be obtained from Professor N. W. Murray, Department of Civil Engineering, Monash University with whom applications close on 28th February, 1970. It is hoped to hold interviews in Britain and Australia during March.

Application forms are available from the Agent General for Victoria, Victoria House, Melbourne Place, The Strand, London, W.C.2.

J. D. BUTCHART,
Academic Registrar

Monash University,
Clayton, Victoria, 3168.
Australia.

Railway Transport Research

MAJOR PHYSICS PROJECTS

The British Railways Board is engaged on a major expansion of its research activities involving a wide range of scientific and technological work. There are several major physics projects, some of which have special funding from the Ministry of Transport. This work has also attracted financial support from abroad.

This expansion has created a further three posts in the Electrical Research Division for work in the field of environmental physics and ergonomics. Candidates for the more senior posts should have research experience, good knowledge of basic physics and the ability to plan experiments. Familiarity with electronic techniques of measurement and information display, or a general knowledge of measuring techniques met in environmental studies is desirable.

The third post needs a keen practical experimentor with a good physics or electronic engineering background, interested in making and using apparatus for measuring the physical effects of environment on men and machines.

An Honours Degree or equivalent academic attainments will be necessary for all these posts. Salaries will be in the range £1810 to £2340 or £1700 to £2010 per annum depending on experience and qualifications. All posts will be located in the Railway Technical Centre, Derby.

The Board operates a contributory pension scheme and has arrangements with many employers for the preservation of pensions. There are also free and reduced rate rail travel facilities.

Applications giving age, education, qualifications, experience and present salary should be sent to the **Headquarters Staff Manager (quoting reference RD.E/U), British Railways Board, 222 Marylebone Road, London, NW1.**

(606)

Glaxo

IMMUNOLOGIST

A vacancy exists in the Biological Research Department of Glaxo Research Limited at Greenford, Middlesex, for an Immunologist to join a team engaged in a variety of problems connected with immunostimulation and immunosuppression.

The post is an interesting and challenging one, offering considerable opportunities for original work. Ideally, applicants should be between 25 and 35 years and should have a Ph.D. in Immunology, but graduates in Biological Sciences with post graduate experience in Immunology will also be considered.

An attractive salary will be offered to secure the right candidate. Conditions of employment include participation in the company's profitability, contributory pension scheme and assistance with removal expenses where appropriate.

Please write, quoting reference U.93, to the Senior Personnel Officer (GJB), Glaxo Laboratories Limited, Greenford, Middlesex. (607)

UNIVERSITY OF OXFORD

UNIVERSITY LECTURERSHIP IN GEOCHEMISTRY

University Lecturer in Geochemistry (in the Department of Geology and Mineralogy) required with effect from October 1, 1970.

Applicants may be graduates either in chemistry or in geology, and must be prepared to teach a course in inorganic and physical chemistry for the Preliminary Examination in Geology, and to be responsible for the organisation of, and some of the teaching for, the postgraduate Diploma in Geochemistry. Some assistance in teaching other relevant courses for the Honour School of Natural Science (Geology) may also be required. The person appointed will also be responsible for the working of the chemical laboratories within the Department.

The University Lecturership may be held in conjunction with a college Fellowship or Lecturership, particularly if the successful candidate were able to devote some of his time to college tuition in inorganic and physical chemistry for the Honour School of Natural Science (Chemistry).

The initial stipend will be according to age in the range £1,240 (at twenty-four and under) by £115 to £2,850 (at thirty-eight) by £90 to £3,120 (at forty-one), with F.S.S.U. benefits.

Four typed copies of applications (one only from overseas applicants), including the names of two referees, should reach Professor E. A. Vincent, Department of Geology and Mineralogy, Parks Road, Oxford, OX1 3PR (from whom further information may be obtained), not later than March 9, 1970. (628)

Searle Scientific Services

a division of G.D. Searle & Co. Ltd.

BIOCHEMIST

A Graduate Biochemist is required to work in the Biochemistry section of our Clinical Pathology Laboratory in London. The laboratory carries out a wide range of tests and is highly automated. Equipment includes Technicon SMA 12/60, 6/60, 7A, P.B.I. and single channel analysers and a B.T.L. Analmatic Clinical Analysis System. It is planned to put these on line to a computer and delivery of the first Digital PDP-12 advance Clinical Laboratory System in Europe is scheduled for early in March 1970. The post is concerned mainly with quality control and data processing and candidates should have an interest in this area in addition to a wide experience in a hospital biochemistry service. Emphasis will be placed on research and development and every encouragement will be given to publication of scientific work.
Salary will be attractive and negotiable; conditions of service are excellent.

Please write with brief details to:

The Personnel Director,
G. D. Searle & Co. Ltd.,
Lane End Road,
High Wycombe, Bucks.

SEARLE

Research in the Service of Medicine.

(572)

Scientific Writer Sweden

PHARMACIA

Leaders in the field of gel Filtration media are offering an excellent opportunity at their headquarters in Sweden. This post is based in Uppsala. The successful candidate should have a degree or equivalent qualification in Chemistry, Biochemistry or allied subjects.

Clear expression in the written word is essential with a high degree of accuracy and English as the Mother tongue.

He will be joining a young team in the Technical Information Department with responsibilities for the production of manuscripts for technical and scientific information and promotional literature. His duties will also include literature searching.

Preferred age 25–30. This is an important post which will command a salary commensurate with qualifications and experience and carries good social security arrangements.

Please apply in writing giving personal details, education, qualifications and experience. All applications will be treated in strict confidence.

To :

Pharmacia (G.B.) Ltd,
(Ref. Personnel F.C.),
75 Utbridge Road,
London W.5.

(655)

MONASH UNIVERSITY

MELBOURNE, AUSTRALIA

DEPARTMENT OF PHYSIOLOGY

Applications are invited for appointment to the position of Senior Teaching Fellow or Teaching Fellow in the Department of Physiology.

The department teaches courses in Physiology and Pharmacology for the degrees of B.Sc., B.Sc.(Hons.) and M.B., B.S., and accepts postgraduate students for the degrees of M.Sc., and Ph.D. Principal research interests are: brain function and ultrastructure, including learning mechanisms, the physiology of sense organs and their central pathways, spinal reflex mechanisms and control of movement by the brain, and biophysics and pharmacology of central and peripheral synapses and of smooth and cardiac muscle; endocrine and circulatory physiological control mechanisms. Increasing attention is being paid to the correlation of ultrastructure with physiological findings, and computer analysis of experimental data.

Salary ranges : Senior Teaching Fellow $A4,390 to $A5,290 per annum ; Teaching Fellow $A3,600 to $A4,275 per annum.

Benefits: Travelling expenses for appointee and family; removal allowance, initial subsidised housing ; repatriation after three years' appointment if desired.

Further general information including details of application procedure is available from the Academic Registrar, Monash University, Wellington Road, Clayton, Victoria 3168, Australia, or the Secretary-General, Association of Commonwealth Universities (Appts.), 36 Gordon Square, London, W.C.1. Information concerning research and teaching programmes may be obtained from Professor A. K. McIntyre, in the University.

Closing date for application : March 16, 1970.

The University reserves the right to make no appointment, or to appoint by invitation.

(624)

PAPUA AND NEW GUINEA INSTITUTE OF TECHNOLOGY

(Formerly Institute of Higher Technical Education)

PROFESSOR OF ELECTRICAL ENGINEERING OR PROFESSOR OF MECHANICAL ENGINEERING

Applications are invited from Mechanical and Electrical Engineers for the post of Head of the joint Electrical and Mechanical Engineering Department.

Salary: $A12,500 per annum. An additional $A360 is normally paid to married male members of staff.

The Chairman of the Council of the Institute is Dr. J. A. L. Matheson, M.B.E., M.Sc. (Manch.), Ph.D.(Birm.), F.I.C.E., M.I.Struct.E., F.I.E.Aust., who is Vice-Chancellor of Monash University. The Director is Dr. W. E. Duncanson, M.Sc.(Syd.), Ph.D.(Camb.), D.Sc. (Lond.), F.Inst.P., C.Eng., F.I.E.E., F.I.E.Aust.

Applicants should have a degree in the appropriate subject with experience in teaching, in research, or in industry. It is not expected that applicants will have had experience in both Electrical and Mechanical Engineering as there will be other senior staff in both disciplines. However, a broad interest in the subjects would be an advantage.

The Institute provides professional technological training for the whole of the Territory and has been charged with the responsibility of undertaking research and development in these subjects. A number of projects are already in hand and others are planned.

Further information about the Institute, method of application and conditions of appointment (including leave and leave passages, F.S.S.U. type superannuation, study leave, etc.), may be obtained from the Secretary-General, Association of Commonwealth Universities (Appts.), 36 Gordon Square, London, W.C.1.

Applications close on March 25, 1970.

The Institute reserves the right to make no appointment or to make an appointment by invitation at any stage. (591)

DEPARTMENT OF PHYSICS

UNIVERSITY OF MANITOBA

Offers generous assistance to highly qualified students wishing to do graduate work in physics. Extensive and modern facilities for work in nuclear structure and reactions, solid state, low temperature, atomic physics, and cosmic rays are available.

For information apply to: Head, Department of Physics, University of Manitoba, Winnipeg 19, Man. (X495)

An Index of Quality

The Pye Trap Index Level Selector is a brilliant new addition to the accessories available with the Series 105 Automatic Preparative Chromatograph. In conjunction with the instrument's punch tape control system, this highly sophisticated control unit, with an electric comparator circuit, achieves an exceptional degree of accuracy in component and fraction collection – even at the end of a separation lasting several hours. Trap rotation and sample collection at any level on the chromatogram are initiated independently of the recorder by the amplifier's signal. And up to six different actuation stages are available. Programming is straightforward – you press the command buttons either to synchronise the tape with the chromatogram and index a trap, or simply to index a trap, then dial the amplifier output level at which the operation is to be carried out.

Write or 'phone for full details of the Pye Series 105 Automatic Preparative Chromatograph and its Index of Quality.

Visual feedback control—Intermittency demonstrated in a repetitive motor task—BEGGS and HOWARTH (Nottingham) 752
Insect physiology—Water uptake from subsaturated atmospheres via anus of *Thermobia domestica*—NOBLE-NESBITT (East Anglia) 753
Fish behaviour—Alarm pheromone and avoidance conditioning in goldfish—KIMBRELL, WEINROTT, MORRIS, SCHEID and SANGSTON (Denison) . 754
Lipids of salmon—After spawning, migration serum has low lipid content—PATTON (Pennsylvania State), CROZIER (Alabama) and BENSON (California) . 754
Plant pathology—Host response of tobacco to *Verticillium dahliae*—MAHANTY (Cawthron Institute, Nelson) 755
Grasslands—Trends in vegetation on grazing land expressed as "relative entropy"—HUGHES and DALE (The Nature Conservancy) 756
Poisons—Creeper found to be antagonistic to jellyfish poison—WASUWAT (Applied Scientific Research Corporation of Thailand) 758
Algae—Introducing the Eustigmatophyceae—HIBBERD and LEEDALE (Leeds) 758
Cell walls—Where is the protein in the alga *Valonia*?—STEWARD, MOTT, ISRAEL and LUDFORD (Cornell) 760
Antibiotic activity—No increase of sensitivity after EDTA treatment of resistant bacteria—NEU and WINSHELL (Columbia) 763
Bacterial genetics—Complete mutagenesis induced in solid medium devoid of thymine—BRESLER, MOSEVITSKY and VYACHESLAVOV (Leningrad) . 764
Population growth—Describable by multi-type Galton-Watson process—SENETA (Cambridge) . 766

University Life Assurance Society

Established 1825 *Incorporated by Royal Charter*

For nearly 150 years the Society has offered life assurance on attractive terms exclusively to past and present members of Universities and similar educational establishments within the United Kingdom.

The Society does not pay commission for the introduction of new business.

Special plans for Students or Young Graduates

The "Minimax" Policy **Reduced Premium Policy**
Young Graduate's Policy

Other plans include

Whole-life and Endowment assurance
Educational Policies **Children's Policies**
Pension Policies . Annuities . Family Protection
Unit-linked Assurances and Annuities

NATURE Volume 225 FEBRUARY 21, 1970

Loose Edges in the Grand Design

THE first thing to be said about the discussion so far on the proposed reorganization of the British Government's support for scientific research and development (see *Nature*, **225**, 219; 1970) is that too little of the discussion has been in public. No doubt the hierarchies of official committees are giving the matter their deliberate consideration, but that is unlikely to cut thick ice. A part of the reason is that the committees have usually had their say well in advance, and these opinions have been duly discounted by everybody concerned. But there are also a number of issues raised by Mr Wedgwood Benn's green paper where informed but detached opinion has a great deal to contribute. It will be a great pity if important matters like these are decided arbitrarily, in default of proper discussion.

The second thing to say is that there would be a good deal of merit in beginning public discussion with the question of what is in future to happen to the two parts of machinery of public science which are conspicuously absent from the green paper—the defence research establishments and the research associations. Since one of the more obvious defects of the British Research and Development Corporation which the Ministry of Technology proposes is that it will resemble all too closely what may be called, not with necessarily unkind intent, the rump of the Atomic Energy Authority, it must have taken some fortitude to omit these organizations from the proposed authority. Why, and is it too late to go back on this decision ?

The future of the Research Association is, unfortunately, something of a condominium. The associations have their origins in the pre-history, when research was in any case something of a mystery. Then, in the thirties, it may have seemed to many smallish companies that there would at least be profit in an attempt cooperatively to find out what research is all about. The tendency to cooperate was, however, reinforced by the somewhat shocked discovery, in the fifties, that a great many traditional industries were almost entirely innocent of scientific research and were even unprovided with trained technical people. (Jute manufacturing was one of the most scarifying illustrations of this, and practically, and almost predictably, it has not survived to tell the tale.) In the event, however, only a few of the research associations have become centres of original research. For most of them, the most urgent task is the dissemination of known information more widely and more efficiently. All of them are to some extent perplexed by the diversity of their membership—frequently a single member company may mount a larger effort, even in research on its own account, than the Research Association can support. Now that the annual government subvention has been pegged at £4 million, it is hard for any of them to see a brilliant future opening up ahead. Indeed, the chances are that if the research associations were transferred to the proposed research and development authority, their prosperity would be quickly diminished by the competition from other outlets for public money in research.

Against this background, the future of the research associations must necessarily rest with them. The first need is to define a function which is likely to persist. The most hopeful prospect is the provision of technical information to industries within which, for structural reasons, information does not flow easily. In due course, consultancy could follow. With such a goal, however, there is probably no reason why the research associations should remain as independent of each other as they are bound by their constitutions to be at present. All this suggests that there is a need for a unified organization for the research associations—a framework within which advice, ideas and people could be more readily interchanged than is at present possible. Paradoxically, the present system whereby government grants are channelled to individual associations is an impediment to this. Moreover, there is probably no reason why an organization formed by an amalgamation of the research associations, or at least by their integration into a single framework, could not play a useful part, providing technical advice for small businesses, within the kind of organization which the Government has proposed. To be sure, it is also possible that such an organization could support itself by levying fees on those who used its services. There is no certain choice between these two courses of development, but what is certain is that the research associations can only stay where they are, in limbo, if they are reconciled to extinction in the comparatively near future.

The defence research establishments are a harder nut to crack. The Royal Aircraft Establishment and the Royal Radar Establishment are the two most obvious omissions from the proposed arrangements, but several other smaller laboratories should belong as well. For one thing, it is fair seriously to doubt the viability of the new organization for research and development if these laboratories are not included. What will happen, for example, if under the new arrangements, the board of the British Research and Development Authority considers that it would be prudent to take on work in aerodynamics or telecommunications, thus threatening the defence laboratories with trespass ? Will somebody say no ? And if not, is there not a risk of serious muddle ? But, worse still, without the skill and special knowledge of these defence laboratories, is there not a danger that the British

Research and Development Corporation will be less well equipped than it should be to seize opportunities for which it is supposedly being created? Finally, it is also almost beyond dispute that the defence laboratories will suffer in the next few years the tribulations of finding that they have somehow outlived the purposes for which they were originally established. What will happen then? Will there have to be a second authority for research and development?

These questions call for urgent attention. If they are not answered sensibly, the new authority cannot itself make sense. But it is also only right to acknowledge that the whole fabric of the new proposals rests on the assumption that it will be possible, within the framework of the British Research and Development Corporation, to increase enormously the amount of useful work which government laboratories can carry out for industry, and that it will be possible within the public service to find means by which a public corporation can take financial risks with public money. Those are the questions on which the soundness of the new proposals must ultimately depend.

Can the Health Service Survive?

On the face of things, at least, Mr Richard Crossman seems to have made a set of sensible suggestions about the organization of the British Health Service in his discussion paper *The Future of the National Health Service* (HMSO, 5*s*), published last week. To the extent that the proposed arrangements will bring more closely together general practice, the hospital services and the responsibility for public health which has so far been vested in the great variety of local authorities throughout the country, the proposals are obviously to be warmly welcomed. One of the most serious defects of the working of the National Health Service in the past twenty years is that there has been no easy machinery by means of which medical people can decide among themselves whether, for example, an individual patient is best treated in hospital or at home. The new arrangements offer an opportunity, to say no more, for enabling general practitioners to follow their patients into hospital and, in due course, to retain some professional interest in some special branch of medicine. And who will doubt that the larger hospitals could make an important contribution to the working of the public health services if they were somehow more closely involved?

How well will the new arrangements work? What encouragement will there be for the tendencies which the government is commendably seeking to encourage? Everything will depend on the effectiveness of the proposed area health authorities, one for each of the units defined by the Royal Commission on Local Government in its report a year ago. On this basis, each of the new authorities will be responsible for the health services for between 200,000 and 1,500,000 people, and the intention is that they should consist of between 20 and 30 voluntary members superintended by a chairman who will eventually be paid a part-time salary. To the extent that this proposal will get rid of the anomalies in the present system, it is to be welcomed. Most probably, it is also wise that the new proposals do not follow the Royal Commission on Local Government in handing over the administration of the health services entirely to the local authorities. But is there not a danger that the new arrangements will fall awkwardly between the disadvantages of extreme centralization and excessive devolution?

Has enough thought been given to the possibility that the control of at least some parts of the health service should be entrusted not to voluntary committees of the kinds whose compromises have been traditionally an essential part of British public life, but to more clearly identified full timers who would be more obviously responsible to the community they serve for the efficient conduct of their operations? The dash of syndicalism in Mr Crossman's proposals—one third of the members of the new authorities will be nominated by the health professions (and one third by the local authorities)—is not a sufficient guarantee that the new arrangements will function well—to begin with, indeed, it may be sand in the works.

The potential weakness of the health authorities (with the intellectual dependence on the centre at Whitehall which that implies) is also a reason for anxiety about the proposals for closer links between the health service proper and the public health services at present administered by the local authorities. It is sensible enough that responsibility for matters such as vaccination, home nursing and family planning should be closely linked with the hospital services and with general practice, and there are evidently several valuable opportunities to be seized within the new framework, but it is also clear that the modest successes of the local authorities in the past few decades have depended on such facilities as they possess for carrying important messages to members of the public. What assurance is there that the new health authorities will be equipped in ways like these? Certainly there is nothing in the records of the regional hospital boards which administer the present system to suggest that these tasks will come naturally to the new people.

Public discussion about the organization of the National Health Service, valuable though it may be, is unfortunately only a minor contribution to the problems of public health in Britain which cry out urgently for solution. Mr Crossman's green paper says, quite properly, that the coming of the National Health Service has contributed enormously to the good health of the British population. That this should be is understandable enough. In the fifties, the health service was comparatively well provided with funds even if many of its facilities—hospitals, for example—left a great deal to be desired. Although the system has steadily improved since then, with commensurate increases of cost, the British system is now much less of an international boast than it used to be. The quality of medicine is good, even though it can sometimes cause wry smiles when compared with practice elsewhere. The quality of the service provided is variable, to say the best of it. But hanging over everything is the fear that it may only be a matter of months before there is a rapid deterioration of the efficacy of the system. Plainly the health services have exhausted their goodwill with the nurses. But would the framework which Mr Crossman now proposes be able to meet the strain of paying nurses and other medical ancillaries at rates which are competitive? With this anxiety, is it sensible of him to complain about the continued success of the private medical insurance schemes which are flourishing alongside the health service? Might it not be more prudent to devise some method of mixed financing for the new health service? That is at least a question which deserves serious consideration, quite independently of party politics and separate from the commitment to a totally free health service on which Mr Aneurin Bevan nailed the present government's colours to the mast just twenty years ago.

100 Years Ago

In fact, the Miocene Mammalian Fauna of Europe and the Himalayan regions contains associated together the types which are now separately located in the South African and Indian sub-provinces of Arctogæa. Now there is every reason to believe, on other grounds, that both Hindostan, south of the Ganges, and Africa, south of the Sahara, were separated by a wide sea from Europe and North Asia, during the middle and upper Eocene epochs. Hence it becomes highly probable that the well-known similarities and no less remarkable differences between the present Faunæ of India and South Africa have arisen in some such fashion as the following. Sometime during the Miocene epoch, possibly when the Himalayan chain was elevated, the bottom of the nummulitic sea was upheaved and converted into dry land, in the direction of a line extending from Abyssinia to the mouth of the Ganges. By this means, the Dekhan on the one hand, and South Africa on the other, became connected with the Miocene dry land and with one another. The Miocene Mammals spread gradually over this intermediate dry land, and if the condition of its eastern and western ends offered as wide contrasts as the valleys of the Ganges and Arabia do now, many forms which made their way into Africa must have been different from those which reached the Dekhan, while others might pass into both these sub-provinces.

That there was a continuity of dry land between Europe and North America during the Miocene epoch, appears to me to be a necessary consequence.

From T. H. Huxley's valedictory address to the Geological Society, of which he had been president for the past two years. Nature, **1**, 443, *February* 24, 1870.

OLD WORLD

DRUGS

More L-Dopa in Sight

INITIAL enthusiasm for the drug L-dopa in the treatment of Parkinson's disease seems to have been justified by the results of trials carried out so far. But the problem of supply is still formidable, although the Committee on the Safety of Drugs, in the thick of dealings with chemical and pharmaceutical companies, is doing its best to approve the use of new and reliable preparations.

Impressive evidence of the beneficial effects of the drug was seen at the first open meeting of the Parkinson's Disease Society in London on February 11. A film of two women sufferers whose unsteady gait and handwriting returned almost to normal after treatment was shown by Dr G. Stern, consultant neurologist at University College Hospital, London. This is one of five British centres where clinical trials of the drug are in progress under the auspices of the Medical Research Council. L-Dopa is, of course, the drug which was seen as a potential treatment for Parkinsonism when drugs which cause a decrease in amounts of monoamines, particularly dopamine, in the brain were found to cause the disease (*Nature*, **223**, 889; 1969).

Stern says that these patients are not his most successful cases; in some, for example, manual dexterity has apparently returned to normal from a very poor state. On the whole he finds that two-thirds of Parkinson patients treated with L-dopa during the trials have responded to varying degrees, while for the other third treatment has had no effect. These findings are similar to those reported in the *British Medical Journal* by Dr C. Mawdsley of the University of Edinburgh (1, 333; 1970). Of twenty patients treated for an average of six months he reported marked improvement in nine; this involved renewed ability to rise from a chair and walk comfortably without the need for aid. Fourteen patients experienced moderate improvement, in five it was only slight and a further five experienced no improvement.

Many Parkinson patients treated with L-dopa develop side effects—nausea and loss of appetite seem to be the commonest. Induced voluntary movements of the face and feet are also a frequent effect, but not usually distressing, disappearing as the dose is reduced. Psychiatric effects such as depression may pass off after a few days of treatment. Two of Mawdsley's patients developed hallucinations and paranoid delusions; one refused to take any more of the drug, but the other lost the symptoms when the dose was reduced.

There are clearly various possible side effects of L-dopa, and although many of them seem to be mild enough to accept for the sake of the benefits, neurologists involved in the trials must have great respect for the unknown element. As Stern told his audience on February 11, it is impossible to see yet how long the favourable effects of treatment will last. He was careful to stress that although L-dopa is the most effective form of treatment so far found for some patients, it is not a cure for Parkinsonism. When the drug becomes available for regular treatment patients who benefit from it will have to take it for the rest of their lives. Sufferers and their relatives who have heard so much about the new wonder drug may have been disappointed to hear Stern say that the most fascinating, and probably important, aspect of the work so far—much of it carried out in the United States—is that it has given an insight into the neurological basis of Parkinsonism.

Supplies of the drug are still a problem, and all patients taking part in the MRC trials know that they have to stop taking L-dopa afterwards, even if it has greatly benefited them. This is not as drastic as the Department of Health and Social Security implied when it warned physicians of the danger of suddenly taking a patient off L-dopa. When treatment stops, patients return to the condition they were in before taking the drug; they do not deteriorate further. It is unfortunate that there is insufficient L-dopa for everyone who could benefit from it, but those who have been blaming the Committee on the Safety of Drugs for dilatoriness in passing preparations as safe for use are being unfair: the committee is giving the matter priority treatment.

It is well known that the material used in the MRC trials is supplied by Roche of Switzerland, and until recently this was the only L-dopa approved by the committee. The other principal source of supply when the trials were set up was imported material from the Japanese company Sankyo, and criticism came from importers whose supplies were spurned by the ministry on the advice of the committee. But the committee points out that the companies concerned, primarily dealers in chemical reagents and not pharmaceuticals, were offering a preparation of doubtful quality.

Companies were asked to make a submission in the usual way, with details of manufacture, impurities and so on, together with details of other experimental studies carried out. This Roche had already done, and its preparation had been passed for clinical trials—the last stage before marketing. But in spite of a meeting at the end of last year between Professor Scowen and Dr Mansel-Jones of the committee and representatives of five firms no submissions were received, although the companies agreed to stop supplying L-dopa direct to patients, and only through neurologists. In these circumstances the committee was unable to do other than advise against the use of the preparations.

One company, Chemica Laboratories Ltd, announced publicly that it would sell in spite of the committee, complaining that it was not prepared to divulge manufacturing secrets. This was hardly a fair complaint when all such information is given in strict confidence. Chemica later retracted, however, announcing that it would cease to deal in L-dopa.

There is hope that this sad situation will be eased, for satisfactory submissions from two other companies, Brocades and Ward Blenkinsop, were dealt with at lightning speed two weeks ago. Their preparations have now been passed as safe for use by physicians, who will monitor the effects of treatment and send back detailed reports to the two companies. Ward Blenkinsop is producing L-dopa itself, while Brocades is initially importing the Japanese preparation and re-purifying it as well as making some of its own. Three more companies are actively engaged in research on L-dopa and are expected to make submissions to the committee soon.

HEALTH

Consultation to Curb Panic

ONE of the chief lessons of the cyclamate affair was the folly of one country taking precipitate action on a presumed health hazard without forewarning health authorities elsewhere. The obvious measure to prevent the recurrence of such fiascos (see *Nature*, **225**, 3; 1970) now seems to have been taken. Last week the Canadian minister of National Health and Welfare, Mr John Munro, was host in Ottawa to officials from the United States Department of Health, Education and Welfare and the British Department of Health and Social Security. The purpose of the meeting was to discuss future exchanges of information in areas related to public health. This presumably will include the results of toxicological tests on drugs, pesticides and food additives which, if circulated to other health authorities before the country of origin takes any public action, could avoid the embarrassing international consequences that have been the aftermath of the unilateral bans on cyclamates and other substances.

The next conference between the three countries will be held in London during April or May. Canada, the United States and Britain are three countries who have perhaps the most to gain from coordinating their action on drugs and additives, but if the consultation works well other European countries such as Sweden may well wish to join the club.

SOCIAL MEDICINE

Abortion Amendment

A BILL to amend the 1967 Abortion Act by limiting the number of doctors allowed to perform abortions was "talked out" during a debate in the House of Commons last Friday. This amounts to a defeat, although in principle the bill is not dead but goes to the bottom of the list of private members' bills. The amendment, proposed by Mr Godman Irvine and backed by the British Medical Association and the Royal College of Gynaecologists and Obstetricians, provided that abortions should be carried out "by or under the supervision of a consultant gynaecologist in the National Health Service (NHS) or a medical practitioner of equivalent status approved by the Secretary of State for Social Services" if he and another doctor agree that an abortion is necessary.

Mr Irvine claimed that the bill would make abortions safer and he believed that there would be no shortage of consultants to perform the operations. If half the 500 or so NHS consultants were prepared to carry out abortions, he calculated, the present demand would mean four abortions per week per gynaecologist, which was well within their capability.

The chief argument brought against the amendment was that it would reduce the effectiveness of the Abortion Act which has so far been working extremely well in reducing the number of criminal abortions (see *Nature*, **225**, 580; 1970). By cutting down the number of abortions carried out by doctors without specialist qualifications, the bill would make it more difficult for a woman to obtain an abortion legally, but would not really guarantee any more safeguards against abuse than the act already provides.

Speaking for the government, Dr Dunwoody said that the bill would result in a decrease in the number of private abortions and in consequence an increased demand on the already overburdened health service. An even more worrying effect might be an increase in the number of back street abortions. Because the operation becomes so much more dangerous after the first twelve weeks of pregnancy, a woman faced with delays in obtaining a legal termination might choose criminal abortion.

Under the present act the Secretary of State has extensive powers for inspecting clinics and insisting on an adequate standard of post-operative care. Dr Dunwoody explained that all but one of the private clinics have now been inspected at least once and steps taken to ensure that each patient stays in at least one night after the operation, that suitable autoclaves are installed and that there are facilities for dealing with emergencies. He made it clear that in cases of alleged professional misconduct, the Secretary of State has no power, or wish, to intervene, but that any evidence should be presented to the General Medical Council.

By requiring that the Secretary of State should approve a list of doctors of "equivalent status", Dr Dunwoody said, the bill would impose on him the unrealistic and invidious responsibility of drawing distinctions between individual doctors. Mr Houghton made the point that there is no reason to suppose that NHS gynaecologists, some of whom have done few, if any, terminations, would be any more skilled at carrying out abortions than professional abortionists. Private clinics have in fact a lower proportional death rate from abortion than the NHS.

Mrs Renée Short pointed out that recent public opinion polls show that most people are satisfied with the act or want to see it improved to make it easier for women to get abortions. A similar public opinion poll carried out among doctors shows that 66 per cent of general practitioners in the United Kingdom thought the act should be left as it is or changed in favour of easier abortions.

WILD LIFE

Italy Losing Friends

The Italian Government's decision to permit once again the unlimited netting of small birds (*Nature*, **225**, 494; 1970), three years after severely restricting the practice, has provoked strong reactions from elsewhere. Protests have been sent by the International Council for Bird Preservation (ICBP), the International Union for the Conservation of Nature and Natural Resources, and the European Committee for Bird Ringing; in Britain the Royal Society for the Protection of Birds, the Council for Nature and the British Trust for Ornithology are all completely opposed to the new legislation. The British secretary of ICBP, Miss Phyllis Barclay-Smith, has said that the law is "absolutely appalling"; and the World Wildlife Fund is "deeply concerned".

As a result of the new measure vast numbers of migrant birds will be trapped in mid-course between Africa and northern Europe—estimates of the annual kill are of the order of 20 million. What this means for the total population of the migrating species is hard to say, according to Mr Richard Porter of the Royal Society for the Protection of Birds, because the size of the annual movement is not known with sufficient accuracy. Mr Porter thinks that the warblers may suffer particularly because they congregate around bushes and small trees rather than in open country, and can be easily trapped by nets strung from tree to tree.

The official justification for the reinstatement of netting is that it made it easier to capture birds for scientific research, by which, apparently, was meant no more than ringing them. The European Committee for Bird Ringing nevertheless objects to the new law, and its secretary-general, Mr Robert Spencer, claims that the "scientific" label merely gave it "a veneer of respectability". Critics are united in thinking that the Italian Government is simply trying to make itself more popular with the large number of people who like to trap birds for food or sport. Much of the trapping is on a small scale, using single nets or sometimes more sophisticated methods triggered by decoys.

Italy is not the only European country that allows trapping, but elsewhere scope is more limited. Some birds are netted in Greece, Spain and Portugal. In south-west France some species, notably linnets, can be legally trapped. In Belgium starlings and thrushes can be trapped as a sport for six weeks of each autumn. Britain allows trapping only by ornithologists, who must obtain a licence from the Nature Conservancy.

Hostile public opinion and the possibility of damage to the Italian tourist industry are, it is suggested, the chief means by which the Italian Government could be persuaded to think again. Miss Barclay-Smith of the ICBP is urging people to write to embassies and tourist boards, and is herself compiling a dossier of angry views to send to the Italian Ministry of Tourism. But the basic problem remains the enthusiasm for netting that many Italians evidently have; and, as Mr Spencer gloomily noted, "it takes at least a generation to change people's minds".

CELL BIOLOGY

New European Organization

A new European Cell Biology Organization (ECBO) has been established at Leiden in the Netherlands. Its aims are to promote research in cell biology and to foster international cooperation through exchange of information and people. It intends to promote three types of activity—small working groups studying specific topics, two-day symposia, and exchange of individuals among institutions in Europe. But, unlike the European Molecular Biology Organization (EMBO), ECBO has no intention, as yet, of setting up its own laboratory.

There are other major differences besides that of size between the new organization and EMBO. ECBO will levy no subscription charges on its members, but its executive committee is not sure at the moment where the money to finance its activities is going to come from. It hopes that the symposia may be self-financing, and that some money will be forthcoming from other organizations and perhaps from scientific foundations, but it wants to avoid having to take money from government sources because this might limit participation from Eastern European scientists. Dr L. M. Franks, a member of ECBO's executive committee, said that the organization's field of interest, which will include all aspects of cell biology, will be wider than that of EMBO.

Membership of ECBO will be made up of registered cell biologists, together with representatives of other

European organizations, such as the International Society of Cell Biology, the International Cell Research Organization, EMBO and national societies. The president of the new organization is Professor P. J. Gaillard of the Institute for Cell Biology and Histology, Leiden, and the vice-president is M. Chèvremont of the Institute for Histology at Liège. Other members of the executive committee are W. Bernhard, Institute for Scientific Cancer Research, Villejuif; L. M. Franks, Imperial Cancer Research Fund, London; J. Paul, Beatson Institute for Cancer Research, Glasgow; M. Feldman, Weitzmann Institute of Sciences, Rehovot; and A. Lima-de-Faria, Institute of Molecular Genetics, Lund.

AVALANCHES

Swiss Example to France

Last week's avalanche disaster at Val d'Isère in the French Alps has provoked some searching questions on the adequacy of present monitoring and prevention techniques and on the amount of research that is being conducted on avalanches. Poor coordination of data is reflected in the almost total lack of statistics on avalanches in France, and the nine man enquiry set up by the French government to investigate the disaster may well feel compelled to suggest the setting up of a central institute for avalanches on similar lines to the one at Davos in Switzerland.

The Swiss research institute has an impressive record. More than a hundred major avalanches that have fallen in the last twenty years have caused only 24 deaths, and although no attempt is made to forecast individual avalanches a general pattern of snow conditions is formulated from statistics collected from fifty points throughout the country. Twenty or so physical quantities are monitored, including snow and air temperatures and snow hardness. All data are sent to the centre in Davos, which employs fifty people working full time to analyse and disseminate the information.

Although there are links between the warning services of the countries sharing the alpine land mass, it seems clear that research in France is much more fragmented than in Switzerland.

The CNRS (the government organ for scientific research) has a laboratory at Grenoble university for the study of snow, ice and avalanches, but funds seem to be too short for anything resembling a major programme. There is also a laboratory in the Haute Savoie which specializes in the melting of snow, and a group at the scientific university at Chambéry is carrying out a survey of all avalanches known. The possibility of diffusing avalanches with explosives is being investigated at the nuclear centre in Grenoble, but the Alps are probably too densely populated for such violent techniques.

ATOMIC PHYSICS

Anti-helium at Serpukhov

from our Soviet Correspondent

The Soviet Institute of High Energy Physics reports that nuclei of "anti-helium" have been successfully produced by a team of young physicists at Serpukhov, under the direction of Professor Yu. D. Prokoshkin.

The experiment was carried out using a beam of protons accelerated to 70 GeV, aimed at a target within the vacuum chamber of the accelerator. The negatively charged particles generated by the collision of the protons with the target were deflected by a magnetic field and formed into a beam of defined momentum. A special complex detection apparatus was developed by the Institute of High Energy Physics for the identification of the secondary particles in this beam (several million per second); this apparatus comprises more than 50 high-speed detectors and a nanosecond electronics system containing some 500 elements.

The anti-helium nuclei were identified in several different ways. The charge on each particle passing through the apparatus was determined by two methods: by the ionization produced by the particle and by the Čerenkov radiation. The velocity of the particle was determined in three ways: by means of differential and threshold Čerenkov counters and by direct measurement of the time of flight (this latter method had an accuracy of the order of ten nanoseconds).

The simultaneous application of these methods provided reliable means of recording any nuclei of anti-helium which might be formed. During the experiment, more than 200 thousand million particles passed through the apparatus—of these, five were identified as nuclei of anti-helium.

This discovery of the nucleus of an "anti-element" is, in the opinion of A. Loginov, director of the Institute of High Energy Physics, of great significance as a confirmation of the theoretical concept of anti-matter, and hence to the whole understanding of the nature of the space–time interaction of particles. It is understood from his report that further experiments in this and related fields will be carried out using the Serpukhov accelerator.

ROCKET

Fourth Member of the Space Club

The announcement on February 11 that Japan had succeeded in launching a small satellite by means of a Japanese rocket at the fifth attempt, and so become the fourth member of the "space club", prompts consideration of the space programmes and ambitions of a country whose situation in many respects is so comparable with Britain's. The Lambda 4S solid fuel rocket launcher is claimed to have cost only the equivalent of £138,000—a record in cheap space launchers.

Shortly before the successful satellite launching, the national Space Development Committee announced a programme for eight satellites to be nationally launched in the next six years. Six of these are for scientific purposes; one is described as ionospheric and there will be one communications satellite (largely for proving systems and feasibility, presumably). Further satellites for meteorological and navigational purposes are under consideration but have not yet been definitely adopted. There has been a 17 months delay in developing the Japanese satellite programme because of the shortage of American expertise as well as opposition from fishermen living near Japan's Pacific-facing rocket range who feared that the disturbance would spoil their livelihood.

This year for the first time the Japanese Antarctic expedition will launch rockets from their mainland base in support of their polar research programme. Two geophysical rockets are due for launch this month; next season 12 rockets are intended to be launched into aurorae. The S160 sounding rocket being used has been developed by the Institute of Space and Aeronautical Science of Tokyo University.

The Japanese Meteorological Agency has also taken up rocketry for its advanced high altitude investigations. A new rocket range near the coastal town of Sanriku has been built at a cost of £137,500. The first campaign comprising the launch of 40 4-metre long MT 135 meteorological rockets is due in July.

It is generally held that Britain could have launched her first small satellite by means of the small national space launcher *Black Arrow* at least 3 years ago. Lack of purpose—on which the Japanese cannot be faulted—has prevented this. The disadvantages of not having an alternative to US launchers when it comes to bargaining, as with the hardline Intelsat talks now resumed in Washington, is beginning to be apparent—as has frequently been predicted by the British aerospace industry; Britain has fallen between two stools—the muddles of European cooperation and the cost of going it alone.

COMPUTERS

Mintech's Right of Veto

LAST week's confrontation between subcommittee D of the Select Committee on Science and Technology and representatives of the UK Atomic Energy Authority produced a display of verbal acrobatics from the authority which Mr Ted Leadbitter said could be rivalled only by the Foreign Office. Mr Leadbitter and his colleagues on the subcommittee under the chairmanship of Mr Airey Neave are looking into the development of the British computer industry over the next ten years, and the UKAEA was giving evidence as a major user of computers. What inspired Mr Leadbitter's caustic comparison was the efforts by the witnesses to parry the question of who has the final say when the authority wants to buy a foreign computer—the UKAEA or the Ministry of Technology. This riddle took up much of the session and the answer never came, at least not during the part of the session open to the public. The best that could be done by Mr E. E. Newley, director of the Atomic Weapons Research Establishment, was to say that the view of the UKAEA so far has prevailed when they have wanted to buy machines from the United States.

But the subcommittee was successful in distilling from this knockabout stuff some odd definitions of what Mintech considers to be a British machine. The rules are bent so that the Honeywell computer, which is largely built in Britain, counts as British, but the comparable IBM computer is deemed to be foreign.

Much of the discussion centred on the software which has been developed by the UKAEA, and the subcommittee clearly felt that there was room for inprovement in making this material available to industry. Mr A. Gregory of the subcommittee mentioned complaints from industry about the poor flow of information from government departments such as the UKAEA, but Mr Newley and his colleagues thought that the subcommittee was tending to overstate the commercial returns. The UKAEA was looking at ways of disseminating the information, and marketing consultants had been called in to see how the multi-access system developed in conjunction with IBM might be made available.

The discussion moved to the future needs of the authority, and the highly secret project 52 which ICL is working on received a mention. But whether project 52 will cover the requirements of the UKAEA for the next ten years—the timescale covered by the subcommittee—depends on how the system is likely to expand. At present it is not clear what the upper range of project 52 is going to be, but there is little doubt that the UKAEA will need access to larger machines than the IBM 360/75 at Harwell.

Mr E. Lubbock was surprised that the UKAEA has no large machines on order considering that the doubling time for the growth of computing in the authority is three years. Mr Newley agreed that this was a question that the UKAEA was grappling with, and one solution might be to order more ICL 470s. The UKAEA already has an ICL 470, at Risley, and two more at Culham and Winfrith will be installed by the end of the year after delays which were admitted to be proving awkward for the UKAEA. What the UKAEA requires, the witnesses said, is a good multi-access system, although the need for equipment with a quick response for data acquisition from experiments is a problem. But it seemed clear that the UKAEA has no settled policy on computers with which to start the seventies.

SCIENCE POLICY

Dainton's Thoughts

THE new broom in the Council for Scientific Policy (CSP) does not intend to do much sweeping clean. Dr F. S. Dainton, who took over the chairmanship of the CSP on January 1, this week outlined some of his thoughts on the issues confronting the council during the next few years, and he said that he can see no reason for major changes in the workings of the committee in the near future. One great problem that science policy faces at the moment, said Dr Dainton, is a growing disillusionment with science, expressed in the attitude that science creates more problems than it solves. Such an attitude has grave consequences for future manpower resources, and can be reflected in the size of science budgets. But when asked whether he thought that the membership of the council, which consists almost entirely of pure scientists, tends to make the body rather inward-looking and therefore unable to come to grips with the problem of the swing away from science, Dr Dainton argued that its membership is not unbalanced. The council, he said, is especially well equipped to comment on the economic aspects of scientific research.

The CSP will continue to study various problems through its working groups. Studies already in hand include developing criteria for supporting scientific research in universities, international cooperation in science, especially molecular biology, the quantification of economic benefits of scientific research, and pollution. In addition, the CSP has recently established a study group to look into problems created by expansion of higher education. One of the main questions the council will be asking in this connexion will be whether research facilities need to grow at the same rate as student numbers, and what effects such an expansion would have on the quality of research. On pollution, Dr Dainton said that the CSP has invited the research councils to look at the scientific side of the question, but, because it is purely an advisory body, it cannot concern itself with legislation.

Dr J. C. Kendrew, who has just taken over the vice-chairmanship of the CSP, will be especially concerned with international cooperation and exchange. He indicated that the CSP is looking at the possibility of setting up international groups in existing laboratories, and is attempting to promote scientific exchange between European countries.

MICROORGANISMS

Cultures at Cambridge

by our Botany Correspondent

TEACHERS, pharmacologists and other biologists who use the collection of algae and protozoa at the Botany School in Cambridge can expect an even better service in the future. The Natural Environment Research Council (NERC) has just spent £106,000 on new buildings to house the collection, which it has taken under its wing as a culture centre of algae and protozoa. The NERC grant will allow both the staff and the collection to be expanded and has also provided an electron microscope which will aid the process of identifying protozoa.

The collection, now composed of about 1,500 different strains, is based on a few hundred cultures originally brought to England by Professor E. G. Pringsheim, who left the German University in Prague just before the 1938 invasion of Czechoslovakia. The director of the new centre, Mr E. A. George, began as Pringsheim's assistant in 1947, and has been the curator of the culture collection since 1952. He expects the size of the collection to more than double in the next few years in response to increasing demand.

About 6,000 cultures are dispatched every year from Cambridge for various purposes. Many customers are teachers who need material for their classes. One culture, which costs 10*s* within Britain and £1 if sent abroad, provides enough material for twenty-five students. Industry provides many customers too, for algae and protozoa make a convenient system for testing the effects of untried compounds on living organisms. Before proceeding to rats or human subjects, useful information can be gained from the responses of these microorganisms to potential drugs. Two algae in particular, *Oxomonas* and *Euglena gracilis*, are much used for estimating vitamins, which have a measurable effect on their rate of growth. The food industry and hospitals make frequent use of this method. The culture collection can also save microbiologists a great deal of trouble by supplying particular strains of known uniformity and purity.

Mr George hopes that in their new home the scientific officers on his staff will be able to devote half their time to research, apart from the work they have to do on the collection, which involves isolating new strains, developing new culture media and so on. The initial lines of research will include the study of marine flagellates by electron microscopy and the development of methods for preserving living cultures by freezing or drying.

Parliament in Britain

Lung Cancer

MR GERALD FOWLER, Minister of State, Department of Education and Science, said that the Medical Research Council's Air Pollution Unit is investigating the possibility of a link between lung cancer and air pollution. But no evidence has yet been found of any connexion between lung cancer and atmospheric sulphur dioxide. (Written answers, February 9.)

Fluoridation

EIGHTY-ONE local health authorities in England are opposed to fluoridation of water supplies, and ninety-eight are in favour. Dr John Dunwoody, Joint Under-Secretary of State, Department of Health and Social Security, who gave these figures, also said that the Health Education Council expects to spend about £16,000 in 1969–70 on education about fluoridation, and a similar sum in 1970–71. Dr Dunwoody did not comment, however, on the suggestion from Mr Frank Judd that the government should introduce new legislation on fluoridation, and that it should remove the present discretion given to local authorities. (Written answers, February 9.)

Scowen Committee

DR MICHAEL WINSTANLEY asked the Secretary of State for the Social Services whether he will make changes in the personnel of the Committee on the Safety of Drugs, to restore the medical profession's confidence in the committee following its announcements about adverse reactions to oral contraceptives. But Mr Richard Crossman could see no justification for changes. (Written answers, February 9.)

Radiological Protection

THE radiological protection bill received a second reading in the House of Commons. The bill, which seeks to transfer to a single statutory board the present functions of the Radioactive Substances Advisory Committee, the Radiological Protection Service (run by the Medical Research Council) and the health and safety branch of the UKAEA, received little opposition. The proposed National Radiological Board will undertake research and provide advice and services in connexion with radiation hazards. The estimated gross expenditure on these services for 1969–70 is £822,000, of which 45 per cent will be paid by the Department of Health and Social Services, 30 per cent by the Atomic Energy Authority, 20 per cent by the Medical Research Council, and the remaining 5 per cent will come from the Scottish Office. (Debate, February 10.)

Aircraft Smoke Pollution

SUITABLE locations for measuring the smoke pollution caused by aircraft flying on the glide path into London Airport have been established, and measurement tests should start within six to eight weeks. This assurance was given by Mr Goronwy Roberts, Minister of State, Board of Trade, in reply to a question from Mr Anthony Royle. (Written answers, February 11.)

L-Dopa

THE Committee on the Safety of Drugs has cleared two more preparations of L-dopa for clinical trials. But Dr John Dunwoody, who gave this information, said that it is too early to estimate the likely cost of the drugs. (Written answers, February 9.)

NEW WORLD

The Crusade against Pollution

by our Special Correspondent

THE battle against pollution has now become something between a crusade and an evangelical campaign. The newspapers are full of it. State governors are busy explaining how their plans for new sewage treatment plants are a contribution to the "environmental war", as Senator Edmund Muskie has called it. Administrators who appear before Congress to justify their claims on the public purse now seem instinctively to begin by explaining how their work will diminish pollution. And then, on February 10, President Nixon gave his blessing to the movement with a special message to Congress suggesting new ways of cleaning air and water. In the sharp, clear air of the past few days, it has occasionally been difficult to remember that Washington is now the centre of the anti-pollution movement.

The eloquence of Mr Nixon's message is a good illustration of the spirit in which the anti-pollution movement is being advanced. In the evangelical tradition, it begins with the acknowledgment of past error. "Like those in the last century who tilled a plot of land to exhaustion and then moved on to another, we in this century have too casually and too long abused our natural environment. The time has come when we can wait no longer to repair the damage already done and to establish new criteria to guide us in the future." The peroration is a clarion call—"No longer is it enough to conserve what we have—we must also restore what we have lost . . . The task of cleaning up our environment calls for a total mobilization by all of us . . . [This task] summons our energy, our ingenuity and our conscience in a cause as fundamental as life itself."

Rhetoric apart, Mr Nixon's actual proposals seem sensible enough. The most costly part of the plan is that for helping local authorities to install sewage treatment plants. The legislation for allowing the Federal Government to share in the cost of local treatment systems exists already, but in the past few years the Administration has chosen not to spend as much as it might have done on this good work. It is now estimated that something like $10,000 million will have to be spent to bring municipal treatment plants up to standard, of which the Federal Government's share would work out at $4,000 million. The intention is that this should be spent at the rate of at least $1,000 million a year, and that there should be a formal review of the programme in 1973.

The new proposals will also help to simplify responsibility for the control of inland water pollution. As things stand, the Federal Government is responsible for standards of purity only where waterways run from one state to another. It is now intended that there should be comprehensive plans for the treatment and control of water pollution in whole river basins, and that municipal authorities which use federal money to build treatment plants should be required to operate them properly. There is also a scheme for defining unambiguously the standards of purity to which water effluents should conform, with the intention that standards should be enforced by a uniform and stiffer series of penalties.

The essence of Mr Nixon's proposals on air pollution is a continuation of the war against the automobile. The most fierce of the new proposals is a set of regulations defining the admissible pollution in the exhausts of automobiles coming on the market in 1973 and 1975. In 1973, the output of oxides of nitrogen from motor vehicle exhausts will be restricted for the first time (to less than three grams per vehicle mile), and this limit will be reduced by a factor of three for 1975 models, when the permissible emission of particulate matter will be restricted for the first time (to less than 100 mg of solid matter per vehicle mile). In future, measurements shall be made not merely with an example of each new automobile submitted by the manufacturer but with samples taken from the production lines.

The new standards are a good deal more stringent than those now in force and are even more stringent than those being applied in California, the most adventurous of all states in the struggle with the automobile. It goes without saying that much will depend on how vigorously the new standards are enforced. One difficulty is that, so long as the enforcement of standards is applied to new automobiles, there can be no assurance that devices such as the crank-case ventilators being used to reduce the output of hydrocarbons in exhausts will remain efficient. It also appears that there will be a shortage of facilities and of people for testing automobile exhausts—it turns out that the responsible officials in Washington are being provided with Ringelman charts in the forlorn hope that these will allow them to prevent the emission of excess smoke from cars.

The other side of this coin is the part of Mr Nixon's message which promises "an unconventionally powered virtually pollution-free automobile within five years" or at least "an extensive federal research and development programme in unconventional vehicles". There is talk of legislation allowing government departments to buy such vehicles for actual service so long as their initial cost is not more than twice that of automobiles with internal combustion engines, but, in the meantime, both the manufacturers and the oil companies are parading their willingness to eliminate lead-based additives from automobile fuel. One difficulty here is that of designing engines of high performance which will run on 92 octane fuel—the highest octane number at which lead additives can be dispensed with. Another is that there appears to be very little evidence to show what happens to the lead which does manage to escape from motor vehicle exhausts.

No doubt these proposals, which include provision for the tighter and more closely integrated control of air pollution, a research programme aimed at producing more easily disposable packaging materials and the like and also a promise that land now occupied by the military and other government departments will be returned to public use, will help the great clean-up on its way. The fact that some of the extra funds for sewage plants will pay for certain works already built in anticipation of some relaxation of the purse-strings is probably no tragedy—these plants would in any case have had to have been built. In many ways, the manifest difficulty of applying the new regulations on motor vehicle exhausts may help to make a gentle mockery of some parts of the programme, but this is less serious than the danger that the evangelical overtones in the battle against pollution may raise expectations which cannot be fulfilled.

Senator Muskie, who is influential in these matters, not merely because he is chairman of the Senate subcommittee on Air and Water Pollution but also because he may well be a candidate for the Presidency in 1972, has at least been doing something to help people to appreciate that pollution is not the inevitable accompaniment of technology. Speaking in Pennsylvania last week, he said that "America must stop on a dime and make a 180 degree turn, not away from technological growth but towards new uses of that strength".

Among scientists, there has been a good deal of public speaking about the ways in which technology must help in the great pollution battle. Mr John T. Middleton, Commissioner of the National Air Pollution Control Administration, told the centenary conference for the Weather Bureau last week not merely that "quite simply, we have not been winning in the battle against pollution" but that it will take a sizable force of meteorologists to devise and administer more effective controls. A few days earlier, Dr Glen Seaborg, chairman of the United States Atomic Energy Commission, which has been vigorously attacked in the past year by those who fear that nuclear plants may cause severe damage to the environment, promised a programme of research to study the effects of neighbouring nuclear power stations on bodies of water such as Chesapeake Bay.

Elsewhere, the problem of the environment is regarded with more ferocity. The Graduate School of Fine Arts at the University of Pennsylvania seems to be one of the prime movers behind what is called "Earth Week" from April 16 to April 22, which will consist of three days of technical discussions "by experts on the environmental crisis" followed by a week-end when churches and synagogues in Philadelphia will be asked "to re-examine man's role in his environment". It will be interesting to see how many of them take as their texts passages like the following, from the leading article in the current issue of *Bioscience* :

> Over the past 200 years or so, man has been engaged in a positive feedback system with his environment in which ever higher levels of population encourage economic and technological growth at an ever-increasing expense to the diversity, complexity and stability of the whole world ecosystem. As with any other positive feedback system, this one will self-destruct [*sic*] if it continues long enough. Meanwhile, there have been real benefits from this process, which are manifest in the unfolding of the rich potentialities of the human species. The present concern with dehumanisation in a technicised society and the degradation of the quality of man's environment, however, may be cybernetic signals that are important in the conversion to a negative feedback system through which a viable homeostatic stability can be achieved. The time for conversion is now, and the changeover must take place rapidly. The momentum of the population explosion alone, assuming zero growth could be achieved overnight, is such that further degradation of the world ecosystem is unavoidable even with a rapid mobilisation of economic and human resources in the conversion process.

OIL PRODUCTION

Santa Barbara Spill Examined

A DETAILED geological explanation of the escape of petroleum and natural gas in January 1969 from an oilfield off the Californian coast near Santa Barbara has now been compiled by members of the United States Geological Survey (*Geological Survey Professional Paper 679*). As well as making it possible to understand why there should have been such a sudden escape of petroleum from the sea bed, the report will probably become one of the classic cautionary tales for petroleum engineers. What seems to have happened is that by drilling through a series of at least six oil reservoirs lying beneath a comparatively thin layer of unusually porous rock, the engineers of the Union Oil Company made it possible for fluid hydrocarbon at high pressure to enter and to fragment the thin layer of sandstone separating the uppermost reservoir from the sea.

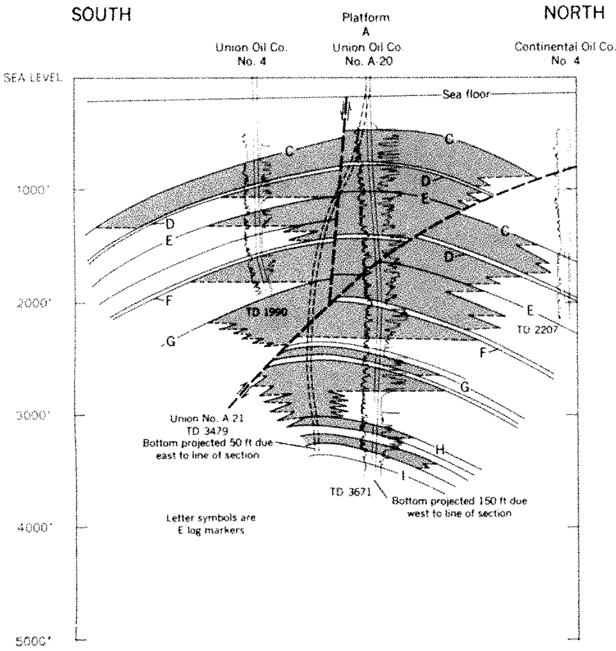
The sea bed off the coast at Santa Barbara has a long history of natural seepages of oil, and one of the earliest observations on record is apparently that of Captain Cook, who described a thick slimy substance floating on the surface of the sea in the Santa Barbara Channel one day in 1792. More recently, the submarine escape of oil and gas has been recorded over a wide area out as far as Santa Cruz Island, some 30 miles offshore. The well, which was being drilled immediately before the escape of oil and gas on January 28, 1969, is the farthest west so far on an antisyncline structure running for some thirty miles westwards towards the coast south of Santa Barbara and then for at least an equal distance out to sea. One part of the submarine structure has been exploited successfully since 1966, and now has close on 100 wells in it. The Dos Quadras oilfield from which the oil eventually escaped is a comparatively small domed structure about four miles long and half a mile across. The first wells were sunk in the formation and eventually closed off during 1968, but the well being drilled in the first few days of 1969 was intended to penetrate the superficial stratum of rock at almost its thinnest point, at the greatest height in the submarine reservoirs.

According to the description of this structure by T. H. McCulloh, the Dos Quadras offshore oilfield is "unique in one special way" among oilfields with reserves of 100 million barrels or more—the comparative thinness and permeability of the 300 feet of rock separating the uppermost part of the petroleum reservoir from the sea bed. There is a good deal to suggest that this covering is not a perfect seal for the petroleum beneath—for one thing, it contains substantial amounts of free hydrocarbons, while the comparatively high density of the oil in the topmost layers suggests that lighter and more mobile fractions have been lost progressively since the Middle Pliocene, when the anticline was formed.

The sequence of events during the blow-out of the well numbered A21 is hard to reconstruct because of the way in which the oil reservoir is intersected by at least two fault systems. First, there is a thrust fault by means of which the northern part of the antisyncline has already been driven beneath the southern part by about 500 feet. This is associated with an almost vertical tear fault. The line of well A21 manages to intersect both faults, thus making sure that the several zones of the oilfield were hydrostatically connected with each other, although it is only fair to say that the same effect would have been obtained if an unlined hole had been drilled through an uncomplicated part of the reservoir.

One of the most telling parts of the argument now published is the calculation which it has been possible to make of the hydrostatic pressure of the petroleum occurring in the successive layers of sandstone. Although it seems that the pressure of the hydrocarbons in the first 2,000 feet or so of the reservoir is that corresponding to an equivalent depth of water, the deeper strata contain hydrocarbons at greater pressure. Moreover, it appears that the lower layers contain larger quantities of gas, which means that the petroleum which they contain is less viscous and less dense than at lesser depths.

Mr McCulloh says that these relationships can account satisfactorily for the sequence of events following the blow-out. The first observation was that a "heavy condensate mist" followed the mud blown out of the hole, but that after the drill pipe had been dropped back down the hole, it seemed for a time that the well had been successfully closed off again.



Transverse section through anticline showing position of boreholes and faults (heavy broken line).

The first signs of trouble were the appearance of turbulent boiling of the sea something like a quarter of a mile from the drilling rig about two hours after the blow-out. Mr McCulloh says that the time lag would have been that required for the surface stratum to be fractured under the pressure of petroleum from the deeper layers of the reservoir, in exactly the way in which it is a part of normal petroleum practice to use large hydrostatic pressures for increasing the permeability of oil-bearing strata and thus the productivity of wells. He also points to the significant way in which drilling fluid was quickly lost from the well while cutting through the upper layers of rock, indicating unusually permeable material. The nearest Mr McCulloh comes to direct criticism, however, is his approving quotation of a statement that in "modern soundly engineered deep drilling" it is necessary accurately to predict the pressures likely to build up in the successive formations of the reservoir as well as the liability of some of these to fracture.

As things have turned out, it seems that the best cure has been more drilling. By now, more than a score of wells have been sunk into the formation, partly in the hope of drawing off enough oil to reduce the pressure and the risk of further seepages.

METEOROLOGY

Centenary for Weather Bureau

The United States Weather Bureau has been celebrating the centenary of its legal foundation on February 9, 1870, with an international conference on meteorology and other appropriate festivities. Although the conference itself may have been a somewhat sleepy occasion, the centenary does seem to have come aptly at a time when the new methods of meteorology are promising to transform the character of the work. This no doubt was a part of the motive for the way in which Dr Robert M. White, the administrator of the Environmental Science Services Administration, welcomed the coming of "big science" to meteorology, but it was clear last week that many of his listeners were still steeped in the old traditions of meteorology—the cataloguing of tornadoes in the prairies and the daring use of high-flying kites as ways of collecting upper atmosphere measurements.

The Weather Bureau began life as the Division of Telegrams and Reports for the Benefit of Commerce. Although the US Army seems to have been the first, in 1812, to persuade its scattered men to keep weather records, the coming of the telegraph allowed Professor Joseph Henry at the Smithsonian Institution to begin collecting observations systematically, chiefly with the help of telegraph operators. The need for a continuing organization was urged both by Henry and by Cleveland Abbe, the director of the Cincinnati Observatory, who began to set up his own system for correlating observations in 1869, after Henry's network had been partly dispersed during the Civil War. Eventually, the argu-

GRATITUDE

Welcoming the United States budget for 1971, Dr William D. McElroy, Director of the National Science Foundation, said: "It is a real pleasure for us that President Nixon, who is so deeply concerned with all of the Nation's problems, has recognized the importance of scientific research and has provided an increase over the amounts appropriated by the Congress last year. The National Science Foundation has, in turn, responded to the President's challenge to help reduce inflation while making progress in the most necessary Federal problems. Our budget will enable us to maintain a vigorous although austere programme of support for basic research and graduate education. . . ."

ment that a means of making weather observations could help to prevent disasters to shipping on the Great Lakes seems to have carried weight with Congress and with the president, Ulysses S. Grant.

The characteristic flavour of the United States Weather Bureau is its concern for meteorological hazards—which is only natural in the most advanced society which is regularly ravaged by hurricanes, floods, tornadoes and extreme fluctuations of temperature. There has been a flood warning service since 1873, and flood prediction was also one of the themes at the conference last week. There was also great interest last week in the great potential benefits of forecasting natural disasters of climate, from the floods which accompanied the hurricane Camille, which last year killed 320 people in the United States, to the foreknowledge of frost among the citrus crops, estimated to have been worth as much as $75 million on some occasions.

Better prediction was the most widely commended device for avoiding disaster like this, but there was also some talk of artificial weather control last week, not all of it enthusiastic. For the most part, the modifiers seem to have had very little to show for the past decades of endeavour. The most tangible new work was that described by Dr Joanne Simpson, who has been studying cumulus formation by a combination of the techniques of seeding actual clouds with silver iodide and mathematical modelling. She considers that recognizable changes, particularly reductions of windspeed, were brought about by the seeding of the eye of hurricane Debbie in August 1969. She also says that she can now identify cumulus clouds which are likely to grow explosively when seeded with silver iodide, and thinks it possible that the systematic use of this technique might make it possible to increase the summer rainfall over Florida by as much as a third.

Dr E. G. Bowen of CSIRO, Sydney, one of the first of the cloud seeders, was somewhat more perplexed to account for the way in which seeding sometimes seems to diminish the probability of rainfall, and suggested that there may be an unaccountable persistence of the effects of a single seeding in one restricted area. No doubt the dynamic theories of cloud formation and development on which Dr Simpson puts her faith will eventually help to make these points clearer, but there is probably most truth of all in a jibe due to Dr B. J. Mason, director of the Meteorological Office, that if people really want to modify the climate, why do they not begin by removing the Rocky Mountains?

Elsewhere the future for meteorology seems bright. At the conference last week, the promise of infrared sensors mounted in Earth satellites seemed to burn especially brightly. The point seems now to have been reached when some of the conventional programmes of meteorological observation—parts of the GARP programme, for example—should now be altered so as to take fuller account of the potentialities of advanced weather satellites, now able to provide a complete temperature profile throughout the atmosphere to a resolution of about 100 km in horizontal extent except in the tropics (where gradients are not sufficiently sharp to be measured accurately by the infrared devices). With this prospect ahead, people like Dr Mason are now saying that the time has come to concentrate on meteorological observations on a scale of about 1,000 km or even less.

STANDARDS

Error Comes to Light

A DISCREPANCY of 1·9 per cent in the United States secondary standards for the total luminous flux of gas filled tungsten lamps has now been revealed and corrected by the National Bureau of Standards. The bureau's sheepishness at having to admit such a comparatively large error is tempered by the knowledge that it was the first to notice it. The discrepancy first came to light during comparisons of American standard lamps with those used elsewhere, particularly in Canada and Britain. By all accounts, the American secondary standards were consistently found to give results at the extremes of the expected scatter. In the past two and a half years, according to Dr Donald McSparron, it has been possible to re-assess the absolute luminous flux of the standard lamps used at the laboratory by working upwards in the temperature scale from the basic black body standard by at least three different photometric routes. The work has, for example, involved the comparison of the energy output of tungsten lamps with those whose spectral characteristics have been deliberately distorted by the use of filters and the comparison of flux, wavelength by wavelength, using a spectroradiometer. The result is that previous calibrations carried out at the laboratory are now reckoned to have been 1·9 per cent too low.

The bureau is quick to point out that the error now revealed applies only to the secondary standards for tungsten filament lamps—mercury vapour lamps and fluorescent lamps seem to be correctly standardized. At the same time, however, it is hoped that some of the present uncertainties will be diminished when the bureau has completed its project for designing a new black body standard—an illumina crucible containing molten platinum. Dr McSparron explains that the design has been chosen so as to make possible an easier extrapolation from an actual to an ideal black body, but that so far it has turned out to be difficult to arrange for the manufacture of the illumina crucible, which has to be no more than 1 millimetre thick.

NUCLEAR RESEARCH

Swings and Roundabouts for AEC

IT now looks as if high energy physicists in the United States will have to pay for the new high energy accelerator being built at Weston, Illinois, with a reduction of the cost of operating high energy accelerators elsewhere. In the year ahead, it is planned to save $5·2 million on the operating budget by reducing the scale of effort at the Princeton, Pennsylvania, accelerator, the electron accelerator at Cambridge, Massachusetts, and the bevatron at Berkeley, California. The first of these, indeed, which produces a beam of protons at 3 GeV, will in fact be shut down during the year. At Cambridge, work in future will be confined to the use of colliding beams from the storage rings. Although the linear electron accelerator at Stanford (SLAC) and the Brookhaven accelerator will soldier on, as will the alternating gradient machine at the Argonne National Laboratory, the reduction of effort elsewhere will seem to many high energy physicists to be a cold douche of reality, predictable though it may have been. In practice, even the funds available for the construction of the 200 GeV accelerator are less than had been hoped for, but the director of the project, Dr R. R. Wilson, has apparently told the AEC that he will finish on time, in 1972, in spite of the cut. Altogether, high energy physics will get $1·1 million less in the coming year, while the AEC's expenditure on physical research will be $3·8 million less than in 1970 at $274·4 million.

Thermonuclear research has, however, come back into favour. During 1971, the AEC is planning to spend an extra $1·9 million on fusion work, and much of this will go on two new machines—a device incorporating some of the features of the old accelerator and the new Tokamak at Princeton and a new toroidal pinch machine at Oak Ridge. In his statement at the opening of the examination by the Joint Committee on Atomic Energy of the new budget, Dr Glenn T. Seaborg, chairman of the AEC, said that there had been "significant advances in this field of research in the past year".

As it happens, however, the joint committee is unlikely to swallow without protest the new budget which seems to the chairman of the committee at least to fall short of what is needed. Last week, Mr Chet Holifield said that he took a "dim view" of some features in the budget and that he was especially "disappointed" with the lack of funds for the cascade improvement programme by means of which it had been hoped that output of enriched uranium could be increased and by the lack of elbow room in the programme of development for the liquid metal fast breeder reactors (LMFBR)—it will be necessary during the coming fiscal year to make a decision between alternative designs for a prototype reactor. With all this, however, there is hardly a tear shed for the decline of interest in the Plowshare programme. With environment all the rage, who will defend a device for leaving accumulations of radioactive rock in potential gas wells or even Panama Canals?

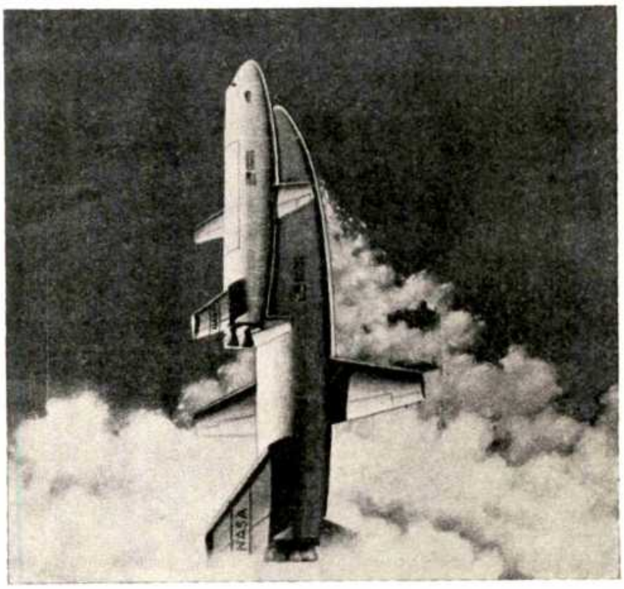
SPACECRAFT

Shuttles in Space

'I STAND before you a man who has just had his budget cut 12 per cent", jauntily remarked Dr Thomas O. Paine, administrator of the National Aeronautics and Space Administration, who was in London last week to receive various trophies commemorating the first manned lunar landing from the British Interplanetary Society. The general demeanour of his agency that he sought to put across in this predicament was one of buoyancy and optimism. Rationalization of programmes and ingenuity in place of blunt power were the means of economizing without compromising.

Central to NASA's revised thinking is the concept of re-usable vehicles and in particular the manned space shuttle for which definition studies are already in hand. It is calculated that fifty flights a year of the space shuttle could be carried out for less than the price of just one flight of the Saturn V. This reflects economy in ground support as well as of hardware.

The concept is for a craft that would take off vertically and land horizontally. Dr Paine indicated that the vehicle would be in two parts; a booster on the scale of a jumbo jet (such as the Boeing 747) and a detachable powered cabin about the size of a 707 or DC-10 which would carry the freight, whether passengers or supplies, and connect up with the orbiting space station for transfer. At the end of mission, each stage would return to base and land separately. Lift-off weight (3·5 million pounds) has been specified but not the payload. The payload compartment's size, however, has been defined; a volume of 15 feet diameter by 60 feet long. A number of configurations are possible but no choice between them has yet been made. They include fixed geometry and variable geometry craft; straight wing as well as delta wing types and lifting bodies. A design lifetime of not less than 100 re-uses is aimed for.



One of several possible configurations for the proposed space shuttle.

Economy in trained manpower and skill is also achieved by the concept. One of the points of the system is that it will get rid of special astronaut training for space visits. "Anyone, regardless of sex, with special reason to be in space—for instance, for scientific research—will be able to go this way", commented Dr Paine. "I would hope to see the first British astronautess fly before the end of the decade . . ." Inherent in the system is that the passenger and cargo environment will be comparable with that encountered in commercial airline practice. In the same way, of course, the craft will be flown by highly trained and specialized crew, but the passengers will not need to share this specialization.

The conventionally powered space shuttle for commuting to Earth orbital space stations is seen as a logical predecessor to a nuclear-powered shuttle for transporting visitors to lunar orbit and on interplanetary missions. The new promise of the space shuttle is so compelling that the British Aircraft Corporation, whose MUSTARD concept dates back to the early sixties, has been asked if it could revive it either for national or international consideration.

Lovell Charts the Future

by our Astronomy Correspondent

ONE of the traditions of the Royal Astronomical Society is that the presidential address should be devoted to the astronomical speciality of the president, but in a departure from convention last week Professor Sir Bernard Lovell spoke not on radio telescopes but on "The Prospects for British Astronomy", although some would say that an eye on the future also happens to be one of Sir Bernard's specialities. The occasion was the anniversary of the founding of the society 150 years ago, and Sir Bernard made clear that the celebrations have occurred at a crucial time for British astronomy. Since the war there has been a vast increase in the astronomy budget but this has brought important changes in the way British astronomy is run.

Sir Bernard cited the way the budget of the Astronomy, Space and Radio Board of the Science Research Council, which is responsible for almost all British astronomy, has risen from 20·6 per cent of the SRC budget in 1965–66 to about 25 per cent, or £11·7 million, now. He anticipated that by the mid 1970s the total annual budget of the SRC will have risen from its present £46·8 million to the region of £63 million, with the Astronomy, Space and Radio Board dealing with between £15 million and £17 million of that.

The share of ground-based astronomy might be expected to rise from its present £3 million to £4 million in 1975, and Sir Bernard reminded the society that this would be equivalent to the amount needed for about fifty per cent of the shelved Whitford programme for the development of ground-based astronomy in the United States. Any exhilaration at these figures should be tempered by the knowledge that astronomers can no longer run their affairs in the old way. They must now be prepared to spend more time on the committees of the SRC because if there is no policy, and no united front among astronomers, then the growth rate of astronomy will fall.

The address concentrated on observational astronomy, and Sir Bernard said this is where the financial and organizational weakness lies—theoretical astronomy is by comparison well nourished with money and talent. There was also a tinge of sadness that the role of the society in the running of British astronomy has diminished, officially at least. "The new radio telescope at Cambridge will be managed and directed by Sir Martin Ryle and the University of Cambridge on behalf of the SRC. If our Mark V radio telescope is ever built, this too will remain SRC property." The same goes for the optical telescopes, and although the Isaac Newton telescope is located at and maintained by the Royal Greenwich Observatory, its programme is essentially controlled by the Large Telescope Users Panel.

With the building of the 150-inch Anglo-Australian telescope at Siding Spring, the major British interest in the southern hemisphere is bound to shift from South Africa to Australia, Sir Bernard said. An urgent problem is to make sure that British astronomers are able to make full use of their half-share of the time on the 150-inch, and an admirable solution would be the establishment of a British supporting unit at Siding Spring equipped, for example, with a 48-inch Schmidt. This would do for the southern skies what the Palomar Schmidt has accomplished in the northern hemisphere.

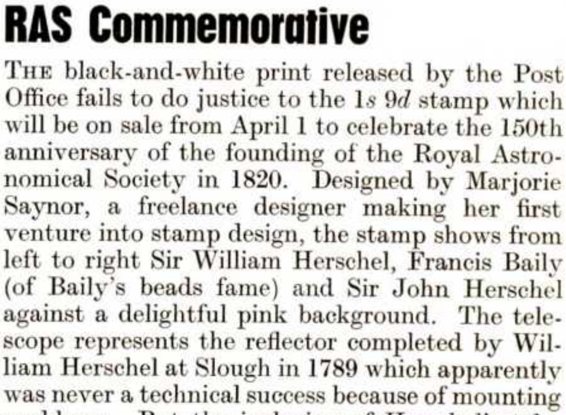
The problems of northern hemisphere astronomy centred on the UK are altogether more intractable, Sir Bernard said. "We have to develop advanced instrumentation, and that for use with the Anglo-Australian telescope is already becoming an urgent matter. We must stimulate the university astronomy departments to teach and train astronomers and we must provide UK observational facilities in the northern hemisphere under the best European seeing conditions to match those which we are developing in the south. Finally we must devise an organization for using the telescopes and directing the money which SRC may be able to provide to the appropriate research groups in the universities and elsewhere." The solutions to these urgent problems have to be based on what Sir Bernard called the somewhat incoherent structure of British astronomy in the northern hemisphere, founded on two royal observatories, one with a telescope still small by world standards working under sky conditions which are far from ideal, and several university departments heavily dependent on the SRC.

STAMP CORNER

RAS Commemorative

THE black-and-white print released by the Post Office fails to do justice to the 1*s* 9*d* stamp which will be on sale from April 1 to celebrate the 150th anniversary of the founding of the Royal Astronomical Society in 1820. Designed by Marjorie Saynor, a freelance designer making her first venture into stamp design, the stamp shows from left to right Sir William Herschel, Francis Baily (of Baily's beads fame) and Sir John Herschel against a delightful pink background. The telescope represents the reflector completed by William Herschel at Slough in 1789 which apparently was never a technical success because of mounting problems. But the inclusion of Herschel's telescope is appropriate because it features on the seal of the society.

A first-day cover service is being provided by the Royal Astronomical Society at a cost of 6*s* 6*d*. For 17*s* 6*d*, however, the deal includes an authentic signature of the president, and Sir Bernard Lovell claims to have made £40 for the society already.



NEWS AND VIEWS

Needles in a Haystack are Hard to Find

MANY of the most interesting physical phenomena have been first recognized as more or less minor departures from statistical regularity in a mass of observational evidence, which is why nobody will scoff and everybody will admire the great care which is being lavished by Professor J. Weber at the University of Maryland on the identification of what may eventually turn out to be gravitational radiation. Professor Weber has built the most elaborate equipment of its kind—perhaps even the only equipment of its kind—for the detection of the gravitational radiation which is predicated by Einstein's general theory of relativity. He has one detecting station at the Argonne National Laboratory and another at the University of Maryland. At each station there are massive metal cylinders which may be set vibrating mechanically either by the arrival of gravitational radiation from deep in space, or by more local phenomena—passing traffic and the like. In practice, comparison of the records of the two detecting stations distinguishes between spurious local phenomena and generalized influences which affect both stations similarly. Inevitably, however, disturbances of the detecting cylinders are so plentiful that purely accidental coincidences between the records of the detecting stations are common. Professor Weber's problem all along has been to find some way of distinguishing between these accidental coincidences and coincidences which may be genuine evidence of gravitational waves. The problem is familiar enough in fields as different as the detection of underground explosions and the hunt for quarks.

A year ago, it seemed very much as if Professor Weber's detecting equipment has indeed provided more coincidences than would be expected to occur by chance. In his first announcement (*Phys. Rev. Lett.*, **22**, 1320; 1969) of his success, Professor Weber appeared to be more firmly confident that he had actually recorded the arrival of packets of gravitational energy. The statistical analysis has turned out to be more difficult than seemed to be necessary at first sight. One difficulty, for example, was that of knowing how the simultaneous oscillation of several detecting instruments at one site should influence the statistical significance of a coincidence between that site and the distant one (see *Nature*, **224**, 411; 1969). Professor Weber is now going very deeply into these points and has put his statistical analysis in a form which is easier to follow, but which also suggests that the coincidences which may be evidence of gravitational radiation are by no means as exceptional as they seemed at first to be (*Phys. Rev. Lett.*, **24** 276; 1970). Thus, for disturbances at individual detecting sites so large that they occur by chance only 100 times a day, Professor Weber calculates that eighteen coincidences would have occurred in 214 days of observation—the effective time for which his equipment was functioning between January and the end of November last year. In practice, he observed 115 coincidences and he now suggests that "a considerable excess of coincidences over the expected number of accidental ones is observed and ascribed to gravitational waves".

No doubt Professor Weber, his colleagues and his critics, will be anxious to strengthen this tentative conclusion. One development has been to look at the rates at which coincidences occur when the records from the two sites are compared simultaneously and when one of them is delayed by two seconds. The result, that delay reduces the rate of coincidence to what would be expected, may again be clinching when more records have been accumulated. To be sure, there remains the possibility that some hidden systematic errors may account for the ten-fold enhancement of the coincidence rate—it could yet be, for example, that sending the records of the Argonne detector directly to Maryland for comparison may make it possible for some spurious influence to affect them both. Time, no doubt, will tell, but in the meantime everybody will wish Professor Weber well in his painstaking but exciting hunt.

PLANETS

Ammonia Ice in Saturn's Rings?

by our Astronomy Correspondent

EVIDENCE that seems to rule out H_2O ice as the chief constituent of the unknown material of the rings of Saturn has come from a comparison of the infrared spectrum of Saturn with that of Jupiter. This conclusion is part of a report by H. L. Johnson of the University of Arizona and the Universidad Nacional de México in the current issue of *Astrophysical Journal Letters* (**159**, L1; 1970). Johnson presents four spectra of Jupiter and one of Saturn in the infrared range 1·2 to 4·2 microns. At the same time, he suggests ammonia ice as a possible explanation.

At the time of the Saturn observation the rings occupied between 5 and 10 per cent of the area of the entrance diaphragm, and Johnson suggests that this factor may account for several differences between the Saturnian and Jovian spectra. At wavelengths around 1·4 microns, between 1·6 and 1·8 microns, and between 2 and 2·5 microns, Jupiter is black (that is, it reflects no light) and the spectral intensity drops to zero. The Saturnian spectrum is never quite zero at these wavelengths, however. Assuming that this contribution to the Saturnian spectrum comes from the rings it can be calculated that the rings contribute about 5 per cent of the reflected light, which agrees with their projected area on the diaphragm.

Granted that this is the explanation of the discrepancies, and this assumes that the planet Saturn is as black as Jupiter in the three wavelength intervals, what does it say about the composition of the rings? The clue here is a fourth band from 3·3 to 4 microns where both Jupiter and Saturn are black; there is no sign of reflected light from the rings of Saturn. According to Johnson, if the rings consist of H_2O ice they ought to contribute in the 3·3 to 4 micron band, and there ought to be an ice absorption band at 3 microns as well. Johnson suggests that this makes ammonia ice a more likely explanation. The point here is that ammonia ice has been put forward as the explanation of the absorption which makes Jupiter black between 3·3 and 4 microns, and therefore might explain why the rings of Saturn fail to register at these wavelengths.

MANY-BODY PROBLEM

Pairwise Harmonic Forces

from a Correspondent

FROM a microscopic point of view all problems in physics and chemistry are many-body problems. The problems become interesting when the particles of the system interact with one another, usually via two-body forces. There are very few systems of interacting particles for which exact solutions are known, and so it is always exciting to study a model of interacting particles which is exactly soluble.

Storer (*Phys. Rev. Lett.*, **24**, 5; 1970) has given a quantum statistical mechanics treatment of a system of particles interacting through pairwise harmonic oscillator forces. Working in terms of the grand partition function he shows that this interacting system behaves like a system of independent particles moving in an external harmonic well with, however, an important modification which implies a greatly reduced density of states. Not only is the density of states reduced but the spectrum of a system of particles interacting through the pairwise forces is shifted down by $\frac{3}{2}\hbar\omega$ (where ω is the oscillator frequency) relative to that of a system of independent particles in an external well.

The problem of describing N interacting particles is usually stated in terms of the N coordinates of the particles $x_1, x_2 \ldots x_N$. In the absence of external forces the centre of mass of the system, with coordinate $\vec{X} = \frac{1}{N}\sum_{i=1}^{N} \vec{x_i}$, has its motion conserved, that is, if we fix the centre of mass there remain only $(N-1)$ independent coordinates. This distinction between N independent coordinates and $(N-1)$ independent coordinates is lost in a statistical treatment.

It follows immediately from the definition of the centre of mass coordinate that the energy of the system of particles interacting through pairwise harmonic forces is equal to the energy of a system of independent particles moving in an external harmonic well the origin of which is attached to the centre of mass, which itself describes harmonic motion, plus the energy associated with the motion of the centre of mass.

When we consider the full spectrum of the system of independent particles moving in an external harmonic well, many of the configurations will correspond to excited states of the centre of mass motion. If we neglect the centre of mass motion the density of states will be decreased as observed by Storer. Further, because the centre of mass undergoes harmonic motion the zero point energy associated with this will be $\frac{3}{2}\hbar\omega$, and so when the centre of mass motion is ignored the whole spectrum will be shifted down by this amount.

The many-body system in which particles interact through pairwise harmonic forces has frequently been examined in the context of nuclear structure theory and the results quoted here have long been the basis for the standard method used to remove states containing spurious centre of mass motion from nuclear shell-model calculations (Elliott and Skyrme, *Proc. Phys. Soc.*, A**232**, 561; 1955).

FRACTURE MECHANICS

Brittle Fracture by Thermal Shock

from our Materials Science Correspondent

ONE of the many obstacles in the path of the design engineer who would like to make use of the high strength of brittle ceramics such as alumina or silicon nitride is their sensitivity to thermal shock. Thermal gradients induced by sudden heating or cooling cannot be relieved by plastic flow (which is why these materials are strong) and so cracks readily form and propagate. Quantitative treatment of this process is difficult and so it is of considerable importance that a unified theory has been published recently by D. P. H. Hasselman (*J. Amer. Ceram. Soc.*, **52**, 600; 1969).

Hasselman has considered three distinct stages in thermal shock: the thermal condition required to initiate fracture (assuming a pre-existing population of small Griffith cracks of uniform size), the length of crack which results and the thermal condition required to cause the arrested crack to start propagating again. It turns out that the temperature difference between surface and core—rather surprisingly, it is the difference and not the gradient that enters the equations—required to initiate fracture is independent of the density of cracks. But it varies slowly with crack size, while the size of crack at which propagation is arrested depends steeply on initial crack size and also on population density. It is particularly noteworthy that there is a particular initial crack size (depending somewhat on the population density) for which the temperature difference to initiate crack propagation is a minimum: that is, as far as initiation is concerned, the material is then at its most sensitive. In these circumstances, however, crack propagation is least favoured; propagation is quasi-static instead of being dynamic. As a result of his calculations (which agree in detail with some careful measurements by Davidge and Tappin of thermal shock behaviour of alumina spheres), Hasselman recommends that, for a given material, sensitivity to thermal shock should be minimized by adjusting the grain size, or population of artificial cracks, so that fracture is easily initiated but unlikely to propagate.

One incidental feature of interest which emerges from the survey is the asymmetry of thermal shock fracture: alumina is much more apt to shatter on heating than on quenching. The difference is connected with differences in the number of nucleation sites in the two cases.

ELECTRON MICROSCOPY

Ion Erosion for Non-metals

from our Materials Science Correspondent

REPLICAS have had their day. Probably nine-tenths of electron micrographs nowadays are made from thinned foils, and nine-tenths of those from metals. Many ceramists, mineralogists and glass scientists would gladly make more use of electron microscopes if the problems of thinning down specimens were less daunting. With inorganic compounds that are lamellar in form and cleave easily, there is no problem, but run-of-the-mill oxides have been troublesome. Some people have used mechanical grinding, others have experimented with chemical thinning—often with indifferent success—and some in desperation have become crystalloclasts and taken to using a pestle and mortar.

Several investigators have profited from the current interest in ion erosion to develop a new method of thinning non-metallic samples for electron microscopy. It has been described independently by D. J. Barber (*J. Materials Sci.*, **5**, 1; 1970) and H. Bach (*J. Non-Cryst. Solids*, **3**, 1; 1970), who concerns himself largely with glasses. Both use focused beams of argon ions at 5–7 kV energy to erode material from the sample surface at nearly glancing incidence. The principal difference between the two scientists is that one erodes one side only, while the other simultaneously bombards from both sides, using a cold finger to inhibit redeposition of sputtered atoms. The apparatus is simple—Barber's is the simpler of the two, and equally effective—and there appears to be no problem about heating of the sample, or controlling the process. The two reports contain several micrographs of glasses and crystalline compounds such as olivine, alumina, quartz and lithium fluoride, as well as some thin films sectioned transversely.

Glasses do not give good micrographs if they are truly vitreous, for lack of contrasting features, but with many samples it is possible to see incipient or advanced breakdown into two glassy phases or into a crystalline phase dispersed in a vitreous matrix. These features show up well, while larger inclusions are revealed by a sort of self-shadowing in the ion beam. Barber reports no problems with crystalline materials, but Bach has found that in some cases the surface layers lose their crystallinity because of radiation damage by the ions. This was clearly revealed by electron micrographs made of ion-eroded quartz, but lithium fluoride was immune. It will plainly be important in this respect to separate the sheep from the goats.

Ion erosion has also been used to remove successive layers from the surfaces of samples in a scanning electron microscope, to permit examination of structures in depth. D. Kynaston, working with a Stereoscan (*New Scientist*, **45**, 256; 1970), has obtained micrographs with the help of a small ion source built into the microscope's specimen chamber; he has applied the technique to both inorganic and biological specimens.

Barber, Bach and Kynaston have all used compact cold cathode sources operating with a glow discharge, which represents a cheap and simple way of obtaining focused beams of ions at moderate energies. It is to be hoped that some enterprising manufacturer will soon market an inexpensive device for conventional electron microscopists—it seems that scanning electron microscopists will soon be provided for.

PLANETARY ATMOSPHERES

Stain in the Clouds of Venus

by our Astronomy Correspondent

THE clouds which perpetually obscure the surface of Venus have been reported to be tinged with yellow, but the notion arising therefrom that the clouds are essentially carbon suboxide, C_3O_2, is scotched in the current number of the *Astrophysical Journal* by W. T. Plummer and R. K. Carson of the University of Massachusetts (**159**, 159; 1970). The possibility that carbon suboxide plays an important part in the atmosphere of Venus has been entertained at various times since the 1950s, but Plummer and Carson show that this is at variance with the infrared evidence.

They have prepared carbon suboxide frost in the laboratory and shown that its infrared reflexion spectrum differs from the spectrum of Venus. Although in the atmosphere of Venus carbon suboxide is likely to be liquid rather than solid, Plummer and Carson say that frost spectra are a good substitute for the spectra of a cloud of droplets. Their measurements show that between 1 and 3 microns the reflexion spectrum of carbon suboxide in general agrees with the Venus spectrum, but there are some important differences.

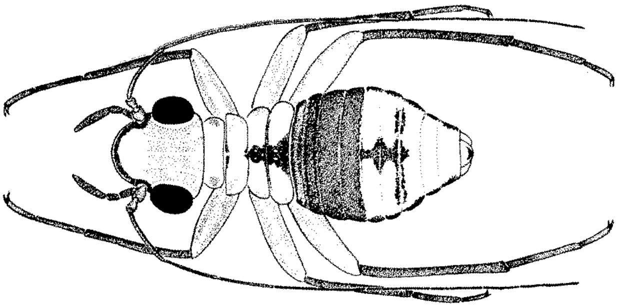
For example, a prominent carbon suboxide absorption feature at 2·25 microns is absent from the Venus spectrum, and Plummer and Carson say that this could only happen if the size of the droplets is suitably small, less than 0·1 micron across. Particles this small are eliminated by polarization measurements of Venus.

Although this seems to rule out carbon suboxide as an important component of the clouds, the point about carbon suboxide is that the monomer which is white in the solid state gradually polymerizes to a yellow, red or brown variety, with the possibility that the clouds might be made up of a polymer, thus explaining the yellow tinge. It is clear, however, that a faint yellow polymer of carbon suboxide cannot form the bulk of the clouds. For one thing, the chemical evidence is that all the polymers have a high reflectivity in the infrared region contradicting the region of low reflectivity in the Venus spectrum which begins on the low wavelength side at about 2·6 microns. What is more, Plummer and Carson say that the effect of ultraviolet light is to continue the polymerization until the product is a deep brown colour which is not likely to go unrecognized. To maintain the whiteness of the clouds the monomer would have to be continually replenished, but this is forbidden by the absence of the 2·25 micron feature. Clearly carbon suboxide is now properly ruled out as a major constituent of the enigmatic clouds—it was never a strong contender—but it is still feasible that a small amount of a polymer of low molecular weight might be responsible for the yellow stain, possibly in clouds which are composed of ice particles.

ENTOMOLOGY

Another Louse

THIS larva of an African louse, which is 1·3 mm long, has been assigned to the species, *Epipsocopsis cincta*, by A. Badonnel in a study of the Psocoptera, or lice, of Angola and neighbouring countries. It appears in one of the lavishly produced publications from the Museum at Dundo in Angola (Companhia de Diamantes de Angola, *Publicaçoes Culturais*, No. 79; 1969). The material for this study was a collection made by A. de Barros Machado and his colleagues, and Badonnel identified 2,220 adult lice.



TUMOUR VIROLOGY

Chasing a Minus Strand

from our Cell Biology Correspondent

WORKING up an experimental system to the point at which it can be used to answer interesting questions is a job most people prefer to leave to someone else, and tumour virologists, especially those who aspire to molecular biology, are no exception. Today it is simpler, and more immediately rewarding, to work with DNA tumour viruses, polyoma and SV_{40}, than to work with the RNA tumour viruses even though, as far as the viral aetiology of cancer is concerned, RNA tumour viruses seem to be the more pertinent of the two groups.

The RNA tumour viruses unfortunately present daunting technical problems. For one thing they have too much genetic information to make analysis of gene functions straightforward and for another they wrap themselves up in a large amount of host cell lipoprotein, which can comprise more than 99 per cent of the total mass of the virions. But in spite of their apparent complexity the RNA tumour viruses may prove at bottom to be very similar to the simplest of all viruses, the RNA bacteriophages. And certainly the RNA phages and small non-oncogenic RNA viruses, such as polio virus, are still valuable models for the RNA tumour viruses.

No one will be surprised, for example, if the replication of the single stranded RNA genomes of the tumour viruses proves to follow the same pattern as replication of the RNA phage and polio genomes. Several groups are busily searching for a tumour virus-specific RNA replicase similar to the well characterized Qβ phage replicase, and Watson and Beaudreau (*Biochem. Biophys. Res. Commun.*, **37**, 925; 1969) have made some progress in this direction. They have isolated a crude enzyme fraction from blood cells of chicks infected with avian myeloblastosis virus which may well contain the virus replicase. The crude enzyme preparation is not template-specific for the virus RNA, although of the several RNA templates tested avian myeloblastosis viral RNA was most effective; the RNA made with the virus RNA as template has yet to be characterized and the amount of RNA made is much less than the amount of template added. Nevertheless, the preparation probably contains the viral replicase, and although Watson and Beaudreau have a long way to go to prove that, the properties of their extract parallel in many respects the properties of crude extracts of Qβ phage replicase in the early days of its characterization.

If RNA tumour virus replication is similar to replication of other single stranded RNA genomes a minus strand complementary to the plus strand in the virion should be made during replication. Biswal and Benyesh-Melnick (*Proc. US Nat. Acad. Sci.*, **64**, 1372; 1969) have claimed recently to have detected such a minus strand in rat cells infected with murine sarcoma–leukaemia virus. They find, after extraction by a phenol–*m*-cresol procedure which could be the secret of their success, two RNA species restricted to the nuclei of infected cells. These sediment at 31–36S and 18–22S and, after heat denaturation, hybridize with RNA from murine sarcoma–leukaemia virions. On the other hand, none of the RNA from the cytoplasm of infected or uninfected cells, or the nuclei of uninfected cells, hybridizes with virion RNA. Biswal and Benyesh-Melnick conclude that the 31–36S and 18–22S RNA species are minus strands or fragments of minus strands, which presumably act as templates for synthesis of progeny virus genomes. The smaller of these two RNAs, the 18–22S RNA, is, moreover, resistant to ribonuclease and therefore probably double stranded. It may be part of a replicative form, but if so it is surprisingly small.

On the face of things these results are precisely as anticipated—the fact that only about 22 per cent of labelled virion RNA hybridizes even with large excesses of nuclear RNA may be a technical artefact—and the way seems open for the characterization of tumour virus RNA replication.

BIOCHEMICAL THERMODYNAMICS

Counting the Calories

from our Molecular Biology Correspondent

THERE is, of course, nothing new about the use of calorimetry to follow chemical and even biochemical processes. Nonetheless, all the indications are that this technique has only just arrived so far as molecular biology is concerned, and that it will not be long before the present trickle of papers becomes a flood. This growth of interest must be presumed to be at least partly a consequence of the development of good commercial instruments, which have gone some way to making the method experimentally foolproof. Two papers in the current literature—both in fact by long-standing practitioners of the art—illustrate well the scope of microcalorimetry in the study of enzymes.

Shiao and Sturtevant (*Biochemistry*, **8**, 4910; 1969) have studied the interaction of chymotrypsin with its inhibitors, and its dependence on protein concentration. In the first place, the heat of dilution of chymotrypsin depends on the initial concentration, and is found to follow it in a manner consistent with a simple dimerization of the enzyme. Correcting for this effect, it is possible to determine the heats of binding of specific inhibitors, by using large molar excesses of the ligand, so that the binding sites are always saturated. It emerges that the heat of binding is in all cases dependent on enzyme concentration, and it can be inferred that the dimer has little or no affinity for the inhibitor. These results, which refer to *p*H 7·8, at which the enzyme slowly autolyses, differ in various respects from those reported by other workers, using different methods, all, however, in more acid conditions. Shiao and Sturtevant suggest that at their *p*H they are observing cannibalistic enzyme–substrate complexes, and the inhibitors are in competition with this interaction. The affinity of the monomeric enzyme for the inhibitors is compounded of a large negative enthalpy and a sizable negative entropy, even when the ligand is uncharged. It is likely that a change in enzyme conformation (induced fit) is responsible for a considerable part of both.

A more complex system has been studied by Ross and Ginsburg (*ibid.*, 4690). This involves the binding of feedback inhibitors, which control its activity *in vivo*, to the twelve-subunit enzyme, glutamine synthetase. Twelve molecules each of tryptophan and 5′-AMP are bound by each protein molecule, indicating that all subunits are functionally equivalent. The heats of binding of the two ligands separately were measured, and also that of both together. The contributions of the two interactions are strictly additive, and this is good evidence that the sites for tryptophan and AMP are separate entities. The binding of either ligand is accompanied by a large entropy change, but one (AMP) is positive, the other negative. This curious phenomenon may be related to the induction of conformational changes by one or other ligand.

An interesting application of microcalorimetry in the polynucleotide field has also appeared (Scruggs and Ross, *J. Mol. Biol.*, **47**, 29; 1970). This concerns the binding of monomeric adenine derivatives to poly-U, a process that always has a 2 : 1 stoichiometry. The principal finding is that the enthalpy is always the same, irrespective of whether the monomeric species is adenine, adenosine or deoxyadenosine. This eliminates any involvement of the 2′-hydroxyl group, or any other part of the sugar, in the stabilization of the helix, at least in this prototypic system. The binding of a derivative containing an extra amino group in the purine ring, so that three hydrogen bonds can be formed with the pyrimidine, causes the enthalpy to become 3 kcalories/mole more negative. Knowing the melting temperatures of the complexes, the entropies of association can be derived, and are large and unfavourable, as one might expect for the immobilization of monomers.

GYNAECOLOGY

Test for Spontaneous Abortion

from our Medical Biochemistry Correspondent

If it is true that a gynaecologist's practice is made up of women desperately anxious either to have babies or to avoid them, they may all be helped by some recent biochemical investigations. Genazzani *et al.* have shown how women whose pregnancies are likely to end in spontaneous abortion can be distinguished by measuring the concentrations of human placental lactogen in their serum (*Lancet*, ii, 1385; 1969).

Human placental lactogen, discovered in 1962, is a polypeptide hormone produced by the placenta, and similar in structure and in some of its effects to pituitary growth hormone. Radioimmunoassay carried out on seventy-four women showed that concentrations of the lactogen steadily increase between the seventh and thirty-first weeks of normal pregnancies. This probably reflects the growth in size of the placenta at this time. In two cases the increase during several weeks was very similar to the mean increase for the group.

Of thirteen women with threatened abortion, who had been admitted to hospital with pain and vaginal bleeding, five experienced an increase in human placental lactogen comparable with the increase in the normal pregnancies. These women all completed their pregnancies successfully. Five of the thirteen admitted to hospital, however, had barely detectable concentrations of human placental lactogen and rapidly aborted. The other three had relatively low concentrations when admitted to hospital, and these rapidly decreased until the women aborted.

In cases when the human urinary chorionic gonadotrophin was also measured it turned out to be a very unreliable indicator of abortion. But the test for placental lactogen, in the early weeks of pregnancy at least, seems to be a good guide to the likelihood of spontaneous abortion, pointing out those patients for whom active therapeutic measures are necessary.

FORESTRY

Trees in Trouble

by our Botany Correspondent

Butt rot is a problem that often occupies the plant pathologists of the Forestry Commission. Their latest manoeuvres against *Fomes annosus*, the fungal cause of the trouble, are described in *Forest Research* 1969 (HMSO, £1.12½). Resistant species of forest trees are being sought to counteract the problem of butt rot, which seems to loom on most acid mineral sites in Britain. A survey of the spread of the fungus in stands of different species has confirmed that infection is less extensive in grand fir, *Abies grandis*, than in some other species. This is a hopeful sign for those who thought that this species might prove to be resistant to butt rot. The aim of the work in progress is to identify species which can be recommended for planting on heavily infested soils.

Another disease which has made surprising progress in the past year is beech bark disease, which had been thought to be of little importance except in mature trees. But there have been two serious outbreaks in young crops in Britain, in the Queen Elizabeth Forest (Hampshire and Sussex) and in Savernake Forest (Wiltshire and Berkshire). Preliminary investigations have indicated that drought is not after all an important causal factor. The cause seems to be a combination of the beech coccus insect and fungi of the genus *Nectria*.

The enquiries which the Forestry Commission pathologists dealt with in 1969 have shown them that elm disease, caused by *Ceratocystis ulmi*, is on the increase, but there was a striking decline last year in damage to weeping willows by *Marssonina salicicola*, which causes leaf spot, shoot canker and dieback. *Cristulariella depraedans*, a fungus previously unrecorded by the commission, caused spectacular damage to sycamore leaves in the south last year.

Larger pests are the problem of the commission's mammal and bird experts. Last year saw the continuation of trials of chemical repellants to prevent severe browsing by roe deer. A Dutch repellant, 'Aaprotect', was sprayed onto the shoots of Norway spruce, and three months after the beginning of the trial about a third of the shoots had been damaged. This represents a marked reduction in the damage done by the deer, but the chances are that a slow accumulation of damage will reach economic proportions in one or two seasons where browsing is a severe hazard to young plantations.

PLANT ANATOMY

New Cells Described

by our Botany Correspondent

A NEW category of plant cells has been recognized after an extensive survey of living material and literature. Drs B. E. S. Gunning and J. S. Pate of Queen's University, Belfast, have suggested that cells with marked ingrowths on their walls, which give them a large ratio of surface to volume, have evolved to cope with the transfer of solutes across the cell membrane. For this reason the cells are called transfer cells (*Protoplasma*, **68**, 107; 1969).

In spite of considerable morphological variations, transfer cells, which are found throughout the higher plants, are always characterized by distinctive, irregular ingrowths of the cell walls. Gunning and Pate have defined five situations in which transfer cells are found, and each case involves transfer of solutes across the membrane. First, there is absorption from the external medium. The ability of the submerged leaves of water plants to absorb and accumulate ions has often been investigated, and there is clear evidence in several species of ingrowths on the outer faces of epidermal cells, which are not covered by a waxy cuticle. Gunning and Pate think that these epidermal transfer cells will be found to be widespread in aquatic plants, facilitating the uptake of solutes by the provision of a large area of cell membrane.

Transfer cells are also common when solutes have to pass to the external medium; for example, in the glands of insectivorous plants. And there are transfer cells in the outer layers of the haustoria of parasitic plants such as *Cuscuta*, dodder, which penetrate into the vascular system of the host to absorb food materials. A similar situation is the placental connexion between the sporophytic generations of mosses and ferns and the gametophytic generations on which they develop. Transfer cells of both generations are found adjacent to each other, and Gunning and Pate assume that this means that there is specialization related to both influx of solutes to the parasitic sporophyte and efflux from the host gametophyte.

When it comes to reproduction in the higher plants, it is common to find situations in which an increased surface area of membrane would enhance absorption from the surrounding nutritive cells to the developing parts of the plant. There is discontinuity of contact between, for example, developing pollen grains and the surrounding tapetum and between the embryo and the embryo sac. Transfer cells always seem to be there to facilitate the passage of nutrients from one to the other.

The final context in which transfer cells have been reported is the transport systems of plants. The cells may be associated predominantly with the xylem or the phloem (Fig. 1*a*) or with both (Fig. 1*b*). Evidently the cells pass solutes between the conducting elements of xylem and phloem, or between the cells of xylem and phloem themselves.

Speculating about the development of transfer cells, Gunning and Pate have pointed to evidence that some secretory cells do not form ingrowths until secretion begins; perhaps the specialization of the wall will be found to be synchronized with the onset of intensive transport of solutes. The frequent localization of ingrowths on the cell walls considered to be most active in transfer suggests that the interaction with neighbouring structures is a determining factor in development. But the mechanism of development of the ingrowths is still a mystery. They will provide botanists with some intriguing problems, and it will be interesting to see how eagerly the name transfer cell is greeted.

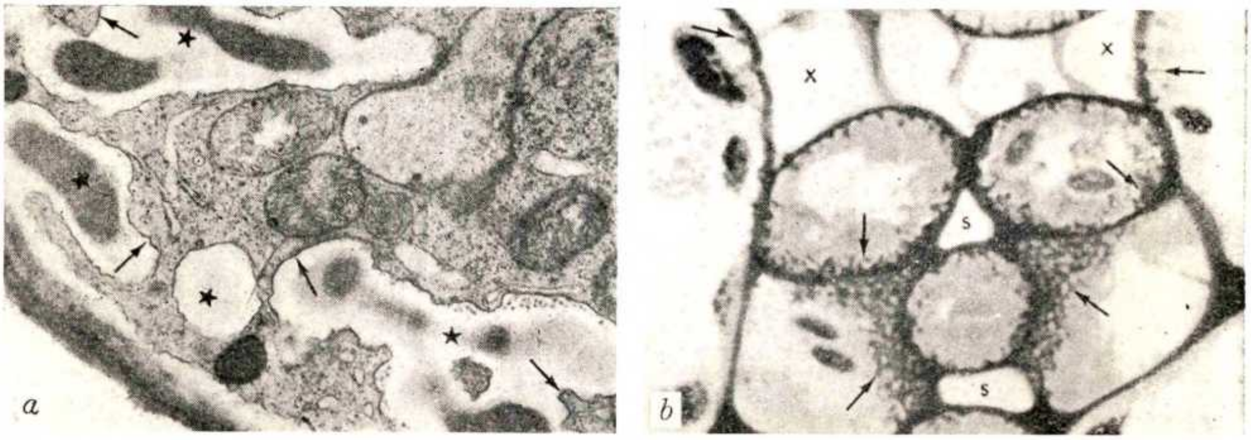


Fig. 1. (*a*) Electron micrograph showing the wall and membrane of transfer cells in phloem of *Vicia faba*. Stars mark the irregular ingrowths, which are associated with plasma membrane, arrowed (×20,000). (*b*) Photomicrograph of transfer cells surrounding sieve elements (s) and xylem (x) of *Anacyclus*. Some of the ingrowths of transfer cell walls are arrowed (×2,100).

CURRENT TOPICS IN DEVELOPMENTAL BIOLOGY

VOLUME 4

edited by **A. A. MOSCONA,** *Department of Biology, University of Chicago, Chicago, Illinois,* and **ALBERTO MONROY,** *Institute of Comparative Anatomy, University of Palermo, and Research Unit for Molecular Embryology, National Council of Research, Palermo, Italy.*

This book presents concise, topical reviews of research and concepts fundamental to the field of developmental biology. The emphasis is on cellular, biochemical, molecular and genetic approaches to the processes of development and differentiation. It provides an interdisciplinary forum for the presentation and discussion of facts and views, and aims to bridge the "interdisciplinary information gap" in this field.

CONTENTS: CLIFFORD GROBSTEIN: Genetics and Genesis. ALEX KEYNAN: The Outgrowing Bacterial Endospore. DAVID YAFFE: Cellular Aspects of Muscle Differentiation in Vitro. BERNARD ROIZMAN and PATRICIA G. SPEAR: Macromolecular Biosynthesis in Animal Cells Infected with Cytolic Viruses. MAX HAMBURGH: The Role of Thyroid and Growth Hormones in Neurogenesis. JACK GORSKI, G. SHYAMALA, and D. TOFT: Interrelationships of Nuclear and Cytoplasmic Estrogen Receptors. JACK E. LILIEN: Toward a Molecular Explanation for Specific Cell Adhesion. LEONARD WARREN: The Biological Significance of Turnover of the Surface Membrane of Animal Cells. Author Index. Subject Index.

THE STRUCTURE AND FUNCTION OF NERVOUS TISSUE

VOLUME 3: BIOCHEMISTRY AND DISEASE

edited by **GEOFFREY H. BOURNE,** *Yerkes Regional Primate Research Center, Emory University, Atlanta, Georgia.*

1970, 645 *pp.*, 308*s.* ($33.00),
subscription price 261*s.* ($28.05)

FISH PHYSIOLOGY

edited by **WILLIAM S. HOAR** and **DAVID J. RANDALL,** *both at Department of Zoology, University of British Columbia, Vancouver, Canada.*

Volume 1: EXCRETION, IONIC REGULATION, AND METABOLISM

1970, 465 *pp.*, 215s. ($23.00),
Subscription price 168s. ($18.00)

Volume 2: THE ENDOCRINE SYSTEM

1970, 447 *pp.*, 215s. ($23.00),
Subscription price 182s. ($19.55)

Volume 3: REPRODUCTION AND GROWTH: BIOLUMINESCENCE, PIGMENTS, AND POISONS

1970, 485 *pp.*, 224s. ($24.00)
Subscription price 187s. ($20.00)

EARLY DIABETES

Supplement 1 to **Advances in Metabolic Disorders**
Proceedings of the First International Symposium

edited by **RAFAEL A. CAMERINI-DAVALOS,** *Director Diabetes Center, New York Medical College, New York* and **HAROLD S. COLE,** *Department of Pediatrics, New York Medical College, New York.*

April, 1970, 478 *pp.*, 215s. ($23.00)

A New Journal . . .

CELLULAR IMMUNOLOGY

edited by **H. SHERWOOD LAWRENCE.** *Infectious Diseases and Immunology Division, Department of Medicine, New York University Medical Center, New York, New York.*

Cellular Immunology will provide an international medium devoted exclusively to publication of original investigations concerned with the immunology activities of cells in experimental or clinical situations. The scope of the journal will encompass the broad area of in vitro and in vivo studies of cellular immune responses. These include, for example, delayed type hypersensitivity of cellular immunity; immunologic surveillance and tumour immunity; transplantation immunology; autoimmunity, resistance to intracellular microbial and viral infection; immunologic deficiency states and their reconstitution; antigen receptor sites; thymus and lymphocyte immunobiology, etc. The chief criteria for acceptance of papers submitted for publication are the originality, clarity, and quality of the work reported.

All manuscripts should be submitted to the editor. The publisher will announce prices for personal and institutional subscriptions in the near future. Interested parties should contact the publishers to ensure prompt receipt of details. A limited supply of sample issues will be made available by the publishers to honour individual requests.

Anticipated publication date: Second quarter of 1970

CELLS AND TISSUES BY LIGHT AND ELECTRON MICROSCOPY

VOLUME 1

by **EDMUND B. SANDBORN,** *Department of Anatomy, Faculty of Medicine, University of Montreal, Montreal, Quebec, Canada.*

This book is a coordinated study of animal cells and tissues as seen in light and electron microscopy. It shows the organization of cells and tissues in unusual detail. Those tissues most frequently encountered in the studies of histology, cytology, and pathology are thoroughly covered. It is the first attempt at providing a study of biological structure that includes both light and electron microscopy. the book also contains examples of cytochemical analyses of membrane and organella function. Legends are in both French and English.

April, 1970, 364 *pp.*, 135*s.* ($14.50)

TRANSPORT PHENOMENA IN MEMBRANES

by **N. LAKSHMINARAYANAIAH,** *Department o, Phamacology, School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania*

1970, 517 *pp.*, 205s. ($22.00)

INTERNATIONAL REVIEW OF CYTOLOGY

VOLUME 28

edited by **G. H. BOURNE,** *Yerkes Regional Primate Research Center, Emory University, Atlanta, Georgia,* **J. F. DANIELLI** and **K. W. JEON,** *both at the Center for Theoretical Biology, State University of New York at Buffalo, Buffalo, New York.*

May, 1970, 384 *pp.*, 196s. ($21.00)

Academic Press announces
a new quarterly journal

Physiological Plant Pathology

An international journal of experimental plant pathology

Editors B. J. Deverall, *London*, and T. F. Preece, *Leeds*

Editorial board *Chairman:* P. W. Brian, *Cambridge*

C. H. Beckman, *Rhode Island*
J. M. Daly, *Nebraska*
J. Dekker, *Wageningen*
J. E. DeVay, *Davis*
J. Friend, *Hull*
R. N. Goodman, *Missouri*
R. Heitfuss, *Göttingen*
J. Kuć, *Indiana*
R. D. Preston, *Leeds*
K. J. Scott, *Brisbane*
M. Shaw, *Vancouver*
I. Uritani, *Nagoya*
R. L. Wain, *Wye*
M. S. Wolfe, *Cambridge*
R. K. S. Wood, *London*

An understanding of host-parasite interactions is now essential to a wide range of biologists. This journal will publish work on physiological, biochemical, ultrastructural, genetic and molecular aspects of host-parasite relationships in plant disease, on the effects of environment on these relationships, and on modifications of host metabolism induced by infection with pathogens. Work involving any kind of infective agent will be included as well as research based on organisms in pure culture having a direct bearing on host-parasite interactions. Particular attention will be given to the publication of high quality plates and photomicrographs.

Aims To present this work to all plant scientists, plant pathologists and to physiologists, biochemists, geneticists and molecular biologists.

Level Undergraduates specializing in plant pathology, postgraduate students and research workers.

Frequency and price One issue quarterly; four issues per volume of 400 pages
Annual subscription: 126s. UK ($17.00 overseas)

Case Histories of Innovations

by
R. W. CAHN
Materials Science Division,
School of Applied Sciences,
University of Sussex

Technologically slanted case histories of the development of industrial products are valuable supplements to more general analyses of technological innovation, which usually centre on economic and organizational considerations. This survey of available case histories shows that several lessons can be learnt from them.

EMERSON said that "if a man . . . make a better mousetrap than his neighbour, tho' he build his house in the woods, the world will make a beaten path to his door". He lived in a confident age, and today we are not so sure. A good deal of anxious soul-searching is going on, chiefly in government committees and at high powered conferences, to discover how a research director may recognize a better mousetrap; how he may persuade his managing director to supply the means to perfect and manufacture the new model; how, alternatively, he can fulfil his strategic function to recognize the need for the new mousetrap, and so constitute and guide his research team that they may as rapidly as possible develop it; and, finally, how to cope with the problems that face him when, with his nice new mousetrap just in the shops, a new breed of supercats is imported from America and the trap gathers dust on the shelf.

The inventors of the jet engine, hovercraft, swing-wing aircraft have all testified that the world was sceptical and slow to be convinced. Many people have accordingly been seeking to discover the reasons why, and what distinguished these inventions from others which were promptly taken up, developed and brought into successful production. Others have analysed the factors that favour the genesis of inventions in the first place, quite apart from the question of their effective use. Much discussion has been in terms of patterns of organization, or analysis of the financial implications of scale, lead-time and discounted cash flow, or else in psychological or social anthropological terms applied to the thought processes and motivational patterns of innovators. All too little attention has been devoted to the detailed scientific and engineering history of individual technological innovations —there is much discussion in general terms as to how research and development is best organized and financed, but little as to the particular detailed circumstances and steps which led to the perfection of a new product or process.

Justification for Case Histories

The justification for expending talent and money in assembling case histories, and time in studying them, has been aptly summarized by Conant in the introduction to his collection of case histories in experimental pure science[1]: "Almost all that a trained scientist has to go on when he passes judgment on the prospects of a new venture far removed from his own speciality is his knowledge of the methods by which science has progressed in his own experience. To a considerable degree a non-scientist may come to have a similar basis for his opinions. An intimate acquaintance with a relatively few historic cases should assist him in finding his way through the complexities of modern investigation as he listens to those who tell him what is being proposed". Conant was concerned only with scientific and not with technological events; yet the educational ends for which he assembled his collection are equally valid for those who guide the advantageous interplay of science and technology—that is, technological innovation.

The kind of case histories which I am recommending cast light on the mechanism of "coupling" between scientists and technologists, to use the term favoured by Price and Bass in their recent survey of scientific research and the innovation process[2]. The decisions which an industrial research manager has to make in organizing his laboratory include such matters as: Should there be a measure of fundamental research, not mission-orientated, so as to provide informal contact between technologists who are mission-orientated and those who can start them off on a new tack, either because of their own research or because of the reading they necessarily do—or is interaction too rare to warrant the cost ? Is it financially more advantageous to make use of external consultants, academic or otherwise, and, if so, should it be *ad hoc* or as a matter of routine ? Should the manager seek to identify what Price and Bass call "gatekeepers", human catalysts who are gifted scientists but devote their energies to seeking out possible applications for scientific discoveries ? Are scientific conferences more likely to foster coupling than frequent in-house colloquia combined with other social devices to foster interaction ? The accretion of case histories alone is not enough, and must be complemented by analysis, but any historian would confirm that analysis depends entirely on the availability of primary source material. This is the value of case histories: they constitute primary source material.

Economically Based Surveys

Many general surveys of organization, information flow and finance have been published recently, especially in the United States. The National Science Foundation arranged a conference on technology transfer and innovation[3], NASA commissioned a report[4] on assessing technology transfer (between different national sectors), the US Department of Commerce invited a panel to discuss the environment and management of technological innovation[5]. In Britain, a concise but illuminating report on technological innovation has recently been issued by the Central Advisory Council for Science and Technology[6], while large scale economic, political and managerial arguments have also been set out by Shanks[7] and Layton[8]. The last of these particularizes to the extent of concentrating on particular industries in separate chapters, whereas all the others make their analysis at a general level. Another study, devoted to a particular industry, is Beer's history of the German dye industry[9]. Particularly effective examples are the analysis of innovation in the plastics[10], electronic capital goods[11] and chemical process plant[12] industries. Although their primary emphasis is economic and international, these reports devote considerable attention to purely technological and organizational factors that have influenced the rate at which innovations have been brought to fruition in different countries and firms.

Freeman's reports come quite close to tackling the problem of managing research and development at the level of the individual industrial firm or laboratory. Analysis at this level is gradually growing: thus Mencher[13] and Blake[14] have reported briefly on two American studies, and Lord Rothschild has published a short survey of some of the research and development problems of Shell[15]. Lord Rothschild's survey, unlike Mencher's and Blake's, deals in part with specific episodes. So does Gowing[16] in her historical analysis of the development of British activity in atomic energy during the war, which is not less instructive for dealing with government research in wartime constraints.

Case Histories

The most thorough attempt until recently to map out the case histories of several inventions was made by Jewkes *et al.*[17], who emphasized the individual inventor; he is often seen as the sole motive force, pushing through his ideas against institutional apparatus and inertia, though institutional facilities play an important part in many of Jewkes's sixty-one case histories. Langrish (talking at the British Association meeting at Leeds in 1967) questioned the set of assumptions which he terms the "innovation myth", which includes the assumption of the preponderant role of the gifted individual, following his own private demon. He analysed five recent British innovations in some depth, treating them in their economic setting and attempting to trace some of the key conversations and contacts between the principal participants. Individual lessons are drawn from these case histories, and his lecture (which reports work in progress) represents a new standard in this form of analysis.

A chapter in a recent book on the zinc smelting industry in Britain[18] traces in detail the steps in the development of the important Imperial Smelting (blast furnace) process for extracting zinc from its ores, taking the story all the way from conception to large scale application. Economic aspects of the innovation are accorded considerable weight. A particularly useful example of this kind of analysis is Allen's[19] survey of the discovery and industrial introduction of polythene, terylene and oxygen steelmaking. Allen traces in considerable detail the intellectual stages of the discoveries, including the important accidents of the stimuli to which the principal protagonists were exposed and the papers they read and responded to. This "micro-innovative" approach is complemented by macroeconomic arguments.

The publication of a report on applied science and technological progress, prepared by the Committee on Science and Science Policy of the National Academy of Sciences for the Committee on Science and Astronautics of the US House of Representatives[20], is an important step forward. This contains seventeen signed articles and a coherent set of conclusions and recommendations, including a set of conclusions under the sub-heading "with respect to individuals who conduct applied research". (The committee emphasizes the importance of the individual technical entrepreneur, not only for his inventiveness but also for his determination; but it recognizes that he is not a *sine qua non* for technological innovation.) Harvey Brooks, of Harvard University, wrote a stimulating introduction, in which he refers to a number of case histories collected by the Materials Advisory Board of the National Research Council[21] and also to the US Defense Department's Project Hindsight[22], which is a continuing attempt to analyse the organization and progress of defence projects in the United States. Brooks particularly emphasizes the fact that most historical studies of innovation have "generally pointed up the fact that the development of technology has been surprisingly independent of the development of science, at least in detail". But he points out that this conclusion emerges from studies of events of fifty years or more ago, and that it is not valid for recent events. He emphasizes that the current intellectual style is towards abstract analysis, in technological innovation no less than in pure science, and suggests that a man like Willard Gibbs would not today start his career with a thesis on the design of gear trains. A critical analysis, in the light of some specific episodes, of the change of emphasis from the empirical to the abstract in modern technological innovation is a worthwhile task for a historian with deep engineering and mathematical knowledge.

The most useful case histories are to be found in the chapter by Suits and Bueche, of the General Electric Company, and they all refer to work done in the laboratories of that company. The projects include the development of man-made diamond, a vacuum circuit-breaker, two new polymers, a new form of an old ceramic, a new form of fuel cell, uses of etched particle tracks in thin films, and some others, including a new form of heat insulation which, though effective, was not a technological success—a rare example of frankness ! Each case history is accompanied by a list of key personnel with their antecedents and qualifications, and lists of patents and of related publications. The story of the vacuum circuit-breaker, for example, spells out the technological need which spurred the research effort, the scientific reasons for hoping that a new effort at a particular time might well be successful, and some of the specific inventions which together constituted the essential background. One of the polymer case histories sets out in some detail the role of chance conversations and more formal colloquia between the members of a laboratory in promoting a vital experiment or new way of looking at a problem. The story of the etched particle tracks (see also ref. 23) is a classic case of a wholly basic piece of research, which, through the freemasonry of the scientific profession, led to a totally unexpected but commercially viable application; the stages of this episode are recounted in detail.

All the General Electric case histories emphasize the critical role of the interaction between investigators, both those primarily involved with the project and those who merely join in conversations. This type of case history must be difficult to assemble, and because it depends in part on the recollection of conversations, no doubt it is subject to the occasional error of memory; nevertheless, it is peculiarly valuable for the lessons it brings for laboratory management. It is plain that someone at General Electric must have made it his business to keep records of some at least of the less formal aspects of research programmes, even before success was assured; laboratory notebooks, patents and papers are a necessary but not a sufficient component of the sort of intimate case history at which the General Electric writers excel. If this is accepted, then it follows that an enlightened organization which wishes to help itself—and people concerned with research and development everywhere—by assembling case histories, will need to pay a good salary to an observer who combines the gifts of scientist, engineer, psychologist, historian and writer.

Price and Bass[2] have already made good use of the case histories assembled by Suits and Bueche and by Frey and

Goldman[20], together with those published by Tanenbaum[21], to analyse the frequency of different patterns of interaction between scientists and technologists.

The Individual Investigator

Suits[24], in his book on the art of research management, accords primacy to the role or the interactions of individual investigators. Several detailed biographical studies of American industrial scientists and innovators are listed in the bibliography to W. D. Lewis's brief chapter on industrial research and development in a recent historical textbook[25]. Some of these studies undoubtedly emphasize the political aspects of innovation, and in particular the role of the determination and advocacy of one man pushing an idea to fruition against opposition. Such studies may refer to events in the distant past and yet carry lessons for the present day: one example is Manuel's essay on Isaac Newton as autocrat of science[26].

The collection of case histories seems to be gathering further momentum in the United States. One interesting experiment is the Suny/Albany seminar on technological change, organized by Professor J. W. Corbett at the Suny/Albany Center for Science and the Future of Human Affairs, at the State University of New York at Albany. This seminar brings about contact between a group of students, on the campus, and active applied scientists, entrepreneurs and research administrators. Much of the teaching is through the medium of case histories, of which Corbett has accumulated a substantial collection. He hopes to publish these and also to film the seminar itself.

Again in America, a further collection of case histories has recently been prepared for the National Science Foundation[27]. These case histories break new ground in that they take into account the discoveries in pure science which, during many years, created a body of fundamental knowledge from which the innovation could spring. The histories (they are acronymically called TRACES) are set out in the form of genealogical diagrams; a distinction is made between non-mission research, mission-orientated research and development and application, and the chronology of the individual "events" in these three categories is plotted backwards from the date of first commercial production, taken as time zero. For full measure, the various events are classified into American and foreign. The chief criticism one can level at this approach is the failure to distinguish major discoveries from more trivial ones; in fact, the authors fight shy of value judgments.

Allen's[19] study of the discovery of terylene and polythene incorporates an attempt to trace the web of antecedents, similar to the TRACES study. Indeed, Allen goes further in one valuable respect: he traces the role of the moves and personal contacts and influences of the scientists principally involved.

Current Developments

A. B. Robertson and his colleagues at the Science Policy Research Unit at the University of Sussex are engaged in a systematic attempt to collect case histories of technological innovation in several British firms; a special feature of this project is that failures are receiving as much attention as successes, in the conviction that only by this means can useful conclusions be drawn for the future. The inclusion of failures in future collections of case histories is particularly to be encouraged, for the sake of the lessons to be derived from them. McLaughlin's[28] study of the demise of the steam-driven motor car is a rare example, even though it may eventually prove not to have been a failure after all.

Clearly case histories of technological innovation can fruitfully be presented and analysed in several quite different ways; primacy can be accorded to economic arguments, to questions of laboratory management, to personal characteristics and interaction, or to long term sequences of scientific and engineering events. It is necessary now for more studies to build on the few precedents that are available, and this can only be achieved with the willing cooperation—indeed, the initiative where possible—of industrial firms. It is asking much of a firm to spell out in detail its own technological workings, even well after the event, and it is asking even more for it to analyse its own failures. Nevertheless, the whole of science-based industry can only benefit from the results of such studies.

A sceptic may well object that the anatomy of an innovation, however conscientiously dissected, will offer little insight into the structure of another innovation, the bones and nerves of which are differently arranged. There is force in this objection, but the force diminishes when case histories are regarded as effectively primary source material, from which science humanists of the future will create an illuminating synthesis.

I thank P. M. Knowlson, A. B. Robertson, Professor C. Freeman, Mrs J. K. Fuller and Professor J. W. Corbett for advice, information and comments.

Formation of the Initiation Complex using Muscle Messenger RNAs

by
STUART M. HEYWOOD
Genetics and Cell Biology Section,
Biological Science Group,
University of Connecticut,
Storrs, Connecticut

In eukaryotes, as in prokaryotes, the smaller of the two ribosomal subunits binds mRNA during the initiation of protein synthesis. The formation of the complete initiation complex, sedimenting at 75S, requires GTP, tRNA and initiation factors.

STUDIES on the initiation of protein synthesis have provided evidence that ribosomal subunits are essential for the initiation of protein synthesis in bacteria. The subunit model proposed by Nomura and his group[1-3] has been confirmed in other laboratories[4-6]. According to this model the 30S ribosomal subunit, in conjunction with initiation factors, interacts with mRNA; this complex in turn binds initiator fMet-tRNA and associates with the 50S ribosomal subunit to form the completed initiation complex. The importance of the initiation factors in the formation of this complex is well documented[7-9]. Ribosomes lacking initiation factors are incapable of translating natural mRNA, and in the absence of these proteins, neither mRNA nor initiator fMet-tRNA is bound to the ribosome[10-12]. Although direct evidence is not available, studies involving the polysome–ribosomal–subunit cycle in eukaryotes suggest that the subunit model for initiation of protein synthesis may also apply to higher organisms[13-15]. Knowledge of the role of initiation factors in eukaryotes is fragmentary and so far only suggests that factors removed from ribosomes by washing with a high concentration of salt are necessary for the *de novo* synthesis of proteins[16-18].

We have recently reported that the "factors" removed from embryonic chick muscle ribosomes by washing with 1·0 M KCl were essential for the *de novo* synthesis of the 200,000 molecular weight subunit of myosin[18]. These "factors" could not be replaced by the 0·1 M KCl wash from reticulocyte ribosomes when 26S myosin mRNA was used to direct the synthesis of myosin on reticulocyte ribosomes. These "factors" were judged to be initiation factors because of their ability to bind mRNA to ribosomes attached to nitrocellulose filters[18]. The initiation factors, in combination with ribosomes washed with 1·0 M KCl, demonstrated a specificity for binding mRNA, that is, only initiation factors from muscle ribosomes were found to bind muscle mRNA. Here are presented observations which suggest (*a*) that native 40S subunits (not 75S ribosomes) are involved with initiation of protein synthesis by binding mRNA, (*b*) that both GTP and tRNA are essential for the association of the 40S and 60S ribosomal subunits into the completed initiation complex, and (*c*) that binding of mRNA to the 40S subunit requires specific initiation factors.

Unwashed ribosomes, 1·0 M KCl washed ribosomes and initiation factors (1·0 M KCl wash of the ribosomes) were

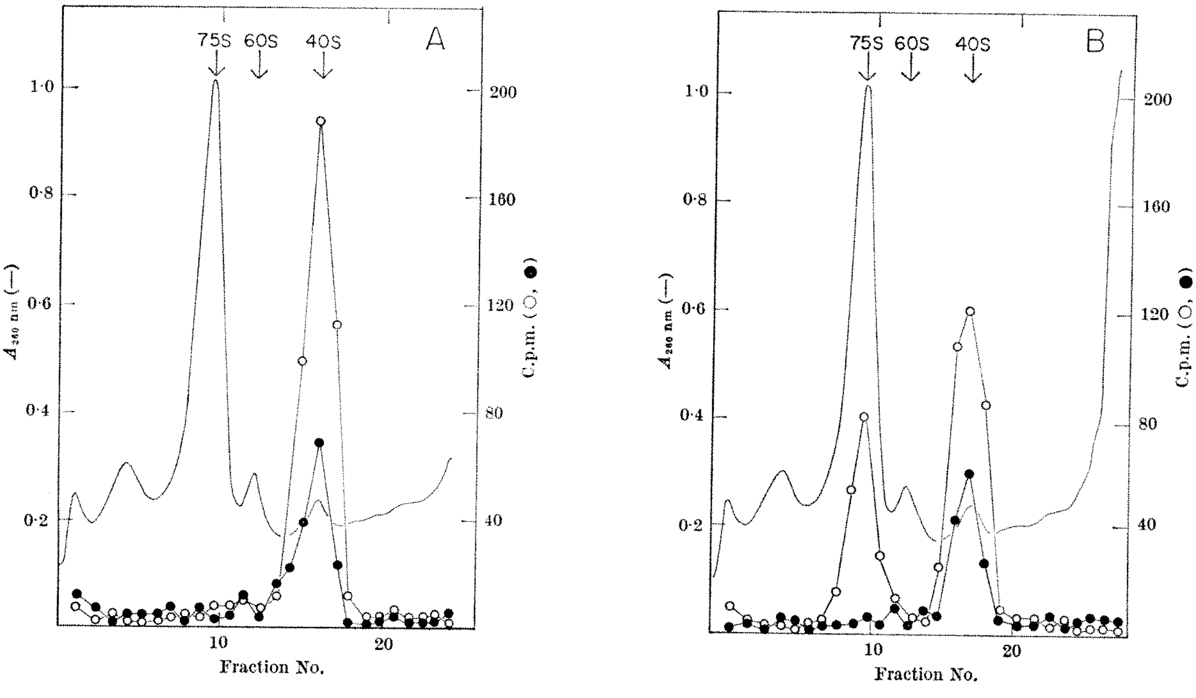

Fig. 1. Requirements for the binding of myosin 26S mRNA to unwashed muscle ribosomes. ^{32}P-mRNA (700 c.p.m.) was incubated in the conditions described in the text. *A*, GTP and tRNA were omitted (●); tRNA was omitted (○); *B*, GTP was omitted (●); complete system with 0·4 mg unwashed ribosomes, 0·25 µmole GTP, 100 µg tRNA (○).

prepared as previously described[19]. NaF treatment of the ribosomes was omitted, for it seemed to decrease the amount of native ribosomal subunits recovered. The ribosomes were stored at $-20°$ C for up to a week without loss of activity; the initiation factors were, however, less stable and were therefore prepared freshly before each experiment. Before being used, the initiation factors were dialysed against 0·15 M KCl–0·005 M $MgCl_2$–0·02 M Tris-HCl (*p*H 7·6)–0·006 M mercaptoethanol. Messenger RNA was prepared from various size classes of muscle polysomes as reported previously[19]. Fourteen day embryonic chicks were injected with 1 mCi $^{32}PO_4$ and incubated for 90 min in order to label mRNA. In this period maximum radioactivity is incorporated into 26S myosin mRNA, a minimum amount being incorporated into ribosomal RNA[19]. Unstripped tRNA was prepared from adult chicken muscle by the method of Von Ehrenstein[20]. ^{32}P-mRNA was bound to ribosomes in 0·5 ml. of 0·02 M Tris-HCl (*p*H 7·6)–0·005 M $MgCl_2$–0·15 M KCl–0·006 M mercaptoethanol containing 0·4 mg ribosomes. 0·25 µmoles GTP and 100 µg initiation factors were added individually or in combination as indicated in the legends. The reaction mixture was incubated for 10 min at 25° C, rapidly cooled, and layered on a 27 ml., 10–30 per cent sucrose gradient containing 0·02 M Tris-HCl (*p*H 7·6), 0·15 M KCl, 0·005 M $MgCl_2$, and 0·006 M mercaptoethanol. The mixture was centrifuged for 5 h at 25,000 r.p.m. in an IEC 'SB110' rotor. Twenty-eight drop fractions were collected and the absorbance was continuously recorded by a Gilford spectrophotometer. The samples were filtered through nitrocellulose membrane filters ('Millipore, HA', 0·45 µm). The filters were then washed with 3 ml. buffer and dried, and radioactivity was determined by liquid scintillation counting.

The conditions used for testing the binding of myosin mRNA to ribosomes were identical to those in which it was demonstrated that the 26S RNA associated with myosin synthesizing polysomes could direct the synthesis of myosin when added to a cell-free amino-acid incorporating system[18,19]. As shown in Fig. 1, these conditions allow for the attachment of myosin mRNA to the ribosomes. The mRNA sediments with the 40S ribosomal subunit and the binding is stimulated or stabilized by the addition of GTP to the reaction mixture (Fig. 1*A*). Addition of tRNA did not result in an increased binding of mRNA to the 40S subunit (Fig. 1*B*), and neither GTP nor tRNA when added singly resulted in the formation of the initiation complex as judged by the absence of ^{32}P-mRNA sedimenting with the 75S ribosomes. But when both GTP and tRNA were present in the reaction mixture a significant amount of ^{32}P-mRNA sedimented with the 75S ribosomes. The results suggest that initiation of protein synthesis in eukaryotes involves the binding of mRNA to the 40S ribosomal subunit followed by a GTP and tRNA dependent association of the 40S and 60S subunits to form the initiation complex. If, in addition, an 'S150' muscle supernatant fraction and an energy source are added to the reaction mixture, radioactivity is also observed in the polysome region of the sucrose gradient (unpublished results).

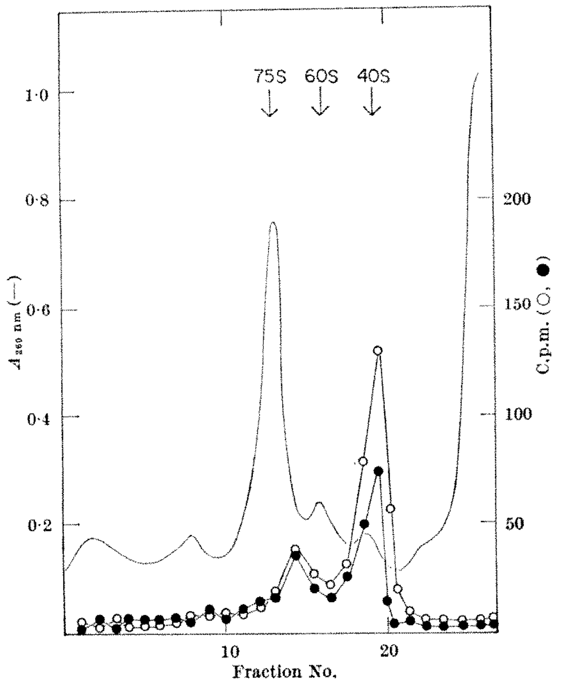

Fig. 2. Ribosomal RNA (28S) binding to unwashed muscle ribosomes. ^{32}P-ribosomal RNA (1,200 c.p.m.) was incubated as described in the text and Fig. 1. Complete system (○); GTP and tRNA omitted (●).

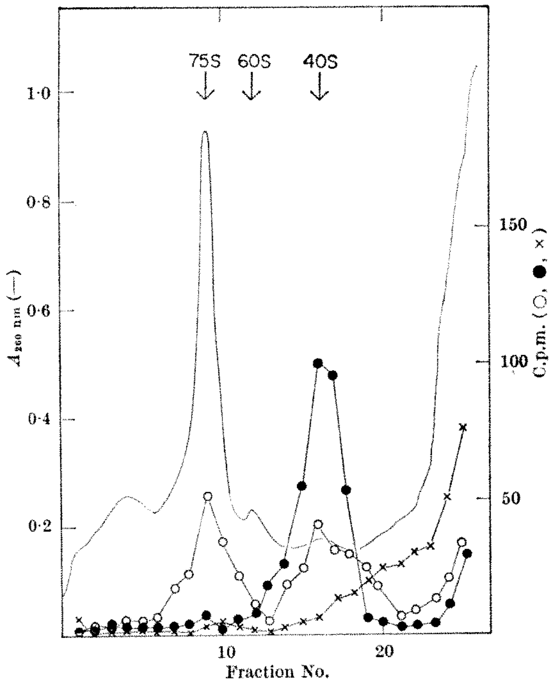

Fig. 3. Initiation factor dependent binding of 10–15S muscle ^{32}P-mRNA to 1 M KCl washed muscle ribosomes. RNA was prepared from small muscle polysomes[19]. ^{32}P-mRNA (500 c.p.m.) was incubated in the conditions described in the text. Complete system with 0·4 mg of 1 M KCl washed ribosomes, GTP, tRNA and 100 µg of initiation factors (○); initiation factors omitted (×); tRNA omitted (●).

Although a minimum of radioactivity is incorporated into the 28S ribosomal RNA of the myosin synthesizing polysomes during the labelling period, it is necessary to ascertain that the binding observed is characteristic of mRNA and not a result of 28S ribosomal RNA contamination. 28S ribosomal RNA was therefore obtained from smaller polysomes and tested for its ability to bind ribosomes and ribosomal subunits. 28S ribosomal RNA sediments with the 40S ribosomal subunit (Fig. 2), and a smaller, faster sedimenting peak, 65S, is routinely observed. The addition of GTP and tRNA results in an increase of radioactivity sedimenting with the 40S ribosomal subunit (GTP alone is sufficient to cause this increase), but no radioactivity is found to sediment with the 75S ribosomes. 18S ribosomal RNA was found to behave in a similar manner except that the 65S peak of radioactivity was absent. The reasons why ribosomal RNA should bind to the 40S subunit and why this is enhanced in the presence of GTP are not clear. Unlike mRNA, ribosomal RNA binds the 40S ribosomal subunit even in the absence of initiation factors. It is clear, however, that ribosomal RNA does not form the initiation complex (sediment with the 75S ribosomes in the presence of GTP and tRNA) as does myosin mRNA. 10–15S

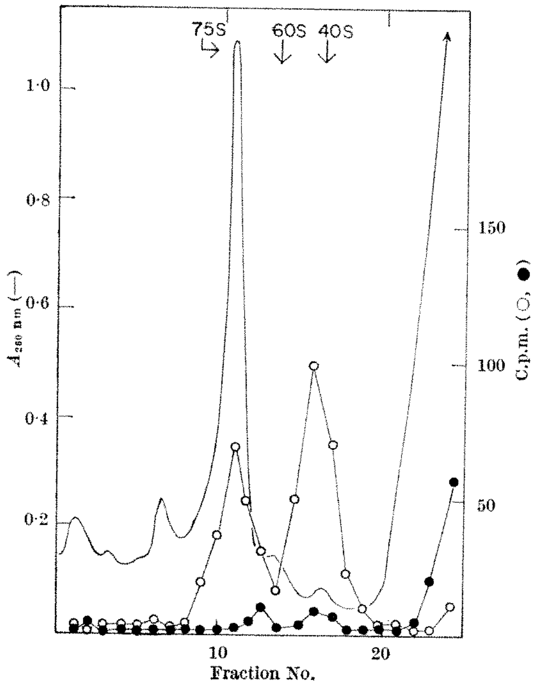

Fig. 4. Muscle initiation factor dependent binding of 26S myosin mRNA to reticulocyte ribosomes washed with 1 M KCl[18]. ^{32}P-mRNA (700 c.p.m.) was incubated in the complete system as described in the text and Fig. 3. 100 μg of reticulocyte initiation factors (●), 100 μg of muscle initiation factors (○).

RNA from the smaller muscle polysomes[19], containing actin and tropomyosin mRNA (unpublished results), binds ribosomes in a similar manner as 26S myosin mRNA. The GTP, tRNA dependent binding reaction may therefore be used as a test for mRNA.

If ribosomes washed with 1·0 M KCl are used in the binding experiments, no ^{32}P-mRNA is found to sediment with the ribosomal subunits (Fig. 3). If the initiation factors—removed by the 1·0 M KCl—are added back to the ribosomes, the mRNA again binds the 40S ribosomal subunit. Addition of tRNA, in the presence of GTP, results in the formation of the initiation complex sedimenting at 75S. The initiation factors are therefore essential for binding mRNA to the 40S ribosomal subunit and the subsequent formation of the initiation complex.

It has been reported that initiation factors, responsible for binding 26S myosin mRNA to ribosomes, are necessary for the *de novo* synthesis of myosin[18]. When myosin mRNA was translated on reticulocyte ribosomes, it was essential to add the initiation factors washed from muscle ribosomes to the washed reticulocyte ribosomes. Myosin mRNA does not bind reticulocyte ribosomes unless the initiation factors from muscle ribosomes are present (Fig. 4). These results extend our previous observations[18] which suggested that the messenger binding factors recognize only those mRNAs derived from the same cell type as the binding factors.

We suggest that the mechanism for the initiation of protein synthesis involving ribosomal subunits is similar in both prokaryotes and eukaryotes. Further, the requirement of GTP, tRNA and initiation factors for the formation of the initiation complex is the same for both prokaryotes and eukaryotes. The identity of the initiator tRNA(s) involved in the initiation of protein synthesis in higher organisms and the precise role of the initiation factors in the formation of the complex are still not clear.

I thank Mrs Janice Jasnos for assistance. This work was supported by a grant from the US National Institute of Child Health and Human Development.

Antigenic Properties of a Homogeneous Tobacco Mosaic Virus–Hapten Conjugate

by

L. I. SLOBIN
Division of Biological Sciences,
Cornell University,
Ithaca, NY 14850

Anti-hapten antibodies may only be induced if the hapten modifies the conformation of the protein carrier.

Although much is known about the structural factors necessary to produce an effective haptenic determinant[1,2], there has been little inquiry into the reason(s) why antibodies can be successfully produced against haptens in the first place. It has generally been assumed that the introduction into an animal of a "foreign" chemical grouping is sufficient to elicit an immune response. Thus the problem has been treated as part of the larger question of why "foreign" macromolecules are immunogenic. By definition, however, haptens are not immunogenic by themselves. They are completely dependent on the structure of the carrier protein in order to produce their effect.

It is our thesis that the immunogenic character of haptens, when attached to protein carriers, is controlled by the degree to which they alter the native conformation of the carrier molecule. As a corollary, the introduction of haptens which have little or no effect on the secondary or tertiary structure of a protein carrier is likely to produce little or no specific immune response.

To understand the experimental basis for this proposal it is necessary to consider the part that protein conformation plays in determining antigenic specificity. The dependence of antibody reactivity on the structure of antigens has been the subject of several recent reviews[3-5]. It seems now generally to be accepted that the conformational integrity of native proteins is essential for the maintenance of their immunological specificity. Three types of experiments lend strong support to this view. (1) It has long been known that antisera to native and denatured proteins exhibit marked differences in immunological reactivity[1]. Two recent examples that clearly illustrate this finding are afforded by work on the antigenic properties of chemically modified ribonuclease and myoglobin[6-8]. (2) It has not in general been possible to inhibit quantitatively a homologous antigen–antibody reaction by using small peptide fragments (of the size of a hypothetical antibody-binding site), derived from antigen by proteolytic digestion[9-11]. These findings include studies on antibodies specific for tobacco mosaic virus (TMV), where Anderer and co-workers[10,12] found that isolated amino-acid sequences from TMV protein only partially inhibited the homologous precipitin reaction. The lack of additivity of the inhibition values given by individual peptides further suggests that specific anti-TMV antibodies are not directed against isolated amino-acid sequences. (3) Using synthetic polypeptides it has been possible to show that the specificity of antibodies produced against L-Tyr–L-Ala–L-Glu is controlled by the conformation of this tripeptide determinant[13]. Studies with antibodies to bradykinin have demonstrated that alterations in residues which had an obligatory effect on conformation, such as changes in glycine or proline, had a profound effect on the binding of homologous antibody[14]. In addition, the results with bradykinin suggest that the conformation of the entire bradykinin peptide was antigenically important.

Consequences of Hapten Attachment

By contrast with antibodies against proteins and polypeptides, antibodies with antihapten specificity are usually elicited by chemical modification of pre-existing native structures. The attachment of the hapten to a macromolecule usually entails significant modification of the charge balance of the protein (for example, by substitution at lysine residues) or alteration of other residues (such as tyrosine or histidine) that are likely to play a critical part in protein conformation. Although little direct information is available on this subject, it seems reasonable to assume that haptenation generally results in conformational change in carrier protein, at least in the region of hapten attachment.

An apparent consequence of the structural changes induced by reaction with hapten is that anti-hapten specificity shows little, if any, dependence on protein conformation. Although it has been established that amino-acid residues adjoining a haptenic group can have a detectable influence on binding reactions[15], this is essentially a second order effect, corresponding to only a small percentage of the total binding energy. In most cases, the conjugate of the hapten with an appropriate side chain can adequately account for the total ΔG of a specific anti-hapten antibody reaction.

Several other observations also lead us to assign minor importance to the role of the conformation of carrier structure in the control of an anti-hapten antibody response. It is possible to obtain an anamnestic anti-hapten response by challenging sensitized animals with hapten–heterologous protein conjugates[16]. Similar carrier-independent effects can be obtained in delayed hypersensitivity reactions[17,18].

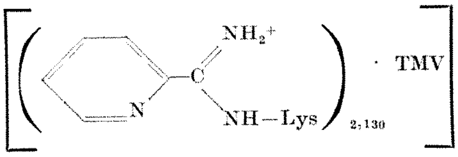
By contrast with protein antigenic determinants, the immunological recognition of haptens seems to involve conformation-independent loci on the surface of the carrier protein. I suggest that addition of a hapten at a single amino-acid residue within a potentially antigenic locus, which did little to alter the overall conformation of that site, would have little immunological consequence. Only by significantly changing the conformation of a protein segment—for example, in going from α helix to a random coil at an antigenic site—or by shifting the contact residues in the tertiary folding of the polypeptide chain, is a new immunological specificity likely to arise. Thus it is not the "foreignness" of a hapten *per se* but rather its effect on protein conformation which determines its ultimate fate as an antigenic determinant. If this proposal has any validity it should be possible to prepare hapten–protein conjugates in which a potentially powerful haptenic determinant is either totally masked or only weakly immunogenic as a result of negligible effect on protein conformation. Support for this idea comes from an examination of the antigenic properties of a homogeneous TMV–hapten conjugate.

The Picolinimidyl–TMV System

It has been shown recently[19,20] that lysine-68 (each TMV subunit contains one additional lysine residue at position 53) reacts preferentially with a variety of nucleophilic reagents, including organic acid anhydrides and imido esters. In particular, methyl picolinimidate has been shown to react exclusively with all 2,130 subunits of the TMV protein coat to form a mono-substituted derivative of each subunit, without apparently disturbing the structural integrity of the virus. Such a derivative presumably places 2,130 potential haptenic groups on or near the surface of the virion, each modified lysine being equivalently related to its neighbouring amino-acid residues by the fixed tertiary structure of the subunits in the virus superhelix[21]. The native virus structure does not seem to be disrupted by this modification as judged by electron microscopy and ultracentrifugation[20].

It is known that amino-acid substitutions adjacent to lysine-68 (at residues 65 and 66) alter the immunological specificity of the intact virus[22], indicating that alterations in this region of the protein subunit can have detectable immunological consequences.

Intact TMV (10 mg/ml.) was treated with methyl picolinimidate[23] (0·1 M) in 0·1 M N-ethylmorpholine–acetic acid buffer (*p*H 8·2) at 22° for 12–14 h[20]. The modified virus



was isolated by several alternate low (10,000*g* for 10 min) and high (50,000*g* for 1 h) speed centrifugations. The final pellet was suspended in distilled water to give a 1 per cent solution and stored at 4° C.

The extent of reaction was determined by the trinitrobenzenesulphonic acid (TNBS) assay for free amino groups[24] using the purified virus coat protein (TMVP)[25]. An equally reliable method for measuring the number of modified lysines, which also gave useful information on the specificity of the amidination reaction, was to subject the protein coat of the modified virus to amino-acid analysis. It was found that in the standard conditions of acid hydrolysis (6 M HCl at 110° C) the half-life for the conversion of an ε-(N-picolinimidyl)lysyl residue to free lysine was greater than 48 h. Extrapolation of lysine values found after various hydrolysis times (24 and 72 h) to zero time therefore permitted a reliable estimate of unreacted lysine in TMVP. Both TNBS determinations and amino-acid analyses gave values of 0·9 ± 0·1 for the number of substituted lysine residues per 17,500 daltons of coat protein. Amino-acid analysis revealed no other alteration in the composition of the protein.

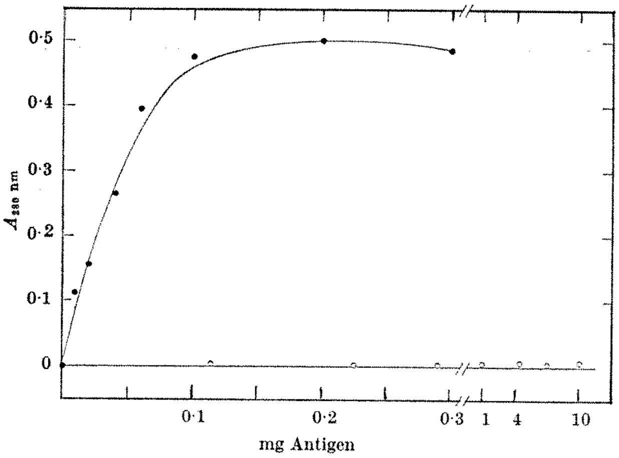


Fig. 1. Precipitin curves of anti-(P-BSA) reacted with P-γG (●—●) and P-TMV or P-TMVP (○—○). Ascitic fluid (0·4 ml.) containing specific antibodies was incubated with varying amounts of test antigen (total volume 0·9 ml.) for 1 h at 37° C followed by overnight incubation (16 h) at 4° C. The precipitates were recovered by low speed centrifugation (2,500*g* for 30 min), washed three times with 1 ml. portions of phosphate-saline buffer, and dissolved in 1 ml. of 0·1 M NaOH. The absorbance was read at 280 nm using a Gilford model 240 spectrophotometer.

Picolinimidated derivatives of bovine serum albumin (P-BSA) and equine γ-globulins (P-γG), containing 11 (out of 57) and 62 (out of 78) moles of substituted lysines per mole of protein, respectively, were prepared essentially as described for P-TMV, except that the reaction time with methyl picolinimidate was reduced to 2 h. After dialysis against phosphate–saline buffer (0·15 M NaCl, 0·01 M sodium phosphate, *p*H 7·4); the protein derivatives were stored as frozen solutions. ε-(N-Picolinimidyl)aminocaproic acid hydrochloride (P-ACA) was prepared by reacting ε-aminocaproic acid with a two-fold molar excess of methyl picolinimidate in conditions identical to those described for TMV. The reaction mixture was acidified with concentrated HCl (to *p*H 1) and taken to dryness on a rotary evaporator. The product was crystallized from ethanol–ether (m.p. 171–173) and was characterized by an absorption maximum at 262 nm ($\varepsilon_M = 5{\cdot}3 \times 10^3\ \mathrm{M}^{-1}\ \mathrm{cm}^{-1}$) (ref. 26).

Two six year old 500 kg geldings underwent a series of intramuscular injections of P-TMV in distilled water (the immunization and bleeding protocol will be published elsewhere), each animal receiving a total of 450 mg of virus derivative in distilled water over the course of 8 months. During this time, although large amounts (titres greater than 1 mg/ml.) of anti-TMV antibodies were produced in both animals, I was unable to detect any antibodies with specificity toward the picolinimidyl group by the following criteria. (1) None of the test sera precipitated either P-BSA or P-γG. (2) An immunoadsorbent was prepared by coupling P-ACA to carboxymethylcellulose using N-3-dimethylaminopropyl-N′-ethylcarbodiimide as the coupling agent. Antisera from various bleedings were passed over columns of immunoadsorbent, and after washing with phosphate–saline buffer, the column was developed with the same buffer containing 3 M KSCM (ref. 27). By this technique no picolinimidyl-specific antibody could be detected (< 20 μg antibody/ml. antiserum). (3) An attempt was made to elute anti-picolinimidyl antibodies by the techniques of hapten elution[28]. Incubation of a washed precipitate of P-TMV, and equine anti-(P-TMV) antibodies (containing more than 1 mg anti-TMV γ-globulin) with 0·1 M P-ACA in phosphate–saline buffer at 37° C for 1 h, failed to elute any globulin (< 20 μg antibody protein in 1 ml. of hapten–buffer solution).

Several trivial explanations of the failure to elicit anti-picolinimidyl antibodies are possible. The two animals may fortuitously have been genetic non-responders[29]. Alternatively, for some unknown reason, the picolinimidyl group might be ineffective as a haptenic determinant. (I know of no attempt to prepare antibodies to picolinimidated proteins.) To resolve these questions, groups of mice (WRAIR albino mice, 2–4 months old) were immunized with P-TMV or P-BSA. The animals received a total of three intraperitoneal injections of antigen, spaced one week apart (1 mg per injection), in complete Freund's adjuvant. Five days after the last injection the mice were inoculated with Ehrlich ascites tumour cells[30]; the tumours were tapped and ascitic fluid was removed 10 days later.

As was the case with equine antisera, it was found that mice immunized with P-TMV, although they produced a vigorous antibody response to the virus, did not make any antibodies with anti-picolinimidyl specificity. As may be seen in Fig. 1, however, the mice responded to treatment with P-BSA by producing substantial quantities (titres approached 1 mg/ml.) of anti-hapten antibody. Somewhat surprisingly, anti-picolinimidyl antibodies failed to precipitate either P-TMV or P-TMVP. To test whether antibody was capable of combining with the picolinimidyl determinant on TMV, increasing amounts of either P-TMV (or P-TMVP) were incubated with a fixed amount of antibody and P-γG. The precipitates that formed were treated as described in the legend to Fig. 1, and the results (Table 1) are based on the percentage of the control (minus TMV derivative) $A_{280\,\mathrm{nm}}$ found in the presence of P-TMV.

Table 1. INHIBITION OF PRECIPITATION OF ANTI-PICOLINIMIDYL ANTIBODIES BY P-TMV AND P-TMVP*

Exp.	Inhibitor	Inhibitor (mg)	(Inhibitor)/ P-γG†	Per cent inhibition
1	P-TMV	1·2	2·8	29
2	P-TMV	6·0	14	54
3	P-TMV protein	1	2·8	33
4	TMV	3·5	—	0

* Each tube contained 0·4 ml. of ascitic fluid and the appropriate amount of inhibitor in a total volume of 0·9 ml. Because of the tendency of P-TMV protein to precipitate when incubated at 37° C, the tubes were maintained at 4° C for 44 h before analysis. Per cent inhibition values represent the average of duplicate determinations.

† The ratio of the concentration of picolinimidyl groups present on inhibitor to that on P-γG, the precipitating antigen.

Clearly P-TMV derivatives behave as simple univalent haptens, capable of inhibiting a homologous precipitin reaction, but unable to cause precipitation directly. As a further check on the specificity of the inhibition it was found that TMV by itself produces no effect. Thus it seems as if the picolinimidyl group is exposed on the surface of the virus, allowing it to interact with an antibody combining site.

In the course of this investigation, it was discovered that Malkiel[31], working with a chemically uncharacterized virus–azoarsanilic acid conjugate, was also unable to detect specific haptenic antibody when rabbits were immunized with modified TMV. The modified virus did, however, react (precipitate) with an antiserum to a heterologous azoarsanilic acid derivative. Furthermore, no appreciable difference was seen in the serological reaction between native tobacco mosaic virus and various chemically altered virus derivatives when tested with antiserum to the native virus.

Modification with Retention of Conformation

The failure to elicit anti-hapten antibody by chemical modification of TMV can readily be interpreted by the idea that such modifications produced no significant alteration of either the tertiary structure of the protein subunits or the quaternary structure of the intact virion. The amidination reaction, which is specific for lysine residues, does not alter the net charge of a protein at neutral *p*H. Extensively amidinated proteins have been found to maintain their biological function with only slight alteration of their physical properties[32,33].

An alternative explanation for the failure to produce anti-picolinimidyl antibodies with a P-TMV conjugate is that because of the homogeneity of hapten attachment only an insignificant number of specific antigen sensitive cells are capable of responding to the picolinimidyl determinant. The chemical homogeneity of a hapten conjugate, however, has not so far been found necessarily to eliminate immunological responsiveness, as witnessed by the success in eliciting hapten-specific antibodies by immunizing with α-DNP-oligolysines[34]. Alternatively, the *in vivo* concentration of haptenic determinant may have been too small to elicit a response. This argument would appear to be vitiated by the positive results obtained with P-BSA, which contained only about twice as many picolinimidyl groups as P-TMV on a weight basis.

Although the details of the mechanism(s) for the recognition of antigenic determinants are still unknown, it is possible that haptenic systems are "recognized" only after being metabolized by macrophages[35], because of an increased susceptibility of the "denatured" protein conjugate to proteolytic digestion[36]. This model would then contrast with native protein systems where the conformational requirements for the maintenance of antigenic structure preclude extensive protein hydrolysis. Whatever differences may exist in the recognition mechanism, it should be possible to examine the validity of my hypothesis by observing what effects, if any, denaturation of "native" conjugates, such as P-TMV, has on the production of anti-hapten antibodies. Studies on the antigenicity of chemically altered immunogens produced by using organic modifications that have only slight effect on protein conformation, such as amidination, should also provide further tests.

This work was supported by a grant from the US Public Health Service. I thank Professor F. Ross for providing infected tobacco leaves, Drs D. Stark and D. Erickson for help with the immunization and bleeding of horses, Dr J. M. Fessenden-Raden for providing WRAIR mice and Miss B. Greenberg for aiding in the immunization of mice. The assistance of Mr D. Hawley is also acknowledged.

Effects of Black Widow Spider Venom on the Frog Neuromuscular Junction

Black widow spider venom causes exhaustion of miniature end-plate activity and depletes the nerve terminal of vesicles.

Effects on End-plate Potential, Miniature End-plate Potential and Nerve Terminal Spike

BLACK widow spider venom (BWSV) renders the stretch receptor of the crayfish inexcitable[1] by depolarizing the cell body (unpublished results of S. Obara and A. M.). The venom seems to act on the nerve cells of the sixth abdominal ganglion of the cockroach in a similar manner[2]. Early studies with the sciatic nerve–sartorius muscle preparation of the frog and toad[3,4] indicated that BWSV had little effect on either the nerve, the muscle or the neuromuscular junction. But Cantore[5] has found evidence of neuromuscular blockade in the rat diaphragm. Moreover, one of us (A. M.) recently noted that occasional fibrillations could be seen in the muscle about 30 min after BWSV had been applied to a frog sciatic–sartorius preparation, and that neuromuscular transmission was completely blocked 2 h later. These observations led us to study the effects of BWSV on single neuromuscular

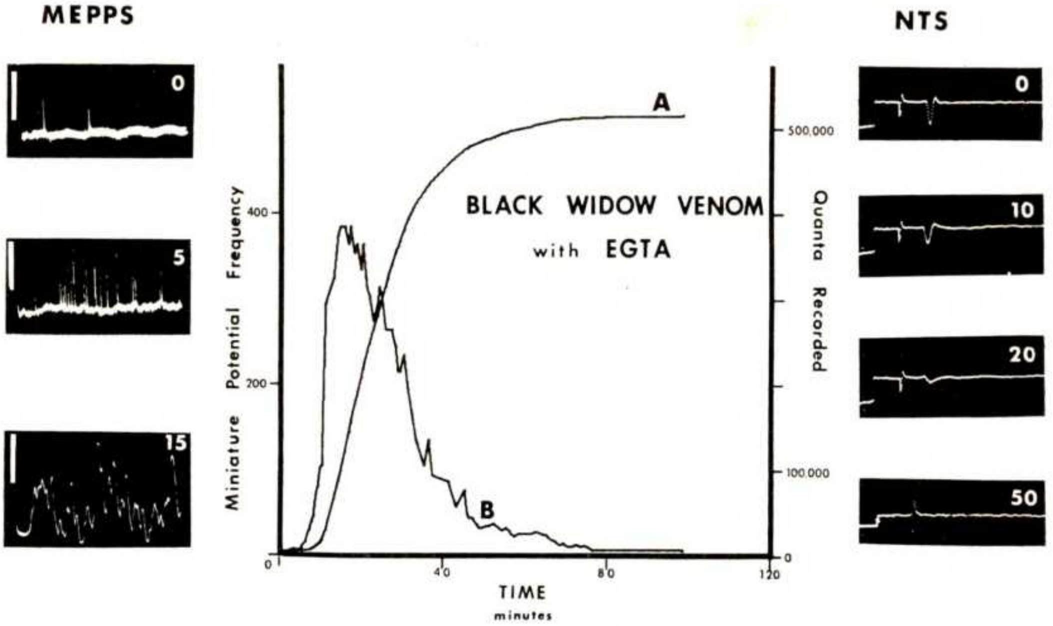

Fig. 1. Effect of BWSV on MEPP frequency and on the NTS in a calcium free solution with EGTA. Numbers in the upper right corner of the left and right columns of pictures are times in minutes after addition of 0·1 ml. of BWSV solution to the muscle chamber. Pictures on the left are intracellularly recorded MEPPs. The calibration bar represents 500 μV. Durations of sweeps from top to bottom are 1 s, 1 s, and 0·1 s. Curve *B* in the central figure is the MEPP frequency per second versus time after addition of BWSV, while curve *A* represents the total number of MEPPs or quanta recorded. Pictures at the right from a different experiment are computed average ($n=20$) nerve terminal spikes. The calibration pulse at the left of each record represents 100 μV and 1·7 ms.

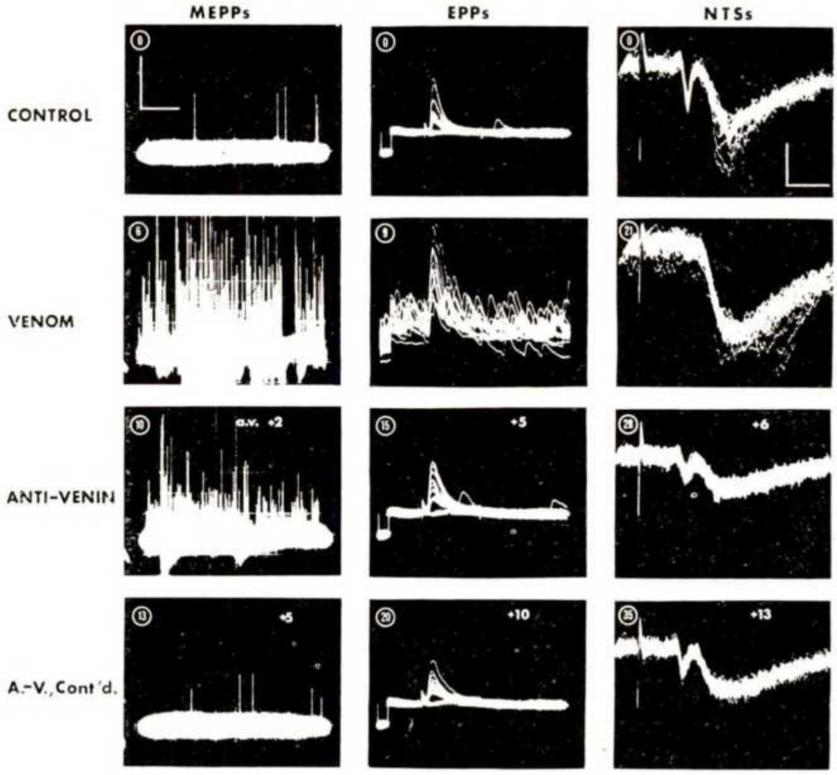

Fig. 2. Reversibility of effects of BWSV on MEPP frequency, EPP amplitude and NTS amplitude produced by addition of antivenin. Circled numbers in the upper left-hand corner of each picture are times in minutes after addition of BWSV. Numbers in the middle of each picture in the bottom two rows are times after addition of antivenin. Intracellularly recorded MEPPs in the left column and EPPs in the middle column are from the same experiment, while the externally recorded NTSs and EPPs (mainly nonspecific) are from a separate experiment. The left column shows single sweeps. Calibration is 500 μV and 2 s. Pictures in the right two columns are composed of 15 traces each. The calibration pulse for the EPPs is 1 mV and 5 ms. Calibration for the NTSs is 100 μV and 2 ms.

junctions of the frog sartorius, using methods of intracellular[6] and extracellular[7] recording.

A sartorius muscle, with its nerve intact, was dissected from *Rana pipiens* and mounted in a 'Lucite' chamber at 20°–25° C. Muscle twitch evoked by nerve stimulation was blocked by bathing the preparation in a solution containing 0·5 mM $CaCl_2$, 4 mM $MgCl_2$, 2·5 mM KCl, 110 mM NaCl, and 5 mM Tris-buffer (*p*H 7·4). Intracellular records of end-plate potentials (EPP) and miniature end-plate potentials (MEPP) were obtained by impaling the end-plate region of surface muscle fibres with glass micropipettes (4–15 MΩ) filled with 3 M KCl. Extracellular records of the nerve terminal spike (NTS), EPPs, and MEPPs were made with micropipettes (0·5–1·2 MΩ) filled with 4 M NaCl. A LINC-8 digital computer was used to determine the mean amplitude and quantum content of the intracellularly recorded EPP and the amplitude of the NTS. Amplitude and frequency of occurrence of MEPPs were monitored with the computer throughout each experiment. If MEPP frequency was low (< 100 s^{-1}), individual MEPPs could be readily discriminated, and the computer was used for continuous recording of the mean MEPP frequency (determined from averages over successive one second intervals). When the MEPP frequency was high (100–1,000 s^{-1}) samples of 0·1 s duration were taken and displayed by the LINC-8 once every 5 s. The responses occurring in each sample were counted manually to estimate the mean MEPP frequency over that 5 s interval. Venom was prepared by dissolving the lyophilized extracts (supplied by N. Toschi, A. Grasso and S. Bettini, Istituto Superiore di Sanità, Rome) of eight poison glands from four spiders (*Latrodetus mactans tridecimguttatus*) in 1·0 ml. of distilled water, and this solution was stored at 3° C. Dissolved venom remained active for at least three weeks. In most of our experiments, 0·1 ml. of this venom solution was added to 5·0 ml. of Ringer's solution in the muscle chamber.

After addition of BWSV, and a lag of several minutes, the MEPP frequency rose during the next 5–10 min from control values of 0·5 to 1·5 s^{-1} to peak values of 300–1,000 s^{-1} (Fig. 1). After reaching a peak, MEPP frequency declined to low levels (less than 1 s^{-1}) along a roughly exponential time course with a time constant of about 5 min. We estimated that about 4×10^5 MEPPs occurred after application of BWSV. (The mean of sixteen experiments was $4{\cdot}6 \times 10^5$ MEPP, *S.D.* $= 2{\cdot}8 \times 10^5$.) As the MEPP frequency increased, the amplitude of the EPP first increased several-fold and then decreased to zero concomitant with the attainment of the peak MEPP frequency. The NTS disappeared at roughly the same time, presumably because the nerve terminal was depolarized. MEPP amplitude remained constant throughout most experiments. Occasionally, MEPP amplitude declined by as much as 50 per cent after several hours. There was no significant change in membrane potential of the muscle fibre after application of BWSV. We infer from these observations that the venom displayed little postsynaptic action.

MEPP frequency may be increased by depolarizing the nerve terminal either with electric current or by increasing the external K^+ concentration. This increase in MEPP frequency requires Ca^{2+} in the external solution[8]. We observed that as the K^+ concentration of the external solution was increased from 2·5 to 20 mM the MEPP frequency rose from 1 s^{-1} to several hundred per second, if the solution contained 1·0 mM Ca^{2+} and no Mg^{2+}. This increase in MEPP frequency was absent in Ca^{2+}-free solution with 4 mM Mg^{2+}. In these experiments the osmotic pressure of the solution was held constant by substituting K^+ for Na^+. In marked contrast to the Ca^{2+}-dependence of the effect of external K^+ on MEPP frequency, the effects of BWSV were fully developed in Ca^{2+}-free solutions with 4·0 mM Mg^{2+}, with or without EGTA[9] (Fig. 1). It is therefore unlikely that the effect of the venom on MEPP frequency was caused entirely by depolarization of the nerve terminal. Black widow spider venom is not the only agent that causes a marked increase in MEPP frequency in Ca^{2+}-free solutions. Hypertonic solutions[10] or tetanic stimulation[11] of the nerve also cause a large increase in the MEPP frequency, in the absence of Ca^{2+}. We have confirmed these observations.

We obtained a discontinuous dose-response curve for the venom. When 0·02 ml. of venom solution was used, no effects on the neuromuscular junction were seen, even after an hour; if 0·03 ml. was used, the results were similar to those described above. Addition of more than 0·03 ml. of the venom reduced the lag time for venom action, but peak MEPP frequency and the number of quanta recorded were similar.

Once the action of the venom had been initiated, it could not be reversed by washing the preparation with venom-free Ringer's solution, but an antivenin preparation obtained from horse serum (Lyovac, donated by D. A. Press, Merck Sharp and Dohme) was very effective in reversing all the effects of the venom, provided that it was applied during the early stages of the venom action (Fig. 2). Antivenin alone or antivenin and BWSV had no effect on the preparation.

Our interpretation of these events is that the venom may react with the nerve terminal membrane, thereby inducing the release of transmitter. This release of transmitter occurs independently of the presence of Ca^{2+} and independently of the depolarization of the terminal. Release proceeds until the total pre-existent store of transmitter has been exhausted. If our counting procedures are adequate and if replenishment of the transmitter due to metabolic mechanisms is not significant, this store of transmitter amounts to about 4×10^5 quanta per nerve terminal. A similar figure has been given by Elmquist and Quastel[12] in their investigations of the rat diaphragm nerve terminal.

Effects on the Fine Structure of the Frog Neuromuscular Junction

FOR a long time, the synaptic vesicle has been correlated theoretically with the quantum of chemical transmitter[1–5], but experimental evidence for the equivalence, especially in the neuromuscular junction, has not been decisive[5–7,12]. The large number of vesicles and quanta in a single nerve terminal[5,10] complicates conventional methods[5,7] of demonstrating their simultaneous depletion. Black widow spider venom (BWSV) and hypertonic solutions of sucrose can eliminate this difficulty. Because neuromuscular junctions in the sartorius are difficult to find with the electron microscope, we chose instead to look for structural alterations of junctions treated with these substances in the cutaneous pectoris[8], a very thin muscle whose junctions can easily be found.

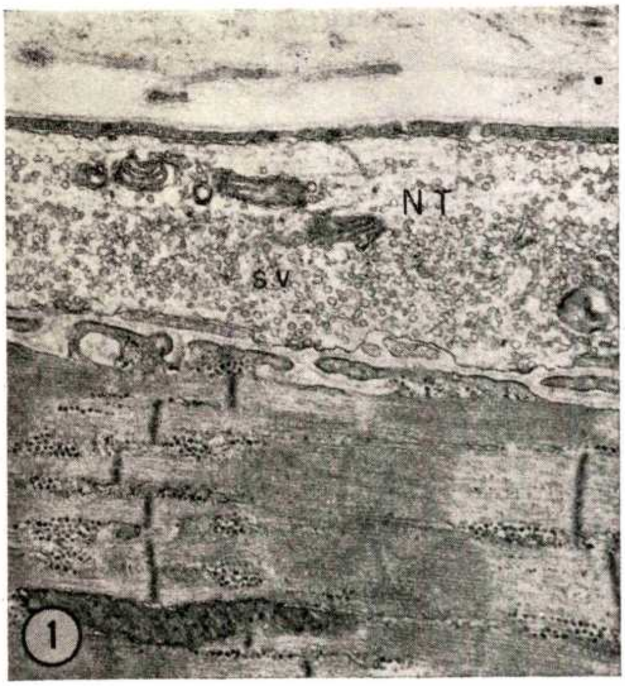

Fig. 1. Electron micrograph showing a portion of an end-plate from cutaneous pectoris muscle of the frog, a control preparation to which inactivated BWSV was added. The nerve terminal (NT) is characterized by a large number of synaptic vesicles (sv) massed along the presynaptic membrane. The nerve terminal also contains mitochondria, neurofilaments, neurotubules, and elements of what we assume to be smooth endoplasmic reticulum. ×18,500.

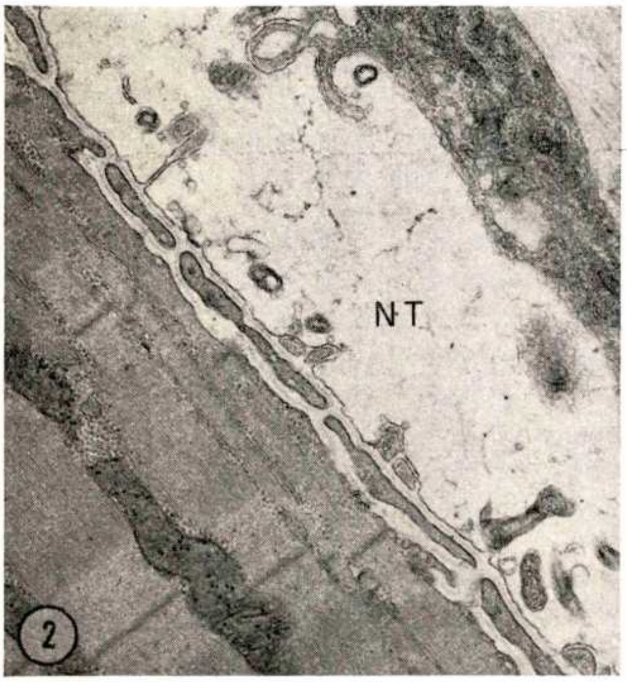

Fig. 2. Electron micrograph showing a portion of an end-plate from the cutaneous pectoris muscle of the frog. Active BWSV was added to this preparation, and it is apparent that very few synaptic vesicles remain in the nerve terminal (NT). ×18,500.

Both cutaneous pectoris muscles with intact nerves were dissected from *Rana pipiens*, and bathed in Ca^{2+}-free Ringer solution. Miniature end-plate potentials (MEPP) were monitored throughout each experiment. Normal MEPP frequency varied from 0·5 to 5 s^{-1}.

Almost immediately after 0·01 ml. of BWSV solution was added to the bath (approximately 2 ml.) directly over the impaling electrode or after beginning the replacement of the bath by hypertonic sucrose solution (360 mM) the MEPP increased greatly and then gradually declined to normal levels over a period of 30–40 min.

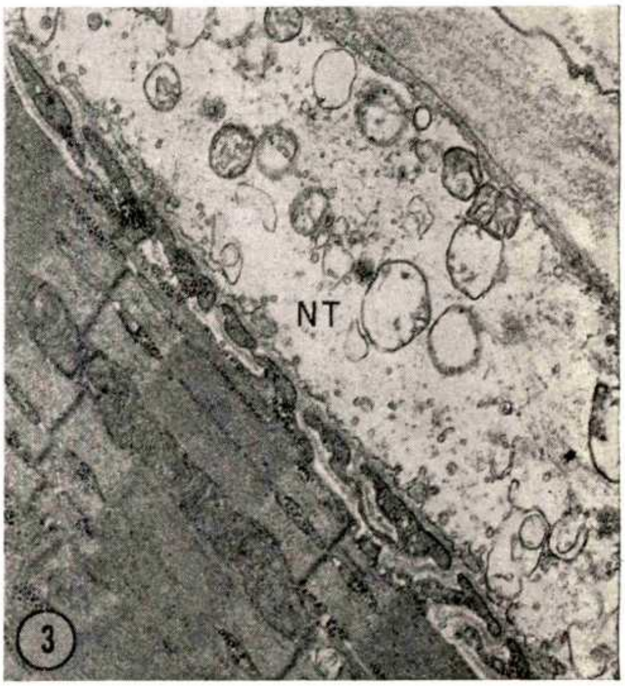

Fig. 3. Electron micrograph showing a portion of an end-plate from the cutaneous pectoris muscle of the frog. Hypertonic sucrose solution was added to this preparation. As in Fig. 2 it is apparent that very few synaptic vesicles remain in the nerve terminal (NT), although the preservation of the other organelles within the terminal is not as good. ×18,500.

One to four hours after the addition of BWSV or hypertonic sucrose, the preparation was rinsed with several changes of fresh Ca^{2+}-free Ringer solution. The bath was then replaced with a solution of 1 per cent formaldehyde, 1 per cent glutaraldehyde, 2 per cent sucrose, and 0·1 M phosphate buffer at *p*H 7·4 (ref. 10). Several changes of fixative were made until all schlieren patterns had disappeared. When the muscle stiffened, it was removed from the 'Lucite' chamber, trimmed and then placed in fresh fixative for a total fixation time of 1 h. The muscle was rinsed for 30 min with several changes of 0·1 M phosphate buffer and 3 per cent sucrose. The muscle was then postfixed for an hour in a solution of 1 per cent OsO$_4$, 2 per cent sucrose, and 0·1 M phosphate buffer. After embedding the muscle in Epon 812 according to standard procedures, it was sectioned with a diamond knife. The sections were picked up in naked copper grids, stained with uranyl acetate and lead citrate, and then viewed on a Hitachi 11B electron microscope.

There were three types of controls. In the first, muscles were pinned out in the same 'Lucite' chamber with the same bath of Ca^{2+}-free Ringer solution, an end-plate region was impaled with a micropipette, and the MEPP frequency was monitored for periods as long as 5 h. The second type of control, specifically for BWSV, was the same as the first except that 0·05 ml. of BWSV solution, inactivated by storage for four weeks at 3° C, was added at the beginning of the experiment. In the first and second type of control, MEPP frequency remained at normal levels throughout the experiment. The third type of control, one of the two muscles from a single animal was soaked in Ca^{2+}-free Ringer solution while the other muscle was being experimented upon.

Control end-plates (Fig. 1) appeared to be comparable with those described by other investigators[5,6,10–12]. In each nerve terminal, there were large numbers of synaptic vesicles that were usually massed along the presynaptic membrane. The terminals were also characterized by mitochondria, neurofilaments, neurotubules and by elements of what seemed to be smooth endoplasmic reticulum.

Experimental end-plates (Figs. 2 and 3) appeared exactly as they did in the controls, with the exception of the nerve terminals. Muscle fibres, Schwann cells, and nearby capillary endothelial cells had a normal appearance. By contrast, the nerve terminals looked relatively "clean" because they contained almost no synaptic vesicles. The other organelles were still present although they seemed to be better preserved in the terminals treated with BWSV. We have not yet answered the question of where the vesicles go when they disappear.

These results correlate closely with those obtained by means of electrophysiology. Although there are alternative interpretations, we believe the most persuasive one supports the idea that the synaptic vesicle and the quantum of chemical transmitter are equivalent.

Fast Spectrophotometric Measurement of H^+ Changes in *Chromatium* Chromatophores activated by a Liquid Dye Laser

by
B. CHANCE
J. A. McCRAY
J. BUNKENBURG

Johnson Research Foundation,
School of Medicine,
University of Pennsylvania,
Philadelphia,
Pennsylvania

The fast changes in hydrogen ion concentration which follow photoactivation of the bacteriochlorophyll complex of *Chromatium* have been measured by observing absorbance changes of the *p*H indicator bromcresol purple using a ruby-pumped dye laser. This acts as an optical frequency converter with an output pulse corresponding to an absorption peak of the chromatophore. The changes in H^+ binding represent a sort of "membrane Bohr effect".

THE first application of the ruby laser to biological problems was as a pulsed light source for the rapid activation of cytochrome oxidation in the photosynthetically active pale green mutant of *Chlamydomonas reinhardii* in 1962[1,2]. This technique was subsequently applied to *Chromatium*[3]. The experimental results suggested that the normal mode of laser operation provided pulses of sufficient power and brevity to identify a turnover of approximately one cytochrome *b* per 10 chlorophyll *A* per s. A continuation of these studies has involved the measurement of very rapid cytochrome oxidation (half-time, 2 μs) following a saturating 20 ns flash from a Q-switched ruby laser[4].

Another application for laser excitation has arisen in the study of rapid changes in hydrogen ions following light activation of chromatophores of photosynthetic bacteria. In this case, it is necessary to evaluate with accuracy the "one-turnover response" of the photosynthetic system with a light pulse short compared with the 2 μs half-time for the oxidation of cytochromes of type *c*[4]. Because the fast changes of external H^+ concentration[5–7] are measured by following the absorbance changes of the *p*H indicator dye, bromcresol purple, having its absorbance maximum in the region of 580 nm, and because it is also necessary to scan the difference spectrum for other absorbance changes in the wavelength region from 540 to 650 nm, the use of the ruby laser emitting light at 694 nm poses problems in effectively guarding the photodetector from emission at this wavelength. The use of selective laser excitation would make it possible to achieve saturation with a minimum of artefact by choosing a laser wavelength which coincides with a chlorophyll absorption peak for the particular species under study.

It is now possible to use laser-pumped liquid dye lasers[8,9] as optical frequency converters to achieve this objective; in particular, the Q-switched ruby laser may be used to pump cyanine dyes to give 20 ns pulses in the near

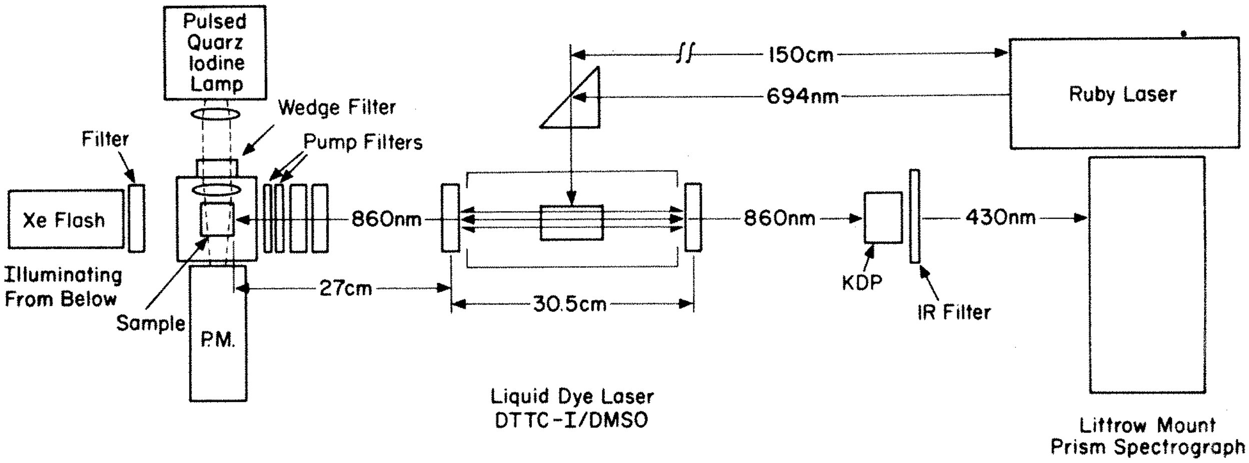

Fig. 1. Schematic diagram of the experimental apparatus (see text for full description).

infrared[10]. An appropriate wavelength may be obtained by selecting the proper dye, solvent, concentration and optical cavity.

We have designed a ruby-pumped liquid dye laser which gives an output laser pulse at 860 nm, which corresponds to an absorption peak of the bacteriochlorophyll complex of *Chromatium*. This laser has been used to obtain the time resolved difference spectrum for the binding of H$^+$ to the chromatophore membrane following a 20 ns pulse over the essential range of measuring light wavelengths from 540 to 650 nm. The experimental results are interpreted to indicate a very rapid light induced change of state of the membrane that is characterized by an increased hydrogen ion binding approximately equal to one H$^+$ per hundred moles of chlorophyll. This reaction has a half-time of 400 µs and is essentially complete in 800 µs.

The Liquid Dye Laser

The laser excitation pulse is obtained by pumping a liquid dye laser with a 20 ns pulse from a Q-switched ruby laser (Fig. 1). The liquid dye laser (LDL) consists of an optical cavity 30·5 cm long, two multiple dielectric mirrors, and a fluorescence cell adjusted transversely to excite the Gaussian mode. The dye solvent system is 3,3′-diethylthiatricarbocyanine iodide in dimethyl sulphoxide, about 10^{-4} M (DTTC–I/DMSO). The wavelength is determined by first frequency-doubling the infrared output of the LDL in an index-matched potassium dihydrogen phosphate crystal and recording the resulting second harmonic wavelength with a Littrow mount prism spectrograph.

Mercury lines were used in combination with the Hartmann formula[11] to calibrate the spectrograph. The resulting spectra (Fig. 2) give a value of 430 ± 2 nm for the second harmonic wavelength, corresponding to an 860 nm infrared laser pulse. The bandwidth is estimated to be about 6 nm.

The mirrors used in the LDL cavity are almost identical, giving two 860 nm output pulses so that wavelength and power measurements can be made without disturbing the apparatus. The conversion efficiency between the ruby pulse and the LDL pulse is about 7 per cent and the energy of one LDL pulse, as measured with a ballistic thermopile, was found to be 109 mJ. The 694 nm ruby pump light was prevented from reaching the photomultiplier by pumping the LDL transversely to the 860 nm beam direction, and by using a filter combination in front of the cuvette which consisted of two Wratten 88A filters, a Corning 4600 glass filter, and an interference filter with a pass band in the infrared. There was no measurable transmission through the filter combination from 340 to 800 nm. Thus light from the xenon flash lamp used to pump the ruby laser was not only attenuated by the distance between the ruby laser and the cuvette (approximately 200 cm) but also adequately eliminated by the filter combination. The transmission of the filter combination, measured at 860 nm, is 6 per cent. Burn patterns were taken at the output of the LDL and, without the filters, just in front of and inside the cuvette, in order to estimate the percentage of the laser beam intercepted by the cuvette; this is found to be 60 per cent. Thus the total energy impinging on the sample from one LDL infrared laser pulse is 4 mJ. The fact that further attenuation by filters or screens caused no measurable diminution of the bromcresol purple response indicates that this energy saturated the fast H$^+$ binding reaction in the chromatophores.

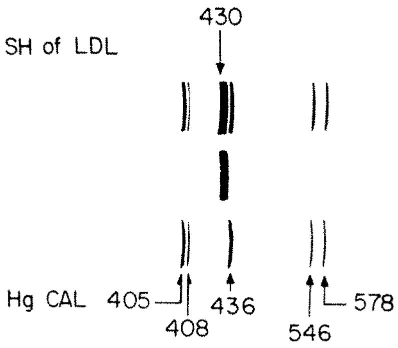

Fig. 2. Optical spectra of the second harmonic of the liquid dye laser output. The first spectrum is a superposition of laser output and mercury calibration. The second and third spectra are, respectively, the laser output and mercury calibration.

Fast Spectrophotometer

The fast spectrophotometer used in these studies was designed to provide maximum acceptable sample illumination with a high degree of stability (about $10^4 : 1$). A tungsten-halogen light source was operated at 6 A. A large aperture optical system, consisting of an $f/2$ lens combined with continuous wedge filters (Schott), 3 mm slit, 7·5 nm spectral interval, was used. The transmitted light was measured in an EMI 9592B photomultiplier equipped with one or two thicknesses of Corning 9782 guard filter. The reaction could be activated by the pulse from the liquid dye laser at 860 nm and by a 200 µs xenon flash as well. Wratten 88A guard filters were used in both cases[12]. The performance of the system is indicated in Fig. 3. It is capable of reading out with a rise time of 40 µs (10 per cent to 90 per cent) an absorbance change of $1 \cdot 6 \times 10^{-4}$ units at a wavelength of 580 nm, through the 8 µM chlorophyll concentration and 67 µM bromcresol purple concentration at a *p*H of 6·5.

Photoactivation of *Chromatium* Chromatophores

The response of the *p*H indicator, bromcresol purple, to 20 ns flashes of 860 nm radiation from the LDL, followed 7 ms later by a 200 µs flash from a xenon lamp over a broad wavelength band from 700 to 900 nm, is illustrated in Fig. 3. In the top trace the LDL flash occurs 6 ms after the recording starts; the laser flash is clearly seen as an upward spindle in the trace, followed by a drop of one scale division (0·2 per cent) with a half-time of 400 µs and a time to plateau of 800 µs. A reaction mechanism is described elsewhere[12]. The apparatus is programmed to provide, 6 ms after the laser flash, a xenon flash with a half-time of 200 µs, which drives the reaction to the maximum of its flash response. The bottom trace merely indicates the absence of electromagnetic artefact; the laser and xenon light is blocked off. The results indicate that photoactivation of *Chromatium* chromatophores causes a fast activation of the *p*H indicator dye, bromcresol purple, with a half-time of 400 µs. Calibrations with HCl show that the laser-induced absorbance change is equivalent to 10^{-7} M H^+ or to 1/100 of the chlorophyll present.

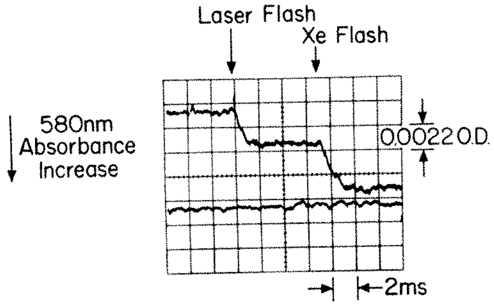

Fig. 3. Response of the *p*H indicator, bromcresol purple, to the 860 nm laser pulse followed by an infrared xenon flash.

Because observations at a single wavelength might be caused by a variety of optical responses of the chromatophores, we have made a scan of the wavelengths from 540 to 650 nm in order to identify bromcresol purple as the absorbing species. This difference spectrum (Fig. 4) is obtained by varying the wavelength of the measuring light incident upon the chromatophore suspension by varying the position of the linear wedge filter. The smaller spectrum (*A*) represents the absorbance changes following the 20 ns laser flash; and the larger (*B*) those arising from the 200 µs xenon flash. Both spectra have peaks at 582 nm, and are sufficiently similar to justify the conclusion that they both correspond to the same chemical species, namely, bromcresol purple.

Hydrogen Ion Binding Reaction

These experiments and others described elsewhere[12] justify the conclusion that the fast bromcresol purple absorbance increase results from the binding of H^+ to the membrane. The extent of the binding (approximately one for every hundred chlorophyll molecules) corresponds roughly to the size of the active centre in these chromatophores[13]. The relative insensitivity of the fast hydrogen ion binding to uncoupling agents and to alterations of membrane cation permeability by antibiotics suggests that the reaction is not intimately associated with an ordinary "pump" mechanism, but rather with primary events of electron transport in the active centre. The time scale of the fast H^+ binding in relation to that of other identifiable electron transport events in *Chromatium* chromatophores[4,12,14-18] is indicated in Fig. 5. The fast H^+ binding reaction, which we have termed "Z"[12], occurs more slowly than the reduction of either of the chlorophyll electron acceptors, X and Y, proposed by Parson[18], or the oxidation of chlorophyll electron donors such as cytochrome c_{555}. This kinetic difference is supported by differences in temperature coefficient and *p*H dependence between the H^+ binding reaction, Z, and acceptor reduction, Y[12,18]. Neither Z nor Y kinetics are affected by reductants of ubiquinone such as ascorbate or succinate[12,18].

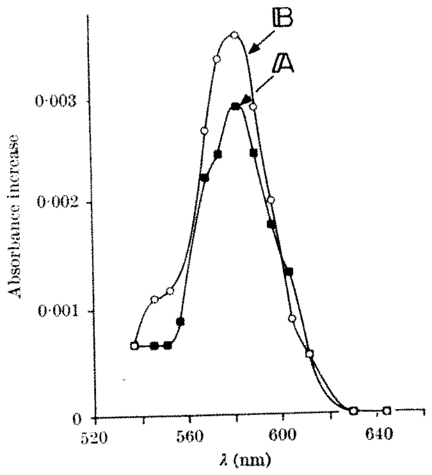

Fig. 4. Laser and xenon flash-induced difference spectra illustrating the specificity of the bromcresol purple absorbance change. *A*, 20 ns laser flash; *B*, 200 µs xenon flash following the laser flash.

It is noteworthy that the H^+ binding reaction does not exhibit reaction kinetics similar to those of the carotenoids of the chromatophore membranes; the more than 10-fold acceleration of the carotenoid absorbance change caused by valinomycin and potassium, observed particularly in *Rhodopseudomonas spheroides*[19] and to a lesser extent in *Chromatium* chromatophores and those prepared from *R. rubrum* (personal communication of M. Baltscheffsky), is not paralleled by a detectable change in the kinetics of the fast H^+ binding—nor, indeed, are the kinetics closely related; the carotenoid absorbance decrease is as short as 100 µs in chromatophores prepared from *Rps. spheroides* and approximately 20 ms in those prepared from *R. rubrum* (unpublished observations of D. DeVault, A. Crofts and M. Baltscheffsky).

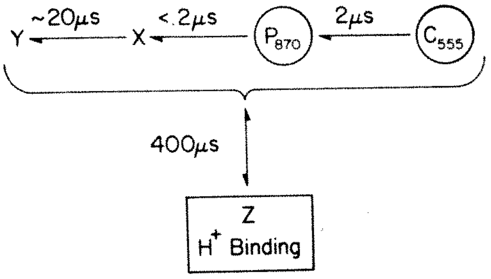

Fig. 5. Simplified scheme for photosynthetic electron transport.

A simple explanation for the light-activated hydrogen ion binding is based on an analogy with haemoglobin, where liganding of the haemoprotein with oxygen leads to structural changes which cause decreased H^+ binding in a phenomenon known as the "Bohr effect"[20]. We would term our finding a "membrane Bohr effect". The half-time of the H^+ binding may be related to a transition between membrane structural states induced by electron transport, in which membrane components—either protein or phospholipid—would exhibit altered charge states.

The alternative viewpoint, that the fast H^+ binding is chemiosmotic in nature[21], requires a correlation of the binding kinetics with the reduction of an electron transport component, presumably other than that indicated in Fig. 5. The correlation of H^+ binding with a reductant of a vectorial membrane-bound electron transport component is, however, not supported by experimental evidence.

The possibility that the light induced increase of H^+ binding causes movements of H^+ across the membrane permeability barrier is of considerable interest, but has not yet been proved by the use of suitable "internal" *p*H indicators.

We thank Dr G. I. Farmer for helpful discussion on liquid dye lasers, Dr M. Nishimura for useful suggestions and Miss R. Fugono for the preparation of chromatophores. The work was supported by a grant from the US Public Health Service.

Lack of Eye to Eye Transfer of an Early Response Modification in Birds

by

H. ZEIER*

Department of Psychology,
Massachusetts Institute of Technology,
Cambridge, Massachusetts

A chick reared on glass over the deep side of a "visual cliff" loses its innate aversion to the deep side. If it is reared with one eye occluded, however, the induced loss of preference for the shallow side is not transferable to the other eye.

BIRDS are useful subjects for experiments on interocular transfer because their optic nerves are completely crossed, and their visually controlled behaviour has been well studied. In precocial birds, this behaviour includes certain components that seem to be "innate" (that is to say, independent of early experience); one of the most striking of these behaviour patterns is the avoidance by the newly hatched bird of the seemingly deep side of a "visual cliff"[1,2], an ingenious device for the testing of depth perception (see Fig. 1). Very young precocial birds also show a special form of learning (called "imprinting" by Lorenz[3]), manifested by their tendency to follow the particular stimulus to which they were initially exposed. This following reaction can be established through one eye (with the other eye occluded); once acquired, the reaction transfers immediately to the other eye[4]. Learned pattern discriminations (for example, triangle versus circle) have also been shown to transfer completely in normal birds[5,6], but such transfers are much less effective if the birds have been reared in diffuse light[6].

This article describes an attempt to sample another task for interocular transfer in unoperated birds. It has been shown that the "innate" preference for the shallow-looking side of a visual cliff could be abolished by rearing chicks, from the time of hatching, on the glass over the deep side of the cliff apparatus[7]. After this kind of rearing, the chick will descend indifferently to the deep and shallow side of the cliff; it has lost its innate aversion to the deep side. I replicated this special form of rearing, on the deep side, with the difference that one eye of the chick was occluded. This was to see whether the induced loss of preference for the shallow side would transfer to the other eye when the occluder was shifted from the previously covered to the previously open eye. As will be shown, such transfer definitely fails to occur, in spite of the apparent integrity of intracerebral commissures.

In the experiment here reported, 156 White Rock chicks in ten experimental groups were reared in different conditions either on the deep or shallow side of a visual cliff (Fig. 1). The chicks were taken within 6 h after being hatched in a dark incubator; their visual input was restricted by contact occluders[8], if this was necessary, and they were placed on either side of the cliff for 45 ± 5 h. The experiments were run in series so that there were never more than six chicks sharing the same space within the apparatus. The glass surface was cleaned once, at half-exposure time, for each group. After the chicks had been exposed to the cliff, the contact occluders were removed and the eyes were cleaned with an isotonic solution. The chicks were then given access to food and water for 1 to 2 h in a brooder. Immediately before testing, the vision of each eye was tested independently by eliciting a pecking response to a small rubber ball on a stick held in front of the chick's head. Chicks failing to peck at the ball or those showing any signs of conjunctivitis were discarded from the experiment.

* Present address: Swiss Federal Institute of Technology, Department of Applied Physiology, Clausiusstrasse 25, Zürich, Switzerland.

For the test, a centreboard was placed across the glass plate at the borderline between the deep and shallow side. Because electric shocks given to chicks do not influence their choice behaviour on a visual cliff[9], an electrified grid was installed on the centreboard. Each chick was placed twice on the centreboard with its face toward the deep side. If no response occurred within 30 s, a shock of from 1 to 5 mA was administered and gradually increased in strength until the chick jumped from the centreboard. An electrode-paste sensitized the chick's feet to the electric shock. After each response, the glass surface was cleaned and the contact occluders were switched if necessary.

The first two control groups received binocular exposure on the deep or shallow side in order to see if they would show the expected behaviour on two subsequent responses. The results, summarized in Table 1, show that members of the deep-reared group lost their visual-cliff avoidance and descended randomly both times, while those of the shallow-reared group clearly preferred the shallow side as normal chicks would do. There was no significant interaction between first and second response.

Table 1. REACTIONS ON VISUAL CLIFF BY CHICKS REARED UNDER DIFFERENT CONDITIONS

Binocularly tested

			1st response			2nd response		
Group	Rearing conditions	*N*	*D*	*S*	%*S*	*D*	*S*	%*S*
1	Deep side both eyes exposed	12	7	5	42	5	7	58
2	Shallow side both eyes exposed	12	3	9	75	2	10	83
3	Deep side one eye exposed	12	5	7	58	5	7	58
4	Shallow side one eye exposed	12	2	10	83	3	9	75

Monocularly tested

			Exposed eye			Unexposed eye		
Group	Rearing conditions	*N*	*D*	*S*	%*S*	*D*	*S*	%*S*
5	Deep side one eye exposed	36	18	18	50	6	30	83
6	Shallow side one eye exposed	24	5	19	79	4	20	83

			Left eye			Right eye		
Group	Rearing conditions	*N*	*D*	*S*	%*S*	*D*	*S*	%*S*
7	Deep side both eyes exposed	12	5	7	58	5	7	58
8	Shallow side both eyes exposed	12	3	9	75	3	9	75
9	Deep side both eyes covered	12	1	11	92	2	10	83
10	Shallow side both eyes covered	12	1	11	92	3	9	75

N, Number of chicks per group; *D*, number of chicks descending to deep side of cliff; *S*, number of chicks descending to shallow side.

The next two groups received their cliff experience monocularly and performed the test binocularly. The deep-reared chicks (group 3) transferred their loss of visual cliff avoidance from a single eye to both eyes, while the shallow-reared chicks (group 4) showed the expected depth avoidance response. Group 5, however, which had the same exposure history on the deep-cliff side as group 3, but had then been tested monocularly (half of the group with the exposed eye first, the other half with the unexposed eye first), showed the normal visual cliff-avoidance response when using only the unexposed eye, in contrast to randomly distributed responses made when vision was restricted to the exposed eye ($\chi^2 = 7{\cdot}71$, $P < 0{\cdot}01$). Loss of cliff-avoidance response apparently does not transfer from a single eye to a contralateral eye.

Results for group 7 demonstrate that the test performance of binocularly exposed chicks is not affected by occlusion of either the left or right eye, while the shallow-reared control groups 6 and 8 showed the expected cliff-avoidance response regardless of which eye was used. Groups 9 and 10, reared with both eyes occluded, showed the same behaviour, proving that the contact occluders used were effective and that light deprivation during the short (≤ 50 h) experimental rearing period did not distort visual functions in such a way that these animals lose the form of depth perception tested in the visual-cliff situation.

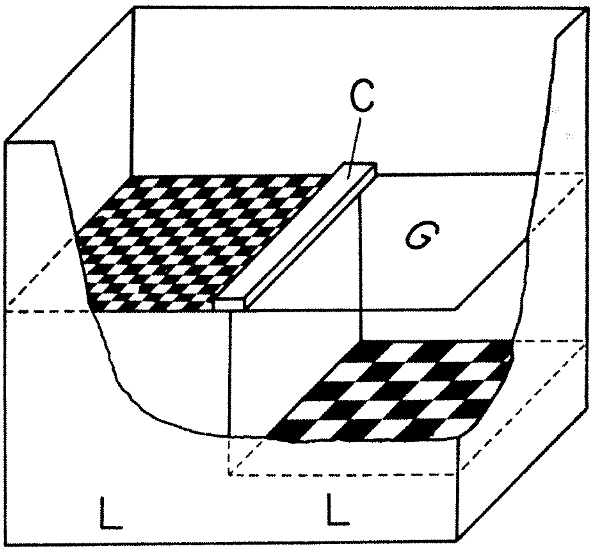

Fig. 1. Visual cliff apparatus with shallow side on the left and deep side on the right. On the shallow side (a square of 35 by 35 cm) textured 6 mm red and white checkered cloth is inserted directly under the glass; on the deep side (35 by 35 cm) an analogous pattern is placed 25 cm below the glass surface, but the squares are 20 mm in length to minimize texture density as a possible cue[2]. *C*, Centreboard (5 cm wide and 2 cm high) for testing procedure; *G*, glass (70 by 35 cm) extending over both sides; *L*, two fluorescent lamps on each side transilluminating the textures.

These findings show that, although the loss of visual-cliff avoidance after exposure on the deep side of a visual cliff transfers from a single eye to both eyes and from both eyes to a single eye, there is no transfer of this behavioural modification from a single eye to the contralateral eye. Such a lack of interocular transfer is particularly significant because chicks "imprinted" with one eye to follow a moving object will readily transfer this following-reaction to the other, untrained eye[4]. It is possible therefore that tasks involving responses for which there is a strong inherent disposition are more easily transferred from eye to eye than are reactions that run counter to an innate response tendency.

The situation in the chick may not be too dissimilar from that in the kitten reared with different exposures to each eye. Hein and Held[10] showed that the visual placing response of the kitten has two components—triggered extension and guided reach. The guided response requires previous sight of the limbs by the controlling eye, and exposure of only one eye to the limb fails to produce guidance of the reach by the other eye. The triggered response requires only exposure of one eye to diffuse light and can then be immediately elicited by stimulation of the other eye[11]. There, too, interocular transfer seems to be less readily accomplished for the response that has a conditioned component[11].

PHYSICAL SCIENCES

The Galactic Halo

THE halo of our galaxy is a nearly spherical region containing very old stars which have a smaller content of heavy elements than our Sun. There is no detailed model for its formation. It is usually assumed that somehow a cloud of gas condensed to form our galaxy, and that the halo stars were formed during the collapse process and left with a nearly spherical distribution[1]. In that case, and in view of the success of the theories of nucleosynthesis in stars, it is very puzzling that the halo stars should have any heavy elements at all.

We reconsidered this problem in connexion with our preparations for the symposium on the chemical evolution of the galaxy recently held at the California Institute of Technology in honour of the sixtieth birthday of J. L. Greenstein. This exercise was a new version of a study carried out a few years ago[2] in which the chemical history of the galaxy is followed by numerically integrating the effects of stellar evolution. The general approach was similar to that of the previous study, except that more details of the integrations could be recorded using the storage of the 360/95 computer of the Goddard Institute for Space Studies. The principal difference between the two studies arose in the assumptions which we have now made about the details of stellar evolution. We shall prepare a full report for publication elsewhere; in this report we give only the principal arguments and conclusions which we reached having a bearing on the origin and evolution of the galactic halo.

Our assumptions about stellar evolution have been influenced very heavily by recent studies of supernova explosions by Arnett[3]. For massive stars up to twenty solar masses, we assumed that a complete nuclear explosion would occur, leaving no remnant but injecting into the interstellar medium the main products of nucleosynthesis between carbon and the iron equilibrium peak[4,5]. For more massive stars, we assumed that the implosion would form a Schwarzschild singularity, that is, a black hole or "collapsar". In both cases we assumed that thirty per cent of the initial main sequence mass would be lost in stellar winds during stellar evolution.

The rate of star formation was governed by the assumption that the gas content of the galaxy declined exponentially, reaching five per cent at $1 \cdot 5 \times 10^{10}$ yr (a number chosen to fit cosmochronological considerations). We assumed the same stellar birth-rate function as in the earlier study, where it was taken from the work of Salpeter[6] and Limber[7].

As before, we found that the heavy element content of the galaxy rose very quickly in the first 2×10^9 yr, and that it increased only slowly after that. The present calculations, however, indicated that about ten per cent of all stars of slightly less than the solar mass (which would never have evolved beyond the main sequence) would contain 15 per cent or less of the solar content of heavy elements. Observations show that such stars are extremely rare, however, and that most stars have a heavy element content within a factor three of the solar content. We therefore felt forced to the conclusion which was earlier reached by Schmidt[8]: in the early history of the galaxy almost all the stars formed were more massive than the Sun.

This is consistent with current thinking about star formation. Fragmentation is greatly assisted during the collapse of an interstellar cloud if strong density-dependent cooling is present. Such cooling reduces the velocity of propagation of pressure waves and hence isolates one part of the gas from its neighbouring part. Cooling is very inefficient below about 10^4 K if heavy elements are not present in the gas to form grains and ions with low-lying excited states. It is therefore reasonable to expect that only quite massive stars can have been formed in the galaxy until the heavy element content of the gas rose to a significant fraction of the solar value. For the purposes of our numerical exploration we assumed that only that part of the stellar birth-rate function above ten solar masses was formed by star formation until the content of elements heavier than helium in the interstellar gas reached 0·005 of the mass, about one-third of the solar value.

The galactic evolutionary histories which we computed had a number of strange aspects, but one feature stood out. In the original birth-rate function, about five per cent of the mass ends up in collapsars according to our stellar evolution assumptions. In the revised birth-rate assumptions the collapsar mass fraction becomes about an order of magnitude larger. This feature points the way to the following suggestions about the early history of our galaxy.

Suppose, as is usually done, that a cloud of gas collapses to form our galaxy. Suppose also that about half of the mass of this gas promptly forms massive stars (something like our revised early birth-rate function). These stars contain no heavier elements and hence are likely to have high surface temperatures, of order 10^5 K. The residual gas is likely to be maintained at a similar gas kinetic temperature and to form a roughly spherical body having an approximation to hydrostatic equilibrium and a radius of order 10^5 pc. The rapid evolution of the massive stars will mix substantial amounts of heavy elements into this halo gas. This heavy element contamination greatly increases the cooling efficiency of the halo gas, thus allowing the formation of low mass stars in the halo and simultaneously allowing the halo gas to collapse to form the galactic disk, because the thermal pressure is suddenly reduced.

We have run some models of the galaxy based on this picture. We doubled the mass of the galaxy and put all the additional mass into stars in the first evolutionary time step. This has given us the best fit to the various observed abundance criteria which we wished to fit by our computed galactic histories. While this success is gratifying, we emphasize that a large number of assumptions is involved, so that the only conclusion which can properly be drawn is that our current assumptions about stellar evolution are consistent with our picture of the formation and evolution of the galactic halo.

These calculations indicate that about half the present mass of the galaxy is in the form of collapsars. The many assumptions mean that this number can only be taken as a rough indication of what we should expect. It is not in conflict with observations, however. We must expect the galaxy to be nearly twice as massive as usually assumed, with most of the extra mass consisting of collapsars distributed throughout the halo. This distribution will have very little effect on the dynamical motions of the stars in the galactic disk. Analyses of the motions of the stars in the solar neighbourhood perpendicular to the galactic disk indicate that some thirty per cent of the local mass density is in an unseen form, subject to the assumption that the unseen mass is strongly concentrated to the disk[9]. If the unseen mass has a more nearly spherical distribution, however, its mass can be very much greater than this[10].

For many years it has been a puzzle that giant elliptical galaxies have such a high mass-to-light ratio[11]. The present considerations lead us to suggest that the majority of the mass of such galaxies is in the form of collapsars.

We thank W. D. Arnett and M. Schmidt for discussions. This research was supported in part by grants from the US National Science Foundation and the US National Aeronautics and Space Administration.

An Oscillating State as an Alternative to Gravitational Collapse

THE possibility of an oscillating universe is often disputed on the grounds that oscillations are not possible when there is no equilibrium position[1]. By the same argument, gravitational collapse can be considered as the only alternative when the mass is over critical (there is no configuration of equilibrium for such a big mass). The argument, however, cannot be generalized from the cosmological case to the case of a big mass, as we will see.

The existence of a critical mass of the order of that of the Sun follows from the equation of state obeyed by matter. This can be seen from the following example of a solution representing a mass as big as desired in equilibrium.

$$\mathrm{d}s^2 = \frac{-2}{1-ar^2}\,\mathrm{d}r^2 - r^2\,(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2) + ar^2\,\mathrm{d}t^2 \qquad (1)$$

from which we obtain

$$8\pi\rho = (1/2r^2) + (3a/2) \qquad (2)$$

$$8\pi p = (1/2r^2) - (3a/2) \qquad (3)$$

The equation of state is

$$\rho = p + k \text{ (with } k = 3a/8\pi) \qquad (4)$$

The element can be joined smoothly to the Schwarzschild exterior solution

$$\mathrm{d}s^2 = -\left(1-\frac{2m}{r}\right)^{-1}\mathrm{d}r^2 - r^2\,\mathrm{d}\,\Omega^2 + \left(1-\frac{2m}{r}\right)\mathrm{d}t^2 \qquad (5)$$

giving for the gravitational mass the value

$$m = (1/3)\,(8\pi k)^{-1/2} \qquad (6)$$

and for the radius

$$R = (8\pi k)^{-1/2} \qquad (7)$$

Pressure and density become infinite at the origin, but there is a theorem[2] applicable in this case which ensures the existence of solutions with the same equation of state, and with a total mass as near as desired to that of our solution provided that the central pressure and density are high enough, though finite.

It is possible therefore to have as large a mass as desired in equilibrium provided we admit an equation of state of the form $\rho = p + k$ small enough. Oppenheimer and Volkoff's proof[3] of the existence of a critical mass of the order of that of the Sun relies on the known equation of state for cold neutron matter.

Misner and Zapolsky[4] have generalized the proof of ref. 3 for the case when matter with over nuclear density obeys an equation of state of the form $p = \rho(\gamma - 1)$ with $1 \leq \gamma \leq 2$ while for under nuclear densities the equation of state is the known equation for cold neutron matter.

Comparing my solution with that of Misner and Zapolsky, both propose the same equation of state for the core (if we take $\gamma = 2$). The essential difference is that the equation $\rho = p$ is considered by Misner and Zapolsky to be valid for over nuclear densities only, while in our case (for k very small) the equation $\rho = p$ remains approximately valid for a considerable range of under nuclear densities. When the equation $\rho = p$ can be extended to a quantity of matter sufficiently larger than that considered by Misner and Zapolsky, there may be equilibrium configurations for masses as great as desired.

The approach of Misner and Zapolsky is sound, so I do not propose my solution as a model for big masses in equilibrium. I accept therefore that there is no configuration of equilibrium for big masses of cold neutron matter. As such big masses collapse, however, most of the matter may become of over nuclear density.

The existence of restoring forces must now be studied with due regard to the equation of state prevailing in the dynamical process during which there exists a much higher ratio of matter with over nuclear density to matter with under nuclear densities than in the static case.

Misner and Zapolsky did not calculate the possibility of equilibrium for such higher ratios of matter obeying the $\rho = p$ equation to matter not obeying it (such higher ratios are unrealistic in the static case). My example proves that in this case there is an equilibrium configuration and therefore there may be restoring forces to this position of equilibrium.

An over critical mass could therefore oscillate in the following way: (1) It starts collapsing because it cannot remain in equilibrium. (2) As it collapses, the ratio of mass with over nuclear to mass with under nuclear density increases and the equation of state of that part of the body, the density of which goes from under nuclear density to over nuclear density, does change. As a result, restoring forces build up. (3) Under the effect of the restoring forces the collapse stops, to be followed by the expansion of the body. (4) While expanding, the ratio of over nuclear densities to under nuclear densities decreases. The body therefore does not cross a position of equilibrium but completes the cycle by reaching the initial state for which no equilibrium position exists.

It would be interesting to establish the precise ratio (as a function of total mass) which separates the cases for which there is or there is not restoring forces. It would be helpful to calculate the limiting mass for which the restoring forces are reversing the collapsing movement before the crossing of the Schwarzschild radius. When the Schwarzschild radius is to be crossed (from the point of view of a comoving observer), the body is to be considered as a collapsing non-oscillating one from the point of view of an external observer who will observe the body as tending asymptotically towards the Schwarzschild radius.

I thank Professor W. Isreal for pertinent remarks.

Long Term Variations of Pulsar Intensities

PULSAR intensity variations may be divided roughly into three classes. There are rapid variations on a time-scale of seconds to minutes which occur simultaneously over a wide range of frequency and must therefore be intrinsic to the source[1]. On a somewhat longer time-scale there are variations typically over a few minutes to a few hours which correlate only over limited bandwidths. There is strong evidence that they are caused by irregular diffraction in the interstellar medium[2,3]. Finally, there are variations on a time-scale of days to months[4] about which little is known because extended regular observations are required. In this report we present some new results obtained during timing observations carried out on a routine basis over 11 months.

The five pulsars CP 0808, CP 0834, CP 0950, CP 1133 and CP 1919 were observed during meridian transit with the 81·5 MHz phased array at Cambridge. A daily measure of the mean intensity was obtained by averaging the ten largest pulses to occur during the 4 min or so that the source was in the beam. Considerable day to day variations must arise from the interstellar fluctuations (extrapolating from the data of Rickett[3]), so the daily values were smoothed by taking a 7 day running mean.

The results are shown in Fig. 1, together with some isolated values at 408 MHz. All five pulsars show similar behaviour in that variations on time-scales extending from a few days to several weeks are clearly evident. CP 0950 is, possibly, the most variable source and has shown the greatest extreme fluctuations. This is not fully apparent in Fig. 1, because the timing records from which the data were taken were saturating for very large pulse intensities. It should be noted, however, that in November 1967, CP 0950 exhibited an increase by a factor of about 200 (ref. 5). The variability of this pulsar is also shown by the data of Downs *et al.* at 12·5 cm (ref. 6).

The points at 408 MHz were included in an attempt to investigate the correlation of long period variations at another frequency. We thank the Nuffield Radio Astronomy Laboratories, Jodrell Bank, for these data, which were obtained from observations with the Mark I telescope usually tracking each source for about an hour. Because the medium period fluctuations are slower at 408 MHz, these points were smoothed by taking a mean over 4 days wherever possible. There is no clear correlation between the strength at the two frequencies for either source, but for CP 0950 the peaks and troughs at 81·5 MHz tend to coincide with those at 408 MHz. The correlation coefficient for the CP 0950 data (unsmoothed at 408 MHz) is 0·37, which is significant at the 5 per cent confidence level. The correlation is almost unchanged by smoothing. There is no significant correlation for the CP 1919 data. This indicates that there may be some correlation of long-term variations over this frequency range, but more extended observations are needed to settle this point.

There seems to be no possibility of accounting for long term variations of intensity by random diffraction in the interstellar medium. Irregularities in the interstellar medium produce a diffraction pattern at the Earth which appears as an intensity variation in time due to the transverse velocities of the irregularities relative to the

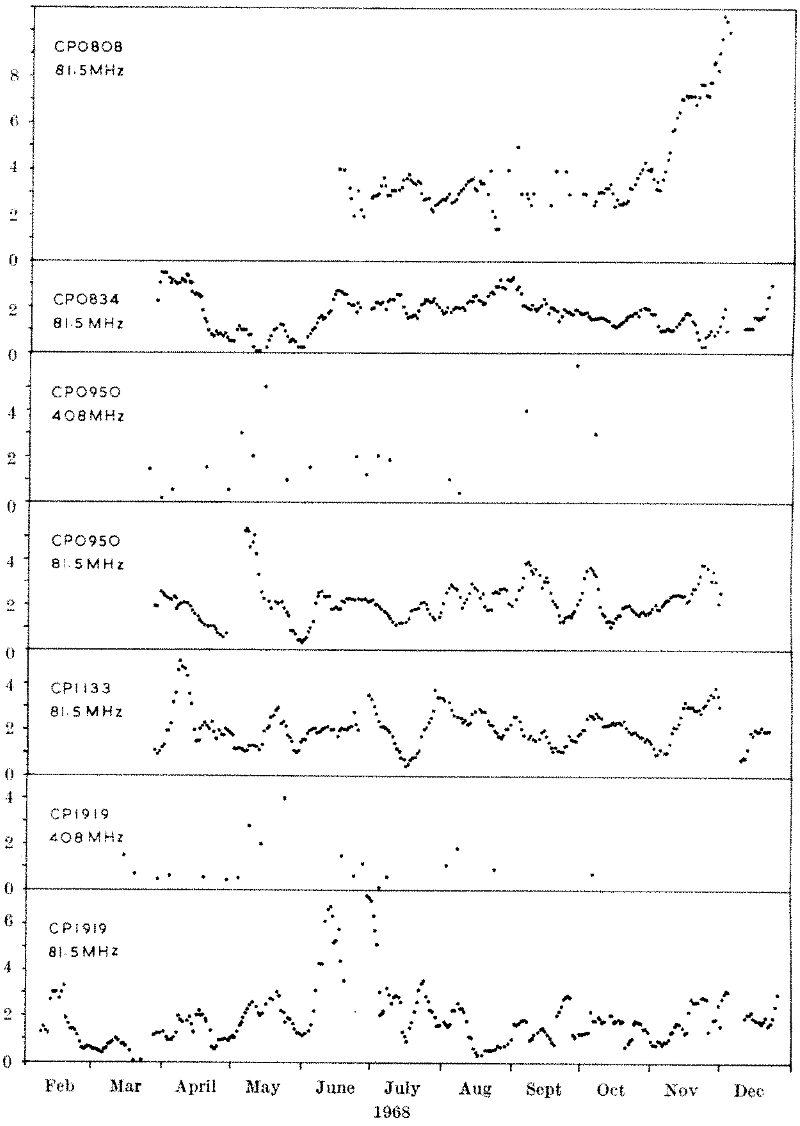

Fig. 1. Plots of intensities (7 day running mean) for five pulsars with an arbitrary linear intensity scale.

Earth. The Earth contributes a transverse velocity component which varies throughout the year, but which is of the order of 30 km s^{-1} for all sources for at least several months in the year. The observed deep amplitude variations have a correlation width of the order of 1 month, so that at 30 km s^{-1} the physical scale, a, of the intensity pattern would have to be greater than 10^{13} cm. The deep modulation implies that the Earth is in the far field of diffraction, however, so the Fresnel distance for the irregularities would have to be less than the distance, d, to the source. Hence $ka^2 < d$, where k is the wave number at 81·5 MHz. For CP 0950, for example, taking $d = 100$ pc, we require $a < 10^{11}$ cm.

Because the scintillation mechanism cannot reconcile these two values for the scale size, and because there is a possible correlation over wide frequency ranges, it may be concluded that the long term variations are intrinsic to the source.

There do not seem to be many processes in a neutron star which will lead to variations on so long a time-scale. Density fluctuations in the escaping plasma might lead to intensity fluctuations for some of the oblique magnetic rotator models, but it is difficult to envisage slow changes in this situation. Variations in the surface magnetic field might also modulate the radio emission, either by altering the beam geometry or by changing the effective dipole moment. Simultaneous observations at different frequencies may provide further clues.

It is also interesting to note that large increases of intensity which persist for a few weeks might give rise to associated variations of period which are large enough to be observable. For example, in the case of CP 0950 radiating 200 times its mean energy for about 3 days, if the radio flux is derived from rotational energy loss at some constant efficiency, the slowdown rate, $\dot{p}$, would rise to about 5×10^{-14}. The change in pulsar phase over the period of $2{\cdot}5 \times 10^5$ s is then $\Delta\varphi = \frac{1}{2}\dot{p}\,t^2 = 1{\cdot}5$ ms. In a plot of pulsar phase, a step of 1·5 ms would be just observable with present observational accuracies; in other cases the effect could be larger. It may be significant, however, that the total radio flux emitted by CP 0950 is only 0·01 per cent of the loss of rotational energy due to the lengthening of the period, whereas pulsars which seem to have less extreme variations in flux have much higher radiative efficiencies. For CP 0808 it is about 1 per cent, and for CP 0328 of the order of 3 per cent. (These values may all be reduced by a factor of up to ten if there is appreciable beaming of the radiation in two dimensions.

Further observations of period changes and of flux variations at several frequencies are needed to investigate these possibilities.

We thank Dr A. Hewish for discussions, and Professor F. G. Smith and G. C. Hunt of Jodrell Bank for the 408 MHz data. T. W. C. and C. G. P. acknowledge maintenance awards from CSIRO and the Science Research Council respectively.

Anisotropic Atomic Hydrogen Distribution in Interplanetary Space

Blum and Farr[1] have suggested modifications of current theories[2,3] concerning the interaction of the solar wind with interstellar hydrogen. One feature of their model involves the motion of the solar system. This motion, coupled with the velocity of the interstellar hydrogen, results in a velocity of 10 to 40 km s^{-1} for interstellar hydrogen relative to the solar system. According to Blum and Fahr the relative velocity gives rise to an anisotropic distribution of neutral hydrogen atoms in interplanetary space. The neutral hydrogen density is enhanced in the direction of approach of the interstellar hydrogen and diminished in the opposite hemisphere. The motion of the interstellar hydrogen is assumed to cause a highly aspherical transition region between the hydrogen and the solar wind.

Our observations[4] with satellite-borne detectors of Lyman α seem to support qualitatively the model of Blum and Fahr. We assume that the radiation detected is primarily solar Lyman α resonantly scattered from neutral hydrogen. The measurements were made with ion chambers filled with NO with LiF windows on two Vela 4 spacecraft launched on April 28, 1967. These Earth-oriented spacecraft are in nearly circular orbits at 110,000 km inclined at 58° to the ecliptic plane and should be above the hydrogen geocorona of the Earth. Each spacecraft carries two collimated ion chambers with 17° half-angle cones of acceptance (0·27 sr). The extensions of the cone axes pass through the centre of the Earth; thus the ion chambers look radially outward from the Earth.

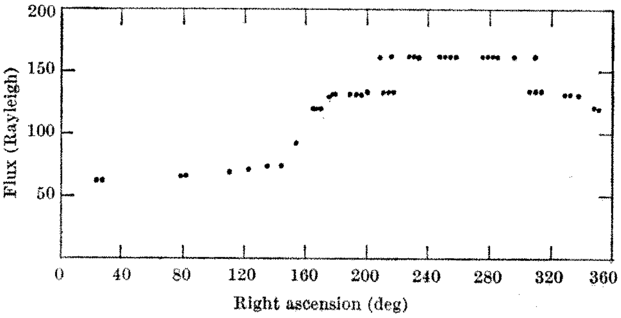

Fig. 1. Scattered Lyman-α flux versus right ascension for June 6 to June 10, 1967. The orbit period is approximately 4·6 days.

The predominant feature of the data is a repetitive and marked asymmetry in the Lyman α flux as a function of right ascension of the cone axes. This feature was evident for a period of 290 days (64 revolutions) after which the sensitivities of the ion chamber were too low for meaningful results. As shown in Fig. 1, the flux typically rises from about 60 Rayleighs to a broad maximum (160 to 190° FWHM) of 160 Rayleighs. The average of many orbits places the centre of the maximum at approximately RA 265°. The motion of the solar system relative to nearby stars is toward RA 270° and δ + 27°. The declination of the cone axes is + 32° at RA 265°.

A distribution of aspherical hydrogen with an enhanced density in the forward hemisphere as suggested by Blum and Fahr could produce the observed asymmetry in scattered Lyman α. A quantitative comparison of the data with the theory is needed and may contribute to a better understanding of the picture of the neutral hydrogen distribution in the vicinity of the solar system, which is still not clear.

This work was carried out under the auspices of the US Atomic Energy Commission.

Lunar Rilles and a Possible Terrestrial Analogue

CALCULATIONS by several authors suggest that the Moon, like the Earth, could not have retained a residue of its primordial atmosphere[1-5]. Gilvarry[6-8], however, has considered the possibility of a lunar hydrosphere and of an early lunar atmosphere replenished, like that of the Earth, from within. On this theory the sinuous rilles (Figs. 1 and 2) might be ancient channel-scouring marks. One possibility is the melting of a frozen sub-surface hydrosphere by cometary impacts, allowing the material to flood the surface.

Cameron[9] suggested the scouring of channels by incandescent ash flows, somewhat similar to nuées ardentes. Ash-flows, nuées ardentes, ignimbrites and tuff lavas are types of pyroclastic flow whose origin and behaviour are uncertain, but there seems to be little factual evidence to support the excavation of sinuous rilles by this agency. Urey[10] remarks that the channels are too narrow and such flows could not simply vanish without trace.

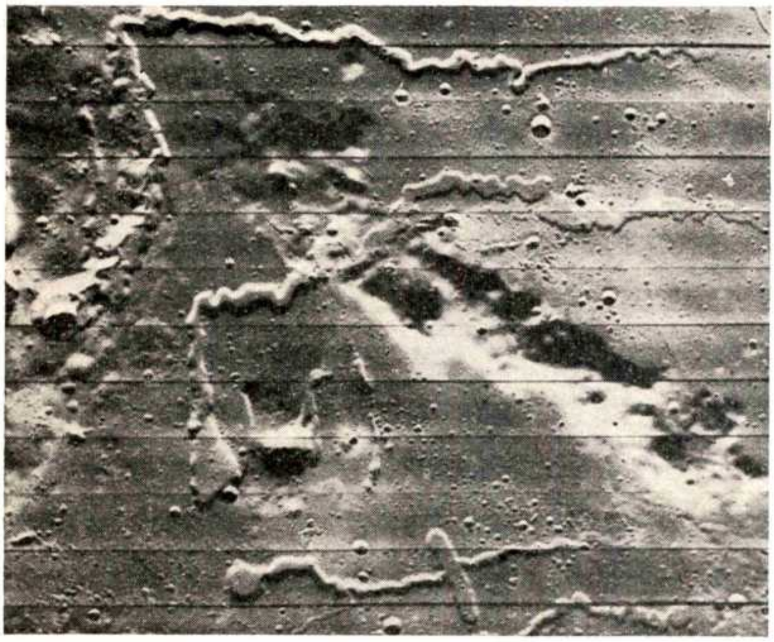

Fig. 1. Harbinger Mountains from Lunar Orbiter V showing Prinz Valleys I and II. The latter starts at a crater on the left, and runs a sinuous course for 40 miles, its width varying from 1,500 to 1,800 feet. A narrower sinuous rille runs within it, 1,000 feet wide. The main rille descends 4,000 feet during its course. Note the control of the rilles by a strong oblique NNW grain and the close genetic relation between a strange sausage-shaped crater and the sinuous rilles.

The question whether the sinuous rilles provide evidence for the movement of surface waters over the lunar surface (or other fluidized scouring agents such as ash-flows) is discussed here from an observational viewpoint.

Apart from sinuosity, there seems to be little real difference in kind between sinuous and straight rilles. Weakly sinuous rilles are a common associate of straight rilles (Figs. 3 and 4). Rilles of all types characteristically appear on dark, smooth areas forming the floors of large craters (Fig. 4), mare floors or floors of obvious trench or graben structures (Fig. 2), of tectonic origin. According to the volcanic–tectonic theory of the lunar surface[11-13], such areas are sites of volcano–tectonic subsidence and thus likely to be traversed by systems of gravity faults. Sinuous and straight rilles grade into one another and intersect, commonly with no variation in smooth floor and shoulder profile (Figs. 1 and 3). In other cases rilles of different depth and profile intersect, but the plateau surface incised by them shows no displacement (Fig. 4). Rilles of all types are commonly interrupted in their course, and even the most sinuous type shown in Fig. 2 reveals, on careful study with a magnifying lens, sectors in which there is no continuous trace but only a weak threadlike continuation, or continuation only in a chain of craterlets of the same width as the rille. These craterlets must be congenetic with the rille[14] and neither water nor a fluidized system such as an ash-flow could flow laterally through such sectors of the rilles. Rilles of all types tend to terminate, haltingly, either in thread-like tails or strings of craterlets (Figs. 1 to 3). There are many examples of undeveloped rilles, trains of craters and incompletely defined groovings (Figs. 3 and 4) and craterlet chains may parallel sinuous rilles (Fig. 3). Echelon arrangements of rilles are not uncommon. Crater floor rilles sometimes show an internal repetition of the shape of the surrounding crater wall, as in the floor of Alphonsus.

Patterns of rilles within rilles are known (Figs. 1 and 2) and may appear to originate in concentric nested craters, through fissures in their walls (Fig. 1). It has been suggested[9] that sinuous rilles always originate from craters in this way and course downhill from them, but this does not seem to be a universal pattern. In Fig. 1 one rille originates in an irregular widening and another in a level floored crater not excavated below the floor of the rille, of very similar character and profile to the widening at the tail of the upper rille in the photograph. The rilles in this photograph do not seem to follow continuous downhill courses. A sinuous rille in an Orbiter IV photo of Mare Orientalis follows the crest of a ridge. The nature of the intersection and cross-over patterns of rilles is not consistent with a scouring origin.

The sinuous deviations tend to coincide with transverse, oblique lineaments (Figs. 1 and 2) and the pattern resembles a progressive linear trace being jogged off laterally to varying degrees. The nature of the surface makes it unlikely that the rille has been displaced after formation (though this explanation cannot be entirely discounted). The more likely explanations are either that a scour channel has deviated to avoid obstructions imposed by crossing fractures or that the sinuosity reflects a mimetic response of a master fracture to intersections with minor transverse fractures, the fracture plane tending to swerve off into them. The topography in Fig. 1 is not consistent with the first explanation and, in any case, it

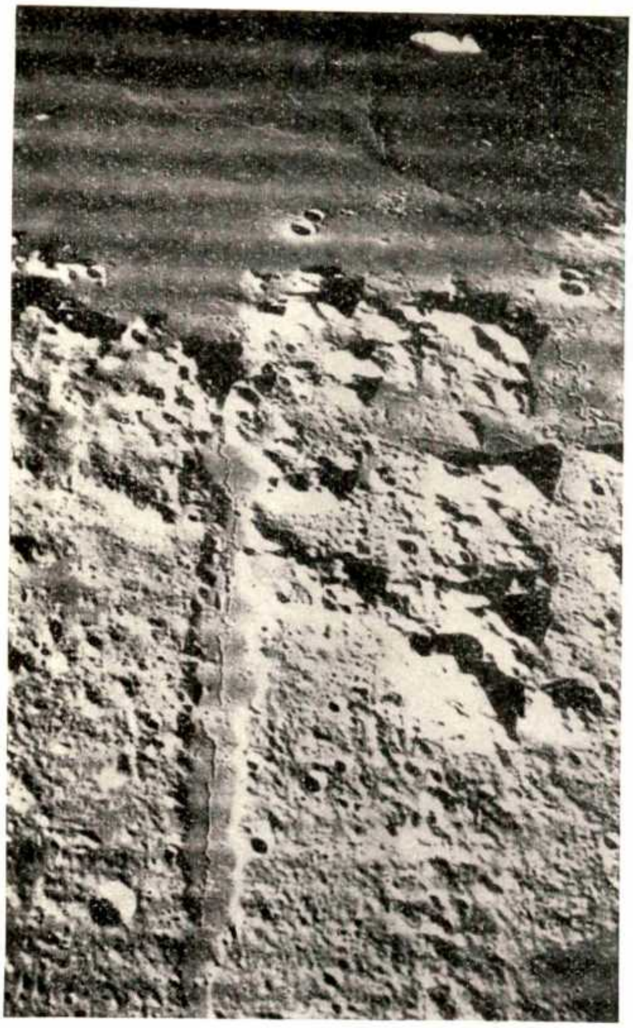

Fig. 2. A narrow sinuous rille following the course of the straight Alpine valley (which is about 25 miles wide). Lunar Orbiter V photograph.

is completely excluded by the fact that the character of the rille within the Alpine Valley in Fig. 2 is interrupted and quite inconsistent with a water scouring process.

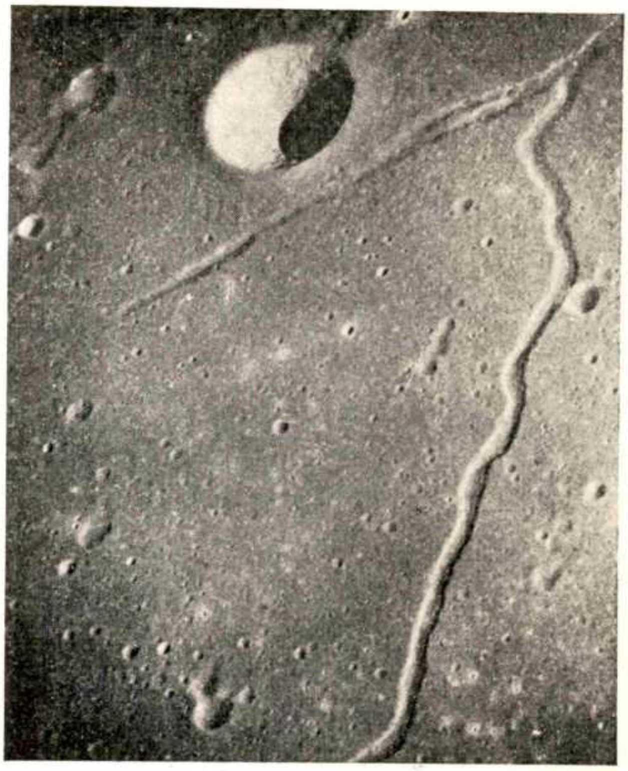

Fig. 3. Diamond-back rille from Apollo 10, a feature close to the Apollo 11 landing site. Note the obvious congenetic relationship of straight and sinuous rilles. No scale given.

My conclusion is that all rilles are reflexions of fractures in the lunar "crust". In some cases the fracture has imperfectly breached the surface (interrupted sections, undeveloped rilles). The craters that punctuate the rilles may show a systematic relationship to rille intersections. Their existence is explained if we interpret the rilles as escape channels for volcanic gases. The gas emission may have been distributed evenly along the fracture line producing a fissure conduit, or a localization of gas emission may have occurred where fractures meet. This pattern, of course, simply repeats the fundamental bimodal control of fissure and central eruption on Earth. The even floor of the rilles in Fig. 1 is, perhaps, surprising, but its character, identical with the surrounding terrain, is not inconsistent with the hypothesis that the present surface has been derived not from the lateral flow of lavas but from a process of "weathering from within" by volcanic gases, bringing up a small amount of solid material with them[13]. The resemblance of the Alpine valley to the Red Sea structure, except for the sinuosity of the internal furrow, may not be fortuitous. This and other rille structures may represent a very feeble process akin to the terrestrial continental dispersion operating long ago in the Moon.

There is some support in a terrestrial analogue for the hypothesis that all rilles are congenetic and reflect volcano-tectonic fractures up which gas has escaped. I have already referred to systems of blowhole craters strung out along closely spaced Quaternary grid faults on the southern slopes of Silali Volcano, Kenya (Fig. 2, ref. 13). On the north-eastern lower slopes of the same volcano there are sinuous fissures, apparently "originating" in large blowhole craters in a similar way to those shown in Fig. 1, and close examination with a magnifying

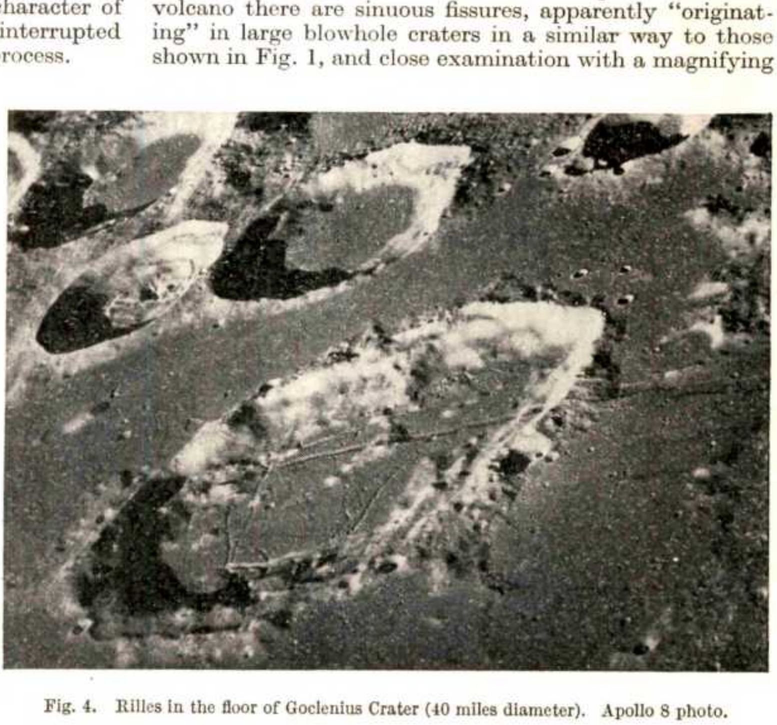

Fig. 4. Rilles in the floor of Goclenius Crater (40 miles diameter). Apollo 8 photo.

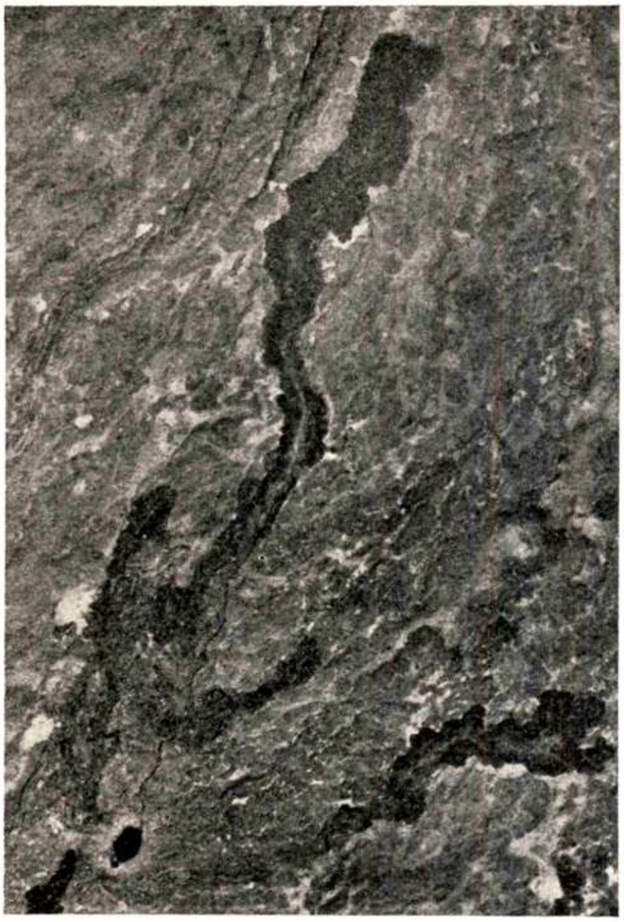

Fig. 5. Blowhole cratering and sinuous fissure association, Silali Volcano, north-east foot, Kenya. The larger blowhole crater (lower left) is slightly more than 100 m in diameter. Sinuous fissures project northwards from it and eastwards from the smaller crater below it. (Photograph, Hunting Aviation, flights for Directorate of Overseas Surveys, Tolworth.)

lens reveals chains of minute blowhole craters along the length of the sinuous fissures (Fig. 5). These fissures cut across the margins of the most recent basalt tongues, and were clearly only channels for the escape of terminal gas. This seems to be a valid analogue of the sinuous rille, and moreover the sinuous fractures are associated with linear fractures in a zone of volcano-tectonic subsidence forming part of an anorogenic zone unquestionably related to the break-up of the continents.

My conclusion is that sinuous rilles are not water scouring patterns, nor are they products of lateral scouring by fluidized systems akin to ash-flows. They are volcano-tectonic fracture traces which are sites of gas emission.

Gaseous Species in Equilibrium with the Apollo 11 Holocrystalline Rocks during their Crystallization

The holocrystalline rocks from the Apollo 11 landing site in Mare Tranquillitatis characteristically contain vesicles and vugs[1] which must have been maintained by an internal gas pressure balancing the overburden pressure. Although the landing site may contain rare fragments from distant craters[1], the common rock types of the Apollo 11 sample are probably of local origin. There are no craters closer than about 50 km which could have excavated samples from more than a few hundred metres depth. The groundmass grain size of the holocrystalline rocks, which is from 0·1 to 1·0 mm, and up to 3 mm in vuggy areas[1], also suggests extrusive or hypabyssal crystallization for these rocks. Crystallization probably took place at depths greater than a few centimetres and no more than two kilometres. The total pressure, which was equal to the gas pressure in the vesicles and vugs of the Apollo 11 rocks, was therefore between 0·01 and 100 atmospheres.

The assemblage iron-troilite-ilmenite has been tentatively identified in the lunar holocrystalline rocks[1]. This assemblage places restrictions upon both the p_{O_2} and p_{S_2} of the rock, and the gas in the voids, provided that equilibrium conditions prevail.

Webster and Bright[2] determined $p_{O_2} = 10^{-12 \cdot 4}$ to $10^{-13 \cdot 0}$ as the stability range for the assemblage iron-ilmenite at 1,200° C. Assuming a slope of 1 log unit per 100°, this range becomes $p_{O_2} = 10^{-13 \cdot 1}$ to $10^{-13 \cdot 7}$ at 1,127° C (1,400 K) and $p_{O_2} = 10^{-14 \cdot 1}$ to $10^{-14 \cdot 7}$ at 1,027° C (1,300 K). These temperatures bracket the solidification range of terrestrial basalts and probably that of the lunar rocks also. Although the lunar melts may have reached much higher temperatures, p_{O_2} and p_{S_2} were not controlled until all members of the assemblage iron–troilite–ilmenite had crystallized.

Solid solution of Ni in the Fe would raise the allowable oxygen pressures. Ni is a very minor constituent of the lunar samples, however – 320 p.p.m. or less in all of the published holocrystalline rock analyses[1], and less than 1 p.p.m. in over half of them. The effect of Ni will therefore be neglected.

Table 1. PARTIAL PRESSURES AND PARTIAL PRESSURE RATIOS OF IMPORTANT GASES IN THE PRESENCE OF GRAPHITE

	1,300 K		1,400 K	
Log p_{O_2}	−14·1	−14·7	−13·1	−13·7
Log (p_{H_2O}/p_{H_2})	+0·01	−0·29	−0·20	−0·50
Log $(p_{CH_4}/p_{H_2}{}^2)$	−2·11	−2·11	−2·37	−2·37
Log p_{CO}	2·05	1·75	2·22	1·92
Log p_{COS}	−1·68	−1·98	−1·36	−1·66
Log p_{CO_2}	1·82	1·22	1·69	1·09

Data for the free energy of formation for FeS given by Larimer[3] yield $p_{S_2} = 10^{-5 \cdot 8}$ at 1,400 K and $p_{S_2} = 10^{-6 \cdot 6}$ at 1,300 K for the assemblage iron-troilite.

The gas in the voids is assumed to be composed of the elements H, C, N, O, S and the noble gases because no other volatile elements are likely to have been sufficiently abundant to contribute appreciably to the total gas pressure. The formation equilibrium constants tabulated in the Janaf tables[4] for the gaseous species involving these elements allow pressures of these species to be calculated from the known values of p_{O_2} and p_{S_2} and assumed pressures for the other elements. Only a small number of gaseous species, H_2, H_2O, N_2, CH_4, CO, COS, CO_2 and noble gases, can have pressures exceeding 1 per cent of the pressure of the constituent elements in the interval 1,300–1,400 K and 0·01–100 atmospheres total pressure. The pressures of the various gases, neglecting the noble gases which form no compounds, are given in Table 1, assuming graphite to be present.

In the presence of graphite, the total of p_{CO} and p_{CO_2} is 73–178 atmospheres at 1,300 K and 95–215 atmospheres at 1,400 K. The pressure range at each temperature reflects the range in possible p_{O_2}. These $CO + CO_2$ pressures correspond to a cover of 1·5 to 4·5 km of lunar mare material. It is unlikely that much of the material on the lunar mare surfaces crystallized at such great depths. Graphite is therefore unlikely to have been a stable phase in the lunar samples at these high temperatures. Although graphite could become stable at lower temperatures, the amount of carbon which could be precipitated from the trapped CO and CO_2 is exceedingly small and is probably not detectable. With the restriction that $p_{CO} + p_{CO_2}$ does not exceed the total pressure, COS cannot exceed 1 per cent of the total pressure. In the absence of graphite, the tabulated data may be simplified as shown in Table 2.

Table 2. PARTIAL PRESSURE RATIOS OF IMPORTANT GASES IN THE ABSENCE OF GRAPHITE

	1,300 K		1,400 K	
Log p_{O_2}	−14·1	−14·7	−13·1	−13·7
Log (p_{H_2O}/p_{H_2})	+0·01	−0·29	−0·20	−0·50
Log $(p_{CH_4}/p_{H_2}^2 p_{CO})$	−4·16	−3·86	−4·59	−4·29
Log (p_{CO_2}/p_{CO})	−0·23	−0·53	−0·53	−0·83
Log p_{CO} ≤	2·05	1·75	2·22	1·92

The pressures of N_2 and the noble gases are not restricted by any important gaseous reactions. Several conclusions may be drawn from these data: (1) Graphite is stable only at total pressures above about 70 atmospheres and is therefore probably absent from the Apollo 11 samples. (2) Only H_2, H_2O, N_2, CH_4, CO, CO_2, and noble gases are likely to contribute significantly to the vesicle gas pressure. (3) H_2 is more abundant than H_2O and CO is more abundant than CO_2, as would be expected in a highly reducing environment. (4) CH_4 can only be a significant constituent at the higher pressures. (5) N_2 and the noble gases are not significantly restricted by gaseous reactions.

Meteoritic Spherules in the Soil surrounding Terrestrial Impact Craters

ANALYSES of lunar material returned by the Apollo missions[1] will raise many questions regarding the formation of splatter particles distributed about the lunar surface by meteoritic impacts, and we report here some results of our searches for and studies of microscopic (10–300 μm) meteoritic particles in the soil surrounding five terrestrial meteorite craters: Sikhote-Alin, Canyon Diablo, Odessa, Boxhole and Henbury. Our aim was to search for particles that had their origin in the cratering process and to investigate their chemical and physical properties. Because of the difficulties of identifying small particles in soil samples, we have limited our attention so far to the magnetic component. Thus our results bear only on the problem of the formation of impact particles from iron rather than from stony meteorites and that contain at least some material from the parent meteorite. We do not report here any information relevant to the problem of the nonmeteoritic impact products or those produced by impacts of chondritic meteorites. It should be noted that virtually all recognized impact craters on the Earth are produced by iron meteorites, a fact that apparently can be ascribed to the greater erosion rate for chondrites, both in interplanetary space and in the terrestrial atmosphere. The lunar surface is expected to show a greater percentage of chondritic craters than is found on Earth.

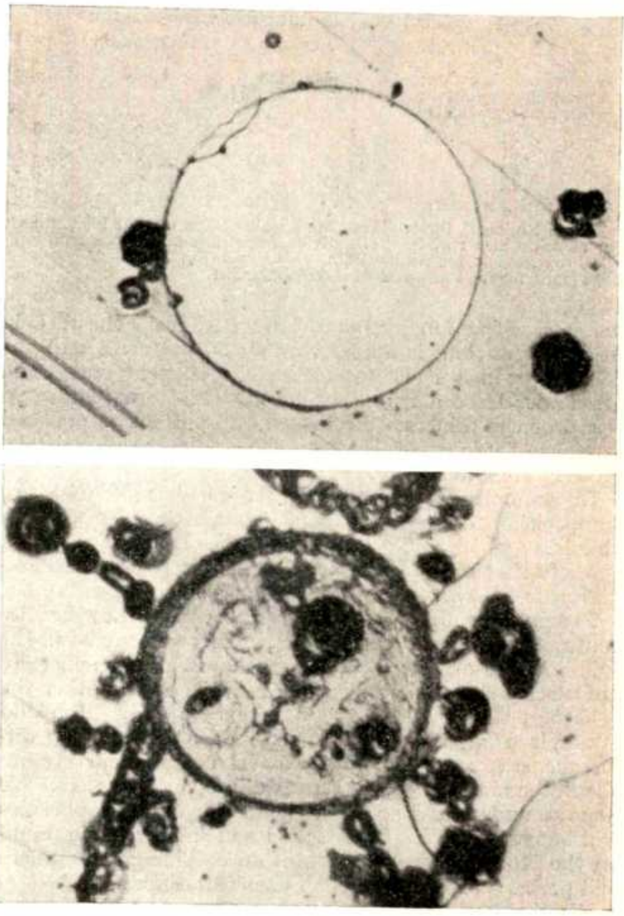

Fig. 1. Photomicrographs of polished sections of two meteoritic impact spherules from the Henbury craters. Top: a typical particle (170 μm diameter) of composition (a) (Table 1); bottom: a particle (150 μm diameter) of composition (b). The black areas (bottom) are cavities in the particle and spots made by the probe beam in the epoxy of the mount.

Table 1 summarizes the results of chemical analyses of meteoritic spherules from the soil surrounding the Henbury and Sikhote-Alin craters. For the Odessa craters we have not found any spherules, and those found in our Boxhole samples have not been completely analysed. (A preliminary report was given by P. W. H. and F. W. R. at the thirtieth annual meeting of the American Meteoritical Society, 1967.) Chemical analyses are by electron microprobes either at the Smithsonian Astrophysical Observatory or at the Advanced Metals Research Corporation. For comparison, similar particles from the Canyon Diablo craters are also described in Table 1; for them we have quoted chemical compositions reported from gross chemical analyses by Nininger[2] and by Mead, Littler and Chao[3]. For the Sikhote-Alin craters, we give data taken from our previous reports[4,5] on particles supplied to the Smithsonian Astrophysical Observatory by Krinov.

The spherical particles found in the soil near the Sikhote-Alin and Canyon Diablo craters are very different from those from the soil of the craters at Henbury. The former are almost purely metallic and/or iron oxide, while the latter are a mixture of iron and nickel from the meteorite and other elements from the soil. In the case of the Henbury samples, the spherules are divided primarily into two chemical families—one in which the

† Figures for the two principal chemical families.

meteoritic fraction by mass, estimated from the nickel–iron composition, is approximately 20 per cent, and another in which it is approximately 10 per cent. The remainder have a composition that can be explained in terms of the minerals in the soil. Fig. 1 shows polished sections of two spherules from the Henbury samples, one of each chemical type.

In comparing the analyses of our spherules with the composition of the Henbury meteoritic glass[6], large chunks of which make up a layer at the Henbury craters[7], we note that our spherules are significantly richer in iron and nickel than is the meteoritic glass.

In summary, we find for three crater areas that spherules containing iron and nickel from the meteorite exist in the soil. At two of these crater sites, however, the spherules are mostly metallic or iron oxide, while at the other the spherules show a mixture of meteoritic nickel–iron and minerals from the soil. The reason for this striking difference is not known, and we feel that similar studies should be made of other terrestrial meteorite craters. We hope an understanding of the production of these spherules will be useful for study of particles of similar origin found on the Moon, where the lack of an oxidizing atmosphere will perhaps provide the chief chemical differences.

We thank F. L. Whipple for support, J. A. Wood and Janice F. Bower for help with the electron-probe analysis, and the National Aeronautics and Space Administration for partial support through a grant to the University of Washington.

Retro-reflexion

THE article by J. A. Howard[1], "Increased Luminance in the Direction of Reflex Reflexion—a recently observed Natural Phenomenon", is no doubt interesting. It may, however, be useful to point out that this "recently observed phenomenon" is identical with the *heiligenschein*, extensively discussed in the classical book of Pernter–Exner, *Meteorologische Optik*[2], with several references to earlier reports. The first observation goes back to Winterfeld[3] (1804), which can hardly be called "recent". A brief description is also found in my book[4].

The aureole around one's shadow is especially bright on a bedewed lawn, but it can also be observed on most other backgrounds. It has been noticed around the shadow of a balloon and lately Professor F. Whipple and others have seen it also from an aircraft[5]. Really recent is the recognition of the *heiligenschein* on the Apollo films and photographs. Two reports of Pohn and Wildey have already appeared[6,7] where the effect is quantitatively measured.

It is, after all, only the opposition effect, studied many times on objects of planetary astrophysics: Saturn's rings[8], the zodiacal light[9], the planetoids[10] and the Moon[11].

It would seem useful to compare and to combine all these various manifestations of the same fundamental and well understandable phenomenon.

Wall Precursor Effects in Gaseous Detonation

THE response of electric probes in the region ahead of ionizing shock waves has been known for some time[1]. The distances over which precursor signals have been obtained are striking; they may vary from a few millimetres to more than one metre ahead of the shock[2]. Various explanations of electrical precursors have been proposed: (1) diffusion of electrons ahead of the shock front from the ionized region behind the front; (2) photoemission from the probe or tube wall; (3) photoionization of the upstream gas[1,3,4]. Although these explanations may well apply in certain circumstances, results of the work described here suggest that at least in some cases so-called precursor effects may be due to electrostatic charging of the shock tube walls by lateral diffusion of electrons from the shock-generated plasma.

Cylindrical brass probes, 1 mm diameter and 5 mm long, were used in an investigation of electrical phenomena in stoichiometric oxyhydrogen detonations produced in a 4 m long stainless steel tube of hexagonal cross-section. The distance between parallel faces was 25·4 mm. To facilitate removal for cleaning and renewal, the probes were sealed into 'Perspex' inserts which in turn were set

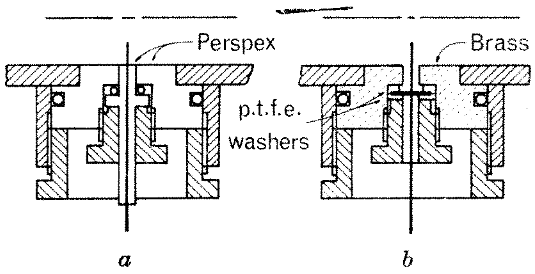

Fig. 1. *a*, Original probe holder. *b*, Modified probe holder.

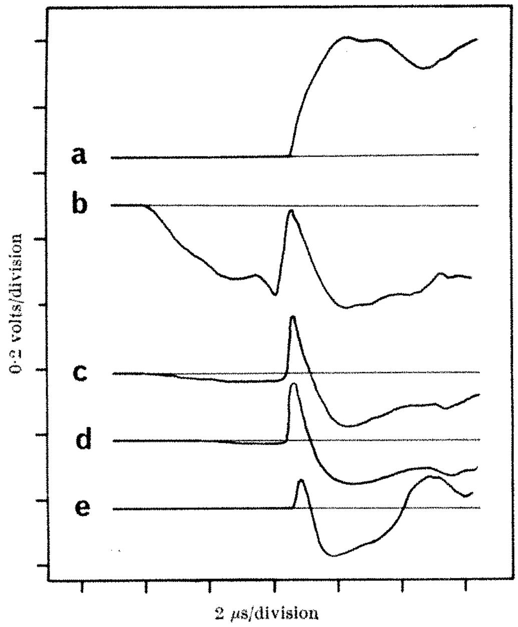

Fig. 2. Probe responses: *a*, double probe; *b–d*, single probe (cleaned before *b* only); *e*, modified probe.

into 'Perspex' windows. The windows replaced one face of the hexagonal tube for a distance of 25·4 mm as shown in Fig. 1*a*. The signal developed across a 10 kΩ load resistor connected between the probe and the earthed tube wall, which acted as a reference electrode, was observed by means of a Tektronix 551 oscilloscope. Two additional probes, separated by 1 mm, were positioned diametrically opposite the single probe and a potential of 1·5 V in series with a 10 k resistor applied between them. This double probe, which was insulated from the tube wall, recorded the time of arrival of the detonation plasma at the plane of observation. Only when both the probes and insulating surfaces were cleaned were reproducible results obtained.

Fig. 2*a* records the response of the double probe indicating the arrival of the detonation plasma at the probe position. Curves *b–d* record typical signals obtained from the single probe immediately after cleaning, and from succeeding identical detonations without cleaning in between. It may be seen that the cleaned probe responds some 4 μs before the arrival of the plasma, exhibiting a pronounced negative precursor signal. In subsequent detonations this precursor progressively disappears. The duration of the precursor signal was found to correspond to the transit time of the detonation wave (velocity 2·9 km s^{-1}) over the surface of the insulator. The influence of the insulator surface on the precursor signal was confirmed by using the modified probe holder shown in Fig. 1*b*. Here the plasma only makes contact with the insulator several microseconds after reaching the probe. With this type of probe, the response of which is shown in Fig. 2*e*, no "precursor" was ever observed in oxyhydrogen detonations.

A net negative charge is always established on insulating surfaces in contact with a plasma so as to ensure zero ambipolar current[5]. As the detonation plasma moves across the surface of the insulating section of the tube wall the insulator becomes progressively charged. While the advancing charge is being established the probe experiences an increasingly negative electrostatic field. It is thus driven to progressively greater negative potentials. The positive excursion on the arrival of the detonation at the probe has been investigated in detail and will be described elsewhere. Provided the surface charge is not disturbed, subsequent detonations are able to add little additional charge and so the precursor effect is diminished. Cleaning the insulator serves to remove this surface charge, allowing the maximum charge to be established by the succeeding detonation. The accumulated charge may also be removed by placing the exposed surface in contact with a bath of mercury. After such treatment the maximum precursor signal is obtained from the subsequent detonation regardless of the number of detonations that had preceded the immersion of the insulator. A similar procedure was used to show that possible charging of the insulator surface during cleaning had no significant effect in the production of the precursor.

Although many precursor signals can no doubt be adequately explained by the theories quoted here, the present findings show that an insulating surface can give rise to similar effects. This could be of particular importance to shock studies carried out in glass-walled shock tubes; in the case of metal shock tubes spurious precursor signals of the type discussed in this paper can be completely suppressed by a suitable design of probe holder.

Self-induced Transparency and Dispersion Delays in Potassium Vapour

SELF-INDUCED transparency[1] first demonstrated in ruby[2] was subsequently reported[3] observed in gaseous SF$_6$. We wish to report the observation of this nonlinear transparency effect in the propagation through potassium vapour of coherent pulses of an organic dye laser, tuned to resonance with the λ7699 Å (ground state $4S_{1/2}$–$4P_{1/2}$) transition. Because linear and nonlinear dispersion delays may be confused with delays arising from self-induced transparency[4,5] we have also investigated dispersion effects at frequencies away from resonance. The dye laser frequency can be readily tuned[6] to resonance with transitions between single pairs of energy levels coupled to the laser field by dipole matrix elements, so complexities arising from degenerate transitions[5] are avoided. Dye lasers covering the spectral range 3000 Å to 11,000 Å are now available and nonlinear coherent pulse propagation effects can thus be studied in many absorbing atomic vapours with our experimental arrangement which does not depend on the chance coincidence of a gas or solid-state laser frequency with a suitable electric-dipole transition in the material[2,3].

The apparatus is shown in Fig. 1. A mode-locked ruby laser, producing a train of 1 ns 100 MW peak power

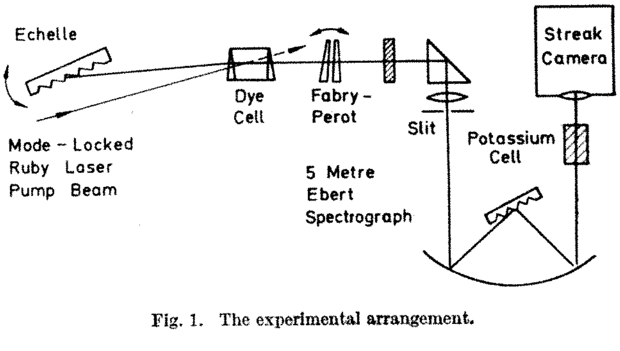

Fig. 1. The experimental arrangement.

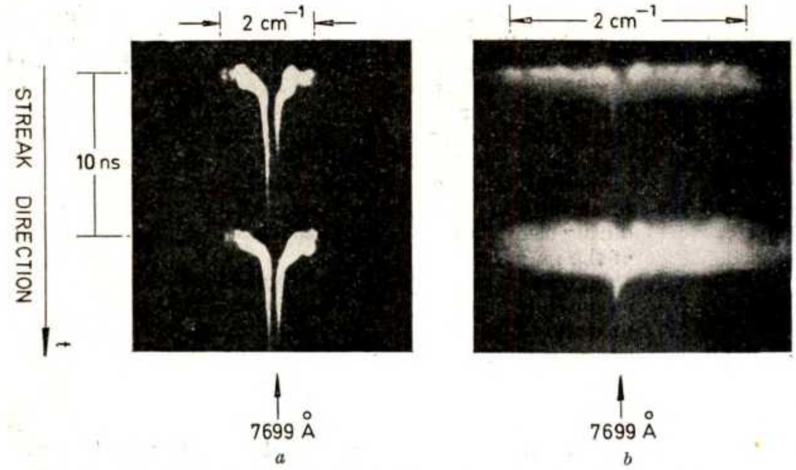

Fig. 2. *a*, Streaked dye laser spectra showing linear dispersion delays. Separation between pulses is 10 ns. Potassium cell temperature of 150° C corresponds to $N \sim 2 \times 10^{13}$ cm^{-3}. Laser power at cell ~200 W per pulse. *b*, Self-induced transparency delays for $N \sim 5 \times 10^{11}$ cm^{-3}. Laser power at cell ~3 kW per pulse.

pulses, pumped, in the near longitudinal configuration[6], a matched dye laser cavity[7]. A rotatable echelle diffraction grating reflector provided both narrowing and tuning of the dye laser output spectrum. Using a 10^{-4} M solution of 1,1′ diethyl-γ-cyano 2,2′ dicarbocyanine tetrafluoroborate in pyridine in a 3 cm wedged-window cell, a train of 1 ns 5 MW pulses at intervals of 10 ns was obtained.

Inserting in the dye laser cavity a tilted Fabry–Perot etalon of plate reflectivity 65 per cent and free spectral range 1 cm^{-1} results in a narrowing of the 2 cm^{-1} wide spectrum of these pulses into two spectral components separated by the interferometer free spectral range and each of width $\sim 5 \times 10^{-2}$ cm^{-1} (ref. 8). With the interferometer tilted at $\sim 10^{-2}$ radians to the output mirror, accurate frequency tunability and stability to $\pm 2{\cdot}5 \times 10^{-2}$ cm^{-1} were obtained. The dye laser spectrum was focused on a 30 μm slit of a 5 m Ebert echelle spectrograph (dispersion 3 mm per Å and limiting resolution $1{\cdot}5 \times 10^{-2}$ cm^{-1}). A 6 cm path length potassium vapour cell was placed inside the spectrograph 50 cm in front of the focal plane. This position improved both the laser beam uniformity at the cell and the overall optical efficiency. Time resolution was achieved by streaking the spectrum with an image tube camera recording on 3,000 ASA polaroid film.

With a potassium cell temperature of 150° C (inhomogeneous line width 3×10^{-2} cm^{-1}) and the 2 cm^{-1} spectral width output of the dye laser (peak pulse power at the potassium cell ~200 W) we obtained streaked spectra as shown in Fig. 2*a*. It can be seen that the pulse delays increase rapidly as the frequency approaches resonance with the λ7699 Å transition, becoming > 10 ns at $7{\cdot}5 \times 10^{-2}$ cm^{-1} from exact resonance. At this point the streaked pulse intensity falls below the polaroid threshold. These delays are just those to be expected from linear dispersion theory[9]. It can be easily shown that far from resonance the small signal pulse delay is

$$\tau_D = \frac{\pi N e^2 f l}{mc}\,\frac{l}{(\omega_0 - \omega)^2} = S(\omega_0 - \omega)^{-2} \qquad (1)$$

where l is the path length, N is the particle density, f is the oscillator strength and ω_0 is the resonance frequency of the potassium transition. For potassium vapour at 150° C, $N \simeq 2 \times 10^{13}$ cm^{-3}, $f = 0{\cdot}33$ and $l = 6$ cm gives $S \simeq 10^{12}$ s Hz^{-2}. An experimental plot of pulse delay τ_D as a function of $(\omega_0 - \omega)^{-2}$ gives a slope of $2{\cdot}5 \times 10^{12}$ s Hz^{-2}, in reasonable agreement with the calculated value of S. (The value of N, which is affected by any uncertainty in the cell temperature measurement, is not known to better than this accuracy.) When the laser beam power at the potassium cell was increased by a factor of 25 (to 5 kW) the pulse delays decrease to ~3 ns at $\sim 4 \times 10^{-2}$ cm^{-1} from resonance, with saturation of the absorption.

Reducing the cell temperature to 100° C, corresponding to $N \simeq 5 \times 10^{11}$ cm^{-3}, greatly reduced the dispersive delays as expected from (1), but delays of 2 ns were observed exactly on resonance as shown in Fig. 2*b*. The results obtained with the interferometer frequency narrowed laser beam are shown in Fig. 3. The set of higher frequency pulses on the left were 1 cm^{-1} off resonance and provided time reference points on the streaked spectrum. The spectra of the first and last of the resonance frequency pulses show absorption, while the other pulses show narrow delay tails exactly on resonance. A maximum delay of 4 ns occurred on the second pulse, which was the most intense with ~100 W total power at the absorption cell. The observation of absorption without delay, and delays which increased with pulse intensity, rules out the presence of any simple dispersion effects[9]. The individual pulse duration, τ_p, of ~1 ns satisfies the condition $\tau_p \ll T_2'$ (ref. 2). (T_2', the dephasing relaxation time, is determined mainly by the spontaneous lifetime of 28 ns of the transition.) Calculating the threshold for self-induced transparency from the condition[2,3]

$$2p/\hbar \int_{-\infty}^{+\infty} \varepsilon(t)\,\mathrm{d}t = n(2\pi) \qquad (2)$$

and putting $n = 1$, $p = 7{\cdot}2 \times 10^{-18}$ e.s.u. gives a threshold power of ≈30 W for $\tau_p = 1$ ns for linearly polarized light in a single laser mode. Using the threshold pulse delay

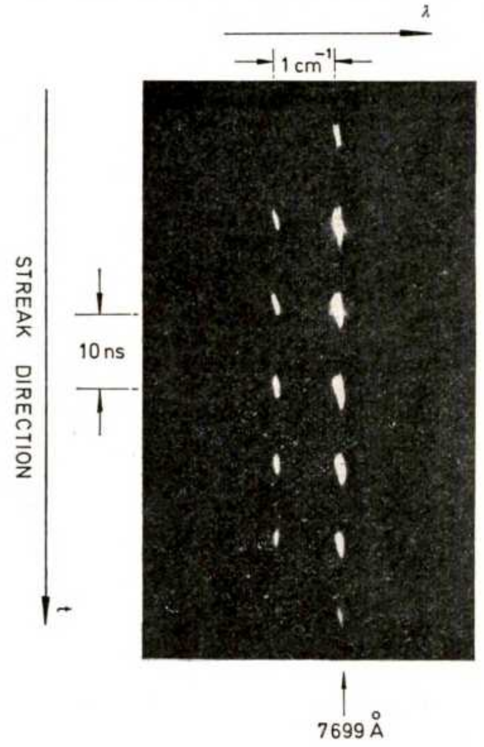

Fig. 3. Self-induced transparency delays with narrow band (5×10^{-2} cm^{-1}) dye laser tuned to resonance with potassium $4S_{1/2}$–$4P_{1/2}$ transition. The second, higher frequency, set of pulses provide time reference points on the streaked spectrum. Pulses are separated by 10 ns. Laser power ~100 W per pulse.

result of McCall and Hahn[2],

$$\tau_D = \alpha l \tau/2 \qquad (3)$$

with α, the small signal absorption coefficient $= 4{\cdot}5$ cm^{-1} ($N = 5\times10^{11}$ cm^{-3}), $l = 6$ cm, and τ, the pulse width, $= 1$ ns, gives $\tau_D = 13{\cdot}5$ ns. Relation (3) was derived assuming plane wave conditions. Any intensity variations across the laser beam, phase modulation or lack of coherence would affect both the output pulse shape and the delay.

These results show that frequency tunable dye lasers have many advantages for experiments involving optical propagation effects including linear and nonlinear dispersion, self-induced transparency and photon echoes[10].

We thank the Science Research Council for the provision of equipment and technical support. Two of us (P. D. S. and G. M. G.) were supported by postgraduate studentships from SRC and the Ministry of Education for Northern Ireland respectively. The special laser mirrors were manufactured by Mr D. Blanc. This work was reported at the Belfast Conference on Nonlinear Optics, September 1969.

Electronic Properties of Well Oriented Graphite

It has recently become apparent that conventional interpretations[1,2] of Hall effect and magnetoresistive phenomena in graphite are consistent neither with one another nor with current ideas on the locations of electrons and holes within the Brillouin zone. Our Shubnikov–de Haas measurements on irradiated pyrolytic and single-crystalline graphite support the reassignment of the positions of the electron and hole Fermi surfaces made by Schroeder *et al.*[3]. We have also obtained evidence that apparent contradictions between the low field Hall coefficients of pyrolytic and single-crystalline graphites[1,2] represent genuine extremes of behaviour. Studies in this laboratory of the anisotropy of the pressure dependence of conduction[4,5] have suggested that electron-hole scattering of majority carriers is more important than carrier–phonon interactions[6–8] in the basal planes, while at the same time the drag effect of majority on minority carriers[9] is unimportant in explaining the low field Hall effect. A potentially confusing situation has thus arisen.

Elegant magneto-optical experiments[3] have shown that the curves of E against $\boldsymbol{k}$ (refs. 1 and 2) as conventionally plotted along the Brillouin zone edge HKH should in effect be inverted so that the Fermi surface centred on K (de Haas–van Alphen period[10,11] about $1{\cdot}6\times10^{-5}$ G^{-1}) encloses electron states, and the two outer Fermi surfaces around H (de Haas–van Alphen period about $2{\cdot}1\times10^{-5}$ G^{-1}) now represent hole states. The assignments of cyclotron masses are also interchanged such that the electron mass is about $0{\cdot}057\ m_0$ and the hole masses range from high values through $0{\cdot}039\ m_0$ at the extremal orbit to about $10^{-3}\ m_0$ at H. The carriers thus comprise heavy majority electrons and holes together with light minority holes.

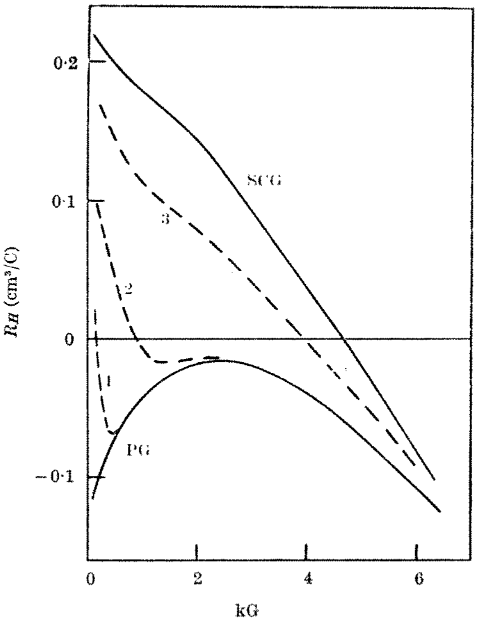

Fig. 1. The low-field Hall coefficient measured in the basal plane at 77 K for single-crystalline graphite (SCG) by Soule[2] and for well oriented pyrolytic graphite (PG) by Spain[1]. The dashed curves 1, 2 and 3 represent three pyrolytic graphites of increasing crystallite size.

The association of majority electrons and holes with the short and long de Haas–van Alphen periods respectively is confirmed by our observations of shifts in these periods induced by light pre-irradiation with fast neutrons (< 10^{17} neutrons cm^{-2} at 30° C). Pre-irradiation produces acceptors which become negatively charged, thus lowering the Fermi energy. According to the conventional (before 1968) band model, the de Haas–van Alphen periods should diverge with increasing neutron dose. In fact, they converge, supporting the new locations of electrons and holes. Furthermore the Dingle temperature of the "new holes" increased more than that for the "new electrons" in agreement with the expectation that negatively charged centres scatter holes more strongly than electrons[12].

These findings necessitate a complete reassessment of the field-dependence of the Hall coefficient. It had been thought[1] that either the low-field characteristics of single crystalline and pyrolytic graphite were fundamentally different, or else one set of data was invalid. Our observations, however, show that if the mean free path in pyrolytic graphite is systematically increased by recrystallization, then the extremes of behaviour can be bridged, as illustrated schematically in Fig. 1 for 77 K.

We conclude that both sets of results are valid, and that the positive (SCG) zero-field coefficient represents long mean free paths, whereas the negative coefficient (PG) results from crystallite boundary scattering.

Using the original (before 1968) version of the effective mass distribution[1,2], the PG result could be easily explained in terms of independent heavy majority carriers and light minority electrons, whereas the SCG result appeared anomalous. Nevertheless, Sugihara[13] managed to account for the positive zero-field coefficient in SCG by introducing a drag effect on the extremely mobile minority electrons by majority holes, thus reversing the sign of their mobility. He found majority electron-hole scattering to be unimportant, at least at the lowest temperatures where the carriers are degenerate. We agree with Sugihara on this last point.

With the new effective mass distribution it is the SCG result which receives a natural explanation on an independent particle model. It is also clear that a reduction of the mean free path will eliminate the strong positive trend at the lowest fields by reducing the mobility of light holes, but an explanation of the strong negative trend now causes difficulty, for here the mosaic boundary scattering which is characteristic of PG precludes the introduction of drag terms. In any event it is unlikely that light carriers which are so strongly influenced by heavy carriers as to have their effective sign reversed will retain a high mobility. It may well be, however, that the general shape of the Hall curves for PG can be interpreted using the majority electron-hole scattering terms which have helped to explain behaviour under pressure of specimens containing charged point defects and mosaic boundaries[4,5] in the nondegenerate region, the essential point being that an attractive elastic scattering event via a screened coulombic field is stronger than a repulsive one[12].

Interaction of Atomic Hydrogen and Nitrogen with Graphite Surfaces

Recent optical studies of the topographical changes occurring at graphite surfaces during oxidation indicate that the cores of non-basal dislocations are often the preferred sites for attack by O_2 molecules[1]. The orientation of the hexagonal etch pits on the graphite basal plane reveal that below 800° C the oxidation rate is faster in the $\langle 10\bar{1}0\rangle$ than in the $\langle 11\bar{2}0\rangle$ directions, whereas the reverse is true above 1,000° C (ref. 2).

Atomic oxygen reacts with graphite to cause pitting uncharacterized by any particular symmetry[3]. In direct contrast to this behaviour, we have observed the formation of regular hexagonal pits on the cleavage surfaces of graphite crystals on exposure of such surfaces to either atomic hydrogen or atomic nitrogen.

Our experiments were carried out with carefully cleaved crystals of Ticonderoga graphite, which were trimmed to approximately 15×4 mm^2 before mounting in the vacuum system. The samples were first degassed in vacuum at 800° C by resistive heating between platinum clips. Purified hydrogen or nitrogen was then passed over the sample at a system pressure of 2 mm, and the temperature of the graphite was measured with an optical pyrometer. The flowing gases were dissociated with a microwave discharge (2,450 MHz) maintained by a cavity[4] located 28 cm upstream from the sample. The cleavage plane of the sample was normal to the flowing gas. During the experiment the gas flow rate, sample temperature and power input to the discharge tube were maintained constant. After termination of the run, the graphite sample was cooled in nitrogen gas and then examined optically with bright field, reflected illumination. No quantitative measurement of the atom concentration in the gas streams was attempted, but our experience suggests that degrees of dissociation of 20–30 per cent may be expected.

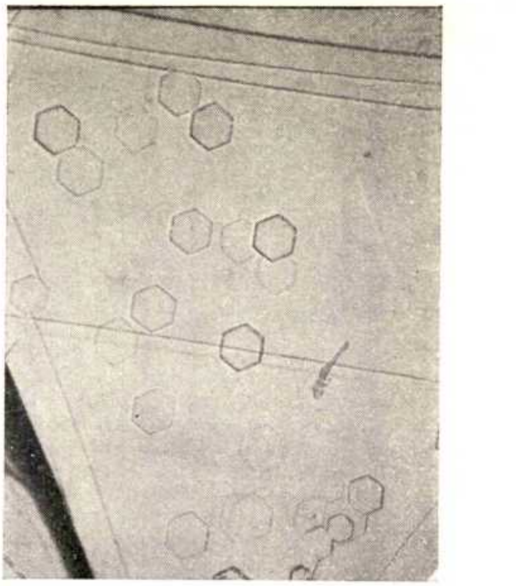

Fig. 1. Hexagonal etch pits of perpendicular orientation produced by atomic hydrogen on graphite crystal at 720° C. × *c*. 130.

Exposure of a sample at 720° C to flowing molecular hydrogen (no discharge) for 8 h produced no observable changes in the surface structure of the graphite crystals. In the presence of the discharge, however, well defined features appeared rapidly on the graphite basal plane exposed to the dissociated gas. Fig. 1 shows hexagonal etch pits formed on the graphite surface at 720° C after exposure to atomic hydrogen for 1 h. The pits were all perpendicular to the $\{11\bar{2}0\}$ twin bands[2]. That is, the sides of the pits consist of $\{10\bar{1}l\}$ prismatic faces. As with molecular oxygen above 1,000° C, atomic hydrogen reacts preferentially at the cores of the non-basal dislocations that thread the graphite crystals, the greatest rate of reaction in the basal plane being in the $\langle 1\bar{1}20\rangle$ directions. Other topographical features elicited by etching with atomic hydrogen include terraced pits, pits within pits, and pits on twist boundaries comprised of *c*-axis screw dislocations. All of these hexagonal pits are of perpendicular configuration.

In the absence of the discharge, an 8 h exposure to flowing nitrogen produced no detectable topographical changes on a graphite surface maintained at 1,100° C. With the discharge switched on, however, hexagonal etch pits were formed in many regions of the graphite basal plane at this temperature. In these conditions the pits developed the parallel orientation, as shown in Fig. 2. The preferred directions of attack in the *a*-plane are along the $\langle 10\bar{1}0\rangle$ directions. The etching behaviour of atomic nitrogen observed here is identical to that observed for diatomic oxygen below 800° C (ref. 5).

The development of macroscopic pits implies that there are significant inequalities in the chemical reactivity of the real, microscopically imperfect graphite surface. With the information now at hand, the nature and relative contributions of all the mechanistic steps that comprise these

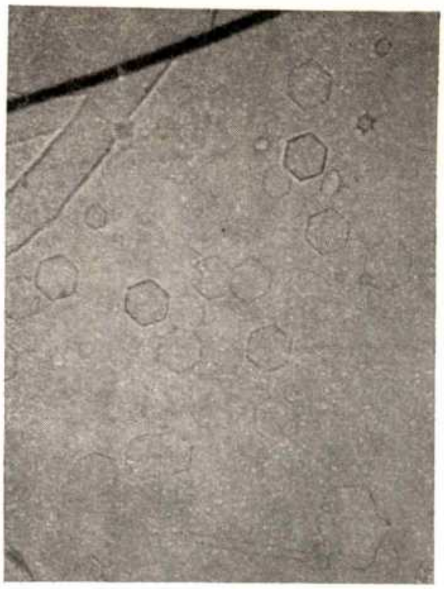

Fig. 2. Hexagonal etch pits of parallel orientation produced by atomic nitrogen on graphite crystal at 1,100° C. × *c*. 130.

reactions are not obvious. The observed differences in the effects produced by atomic oxygen and atomic hydrogen may, however, be tentatively related to the differences in the surface mobilities of these absorbed species. Adsorbed oxygen atoms are believed immobile[3] and adsorbed hydrogen atoms exhibit high mobility on a carbon surface[6]. The behaviour observed here for nitrogen atoms strongly suggests that a mobile layer is involved during the attack on the graphite crystal surface.

Vapour Pressure of $H_2{}^{18}O$ Ice (I) (−17° C to 0° C) and $H_2{}^{18}O$ Water (0° C to 16° C)

WE have measured the vapour pressure isotope effect (VPIE) between $H_2{}^{18}O$ and $H_2{}^{16}O$ ice from −17° C to 0° C and have obtained results in disagreement with those reported by Matsuo and Matsubaya[1]. In order to check our measurements we have also determined the VPIE in the liquid phase and obtained results in good agreement with Szapiro and Steckel[2]. Also we have calculated from the present data an ice–liquid fractionation factor

$$\alpha_{s/l} = (H_2{}^{16}O/H_2{}^{18}O)_{\text{liq}}/(H_2{}^{16}O/H_2{}^{18}O)_{\text{solid}}$$
$$= 1{\cdot}0026 \pm 0{\cdot}0003$$

in good agreement with O'Neil's directly measured value of 1·0030 ± 0·0002 (ref. 3).

Our differential vapour pressure apparatus will be described elsewhere. The samples are contained in a common copper block whose temperature is controlled and measured to 0·001° C. We estimate that the temperature difference between samples is significantly less than 0·0002° C. The pressure differences are measured with a calibrated differential capacitance manometer. The vapour pressure of $H_2{}^{16}O$ water at each temperature can be obtained to sufficient accuracy for the present purpose from standard tables[4], but we have chosen to use a new theoretical relation derived by us which is substantiated by new measurements of the vapour pressure of $H_2{}^{16}O$ ice (results to be published shortly).

The 0·75 cm³ sample of $H_2{}^{18}O$ (H normalized) was kindly supplied to us by Dr G. Jakli of the Central Research Institute for Physics, Hungarian Academy of Sciences, Budapest. Their mass spectrometric analysis gave for oxygen, $^{18}O = 69{\cdot}0 \pm 0{\cdot}5$ per cent, $^{17}O = 1{\cdot}4 \pm 0{\cdot}2$ per cent, ^{16}O by difference. The deuterium concentration was only $1{\cdot}03 \pm 0{\cdot}01$ times normal abundance. The pressure differences were corrected to 100 per cent $H_2{}^{18}O$ assuming Raoult's law and the law of the geometric mean for $H_2{}^{16}O$, $H_2{}^{17}O$, $H_2{}^{18}O$.

In the experiments 71 points were measured in the ice range, 0° C to −17° C, and 40 points in the liquid, 0° C to 16° C, over a ten day period. The two parameter least square fits are

$$\ln(R_{\text{solid}}) = \ln\left(\frac{P_{H_2{}^{16}O}}{P_{H_2{}^{18}O}}\right)_{\text{solid}} = \frac{2{\cdot}110}{T} + 0{\cdot}00656 \qquad (1)$$
$$256 < T < 273$$

$$\ln(R_{\text{liquid}}) = \ln\left(\frac{P_{H_2{}^{16}O}}{P_{H_2{}^{18}O}}\right)_{\text{liquid}} = \frac{13{\cdot}764}{T} - 0{\cdot}03872 \qquad (2)$$
$$273 \leq T \leq 289$$

The calculated logarithms are good to ± 3 to 4×10^{-4} between 0 and −17° C, and to $\pm 2 \times 10^{-4}$ between 0 and 16° C. Our results for ice are thus consistently about 0·002–0·003 ln (R) units above those of reference 1, the only other reported measurements. In the liquid we calculate $\ln(R) = 0{\cdot}0090 \pm 0{\cdot}0002$ at 15° C in agreement with the value $\ln(R) = 0{\cdot}0097 \pm 0{\cdot}0003$ reported by Szapiro and Steckel[2] at the low temperature end of their measurements. Simultaneous solution of (1) and (2) at the melting point gives $\ln(\alpha_{s,l}) \approx \ln(R_{\text{solid}}) - \ln(R_{\text{liq}}) = 0{\cdot}0026 \pm 0{\cdot}0003$ in agreement with O'Neil's value of $0{\cdot}0030 \pm 0{\cdot}0002$. We are thus forced to conclude that Matsuo and Matsubaya[1] are some 20 per cent low in their value for $\ln(R_{\text{solid}})$ $(\alpha_{s,v})$. This is probably due to experimental difficulties arising from their extremely small (10 mg) samples.

A more complete report, including theoretical interpretation, will be submitted for publication in the near future. We acknowledge the financial support of the United States Department of Interior, Office of Water Resources Research, and the Petroleum Research Fund, American Chemical Society.

Pulsatile Flow Instrument for detecting Viscoelasticity in Dilute Polymer Solutions

In very dilute solutions of high molecular weight polymers, turbulent friction may be much smaller than in corresponding flows of the solvent alone[1]. It is widely believed that this drag reduction must be associated with viscoelastic properties of the liquid, but such properties are difficult to detect in very dilute solutions. I describe here an instrument that reveals departures from Newtonian behaviour even with very low concentrations.

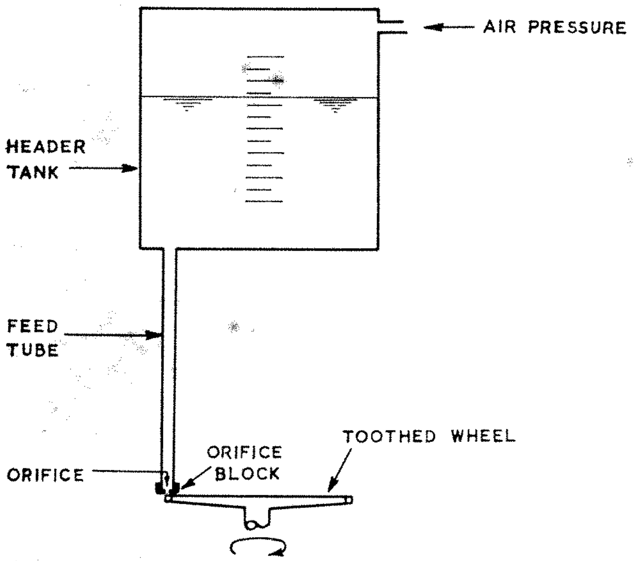

Fig. 1. Diagram of apparatus.

The instrument is sketched in Fig. 1. The liquid flows through an orifice of diameter 0·4 mm, the exit of which is obstructed periodically by a toothed wheel. The wheel has a diameter of 60 mm and 120 square cut teeth with gaps equal to the widths of the teeth. The clearance between the orifice block and the teeth is approximately 0·06 mm. The rate of flow of liquid can be found as a function of wheel speed and applied driving air pressure by timing the passage of the liquid surface in the header tank past graduated marks. The marks that showed the beginning and end of the flow in these experiments were 220 mm and 190 mm above the orifice, representing a flow quantity of $8\cdot7 \times 10^4$ mm^3.

Typical results are shown in Figs. 2–5. Fig. 2 shows the flow times as functions of wheel speed with an applied air pressure of 250 mm of water in addition to the mean gravity head of 205 mm. The results for zero speed correspond to a gap opposite the orifice. With increasing rotational speed the flow times for water at first increase and then decrease slightly. The kink in the curve is associated with liquid leaking between the orifice and the wheel. A relief of pressure occurs, with liquid spurting slightly on to the downstream edge of the orifice block. At zero wheel speed the point for Polyox *WSR* 301 solution is slightly above that for water. With increasing wheel speed the flow times at first increase more than those for water, but decrease markedly between about 1,100 and 1,500 r.p.m. This is associated with spurting, much more marked than for water, of the liquid emerging at the downstream edge of the orifice block. Liquid drops are thrown upwards and backwards from the rotating wheel so that they collect on the top of the orifice block. At higher speeds a narrow jet emerges tangentially from the downstream edge of the orifice block, and spurting ceases. It seems that elastic stresses in the fluid are released as the liquid emerges from under the block.

This behaviour is not critically dependent on mean flow rate. Fig. 3 shows similar behaviour when no air pressure was applied, the flow taking place under the gravity head alone. For more dilute concentrations of Polyox the decrease of flow time occurs at higher wheel speeds. Aged solution has a smaller decrease of flow time, postponed to a higher speed, than fresh solution. Turbulent flow rate measurements in a pipe of bore 1·7 mm, with a flow speed of about 3·3 m/s, showed the aged solution to be considerably less effective for turbulent drag reduction than the fresh solution of the same concentration.

Fig. 4 shows flow curves for other liquids at a pressure of 250 mm of water, as in Fig. 2. The curves for water are a little different in the two figures, possibly because of a slight difference in the clearance between orifice and wheel. Nevertheless, the polyacrylamide *PA* 905, which for a given concentration is a little less effective in reducing turbulent friction than Polyox *WSR* 301, shows a similar, though much less sharp, decrease in flow time at similar wheel speeds. Spurting was also observed at these speeds, though less marked than for Polyox. The whole flow curve for *PA* 905 in Fig. 4, however, is shifted bodily upwards,

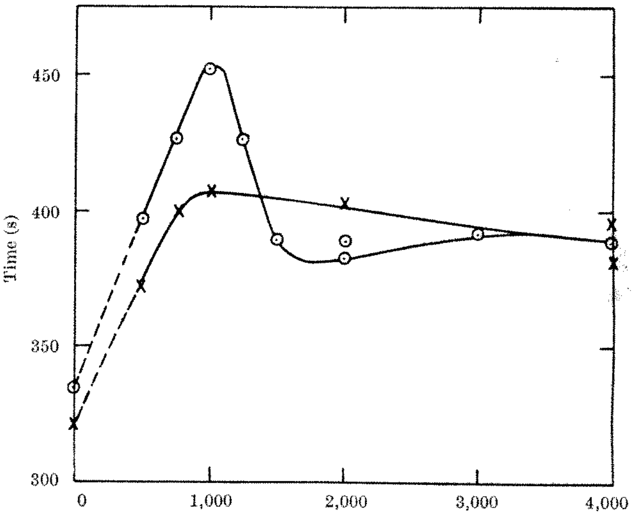

Fig. 2. Results for air pressure of 250 mm water. ×, Water; ○, 46 p.p.m. Polyox *WSR* 301.

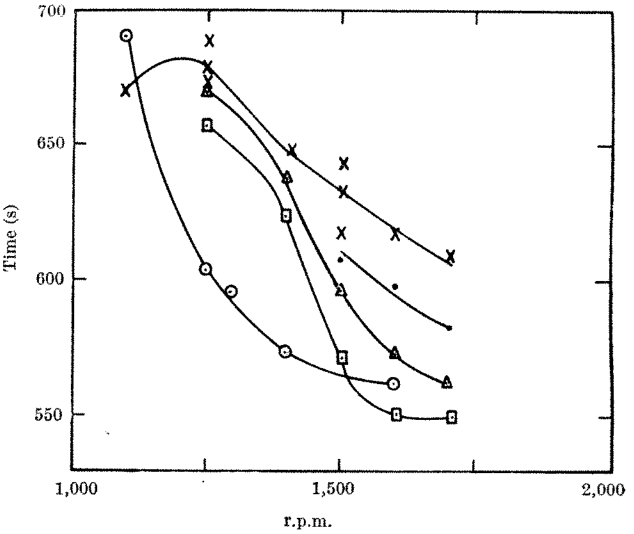

Fig. 3. Results for zero air pressure with Polyox *WSR* 301 solutions. ×, Water; ●, 2·3 p.p.m.; △, aged 23 p.p.m.; □, 23 p.p.m.; ○, 46 p.p.m.

and at zero rotational speed the polyacrylamide produces a far greater resistance to flow through the orifice than Polyox. It has been suggested[2] that such a resistance to extensional flow might be the cause of turbulent drag reduction, but this idea seems to be inconsistent with the relatively small effect of Polyox at zero wheel speed.

The micellar solution of cetrimide and α-naphthol, though effective at reducing turbulent friction at low wall shear rates[3], has a different type of flow curve, with no marked spurting. The shear rates are possibly too high for viscoelastic effects to be evident.

The guar gum solution in Fig. 4 shows a decrease in flow time at higher wheel speeds than for Polyox, as confirmed in more detail in Fig. 5. The flow curve is similar to the curves for Polyox in Fig. 3, though shifted upwards. This behaviour is associated with spurting which begins at about 1,800 r.p.m. A minimum flow time occurs at about 3,500 r.p.m., when there is a pronounced tangential jet flow. The corresponding minimum time for 46 p.p.m. Polyox takes place at about 1,500 r.p.m. The ratio of the two speeds, 7/3, is smaller than the ratio of the threshold wall shear stresses τ_{WC} for the onset of drag reduction[1] in Polyox and guar gum solutions. Lowe's measurements[4] for Polyox *WSR* 301 thus show τ_{WC} to be about 6·5 dyne/cm^2 for 2 p.p.m., decreasing to 1·5 dyne/cm^2 for 35 p.p.m. For guar gum, White[5] finds a value of about 24 dyne/cm^2. Evidently, therefore the wheel speeds for spurting flow in the present experiments do not correspond directly to dominant turbulent frequencies (proportional to wall shear stress) in the wall layer region at the onset of drag reduction. The viscoelastic effects in my experiments may, however, be associated, not with the frequency of passage of teeth past the orifice but rather with the impact of individual teeth on the emerging jet, like the effects that Metzner[6] noted. The maximum impact pressures might be expected to vary roughly as the cube of the speed, as in the experiments of ref. 7, because of the cushioning effect of the entrapped air carried around by the teeth. If turbulence dynamic pressures at drag onset, proportional to τ_{WC}, are compared with the cube of wheel speeds for spurting flow, the correlation is fair. In any case, these speeds are in the same order as the threshold shear stresses for turbulent drag reduction onset, so that my findings suggest that drag reduction occurs when turbulent frequencies close to the wall become high enough for viscoelasticity to affect the turbulence.

Visualization of Spiral Motion in Curved Open Channels of Large Width

The difficulty of recording spiral motion in curved open (river) channels and of visualizing the secondary currents at a cross-section of a bend, particularly when the stream is very wide, has led to differing, and sometimes contradictory, conclusions on the behaviour of flow around bends. Indeed, some observations on sand movements around river bends[1] seem to reject the very existence of spiral motion.

This report describes a method of observing motions in two laboratory open channels of 180° bends, each of different curvature and width. The secondary currents (which are mainly responsible for forming the spiral motion) were made visible and recorded by a photographic technique[2]. The narrow channel was 25·5 cm wide (denoted by b) and 202 cm central radius of curvature (r_c); the wide channel was of $b = 61$ cm and $r_c = 183$ cm. Fig. 1 represents a general layout of the apparatus.

Photographs of the secondary currents were taken using exposures at two cross-sections, and at two depths of flow ($h = 7·6$ cm and 3·75 cm). The patterns of secondary flow at these cross-sections were recorded by photographing in a direction perpendicular to the cross-section concerned, illuminated tracer particles having been fed in at the channel entry, Fig. 2. Two tracer agents were used: in laminar flow, a plastic powder, trade name 'Telco' (specific gravity, 0·96; particle size range, 0·1–0·2 mm); in turbulent flow, another tracer agent, consisting of droplets of a mixture of nitrobenzene, olive oil and water (specific gravity = 1). The latter tracer was adopted because its relatively larger particle size reflected more light on to the film. The cross-sections were illuminated by a 1,500 W Phillips 'Lino-lite' lamp through a 2·5 cm slit. The projection of the pathlines of the illuminated particles on the plane of the cross-section gives the pattern of secondary flow. To define the

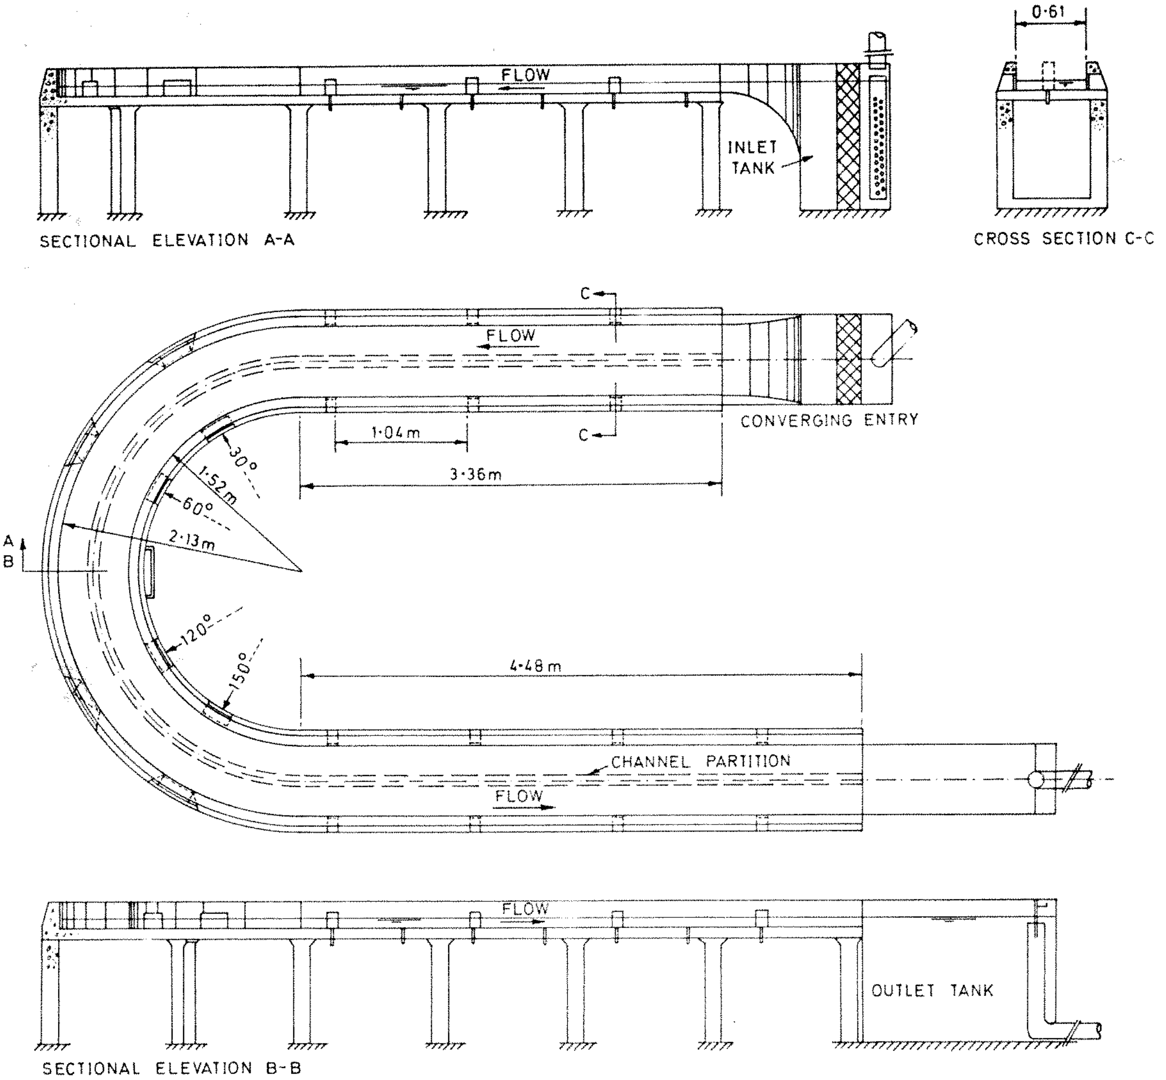

Fig. 1. Plan and elevation of concrete channel.

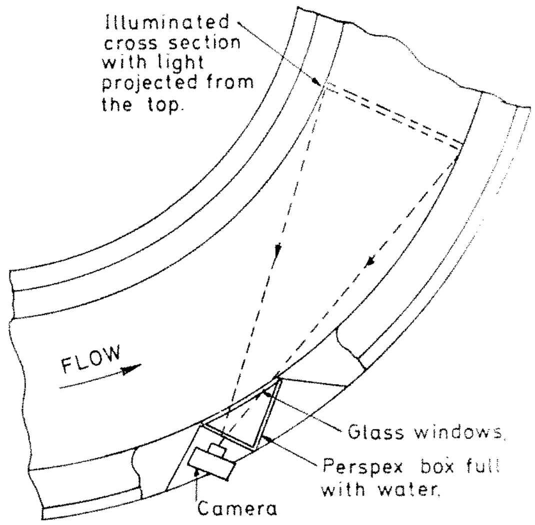
direction of the secondary flow at every point, the rear (upstream) half of the slit width was covered by a strip of unexposed developed negative film, so that the brighter half of a particle pathline image on the picture showed the secondary flow direction at that point. By changing the velocity only, the two depths of flow were studied for different values of Reynolds' number (defined as $\frac{\text{velocity} \times \text{mean hydraulic radius}}{\text{kinematic viscosity}}$). At each Reynolds' number, photographs were made at angles $\theta = 30°$ and $150°$ from the beginning of the circular bend.

In Figs. 3–8 some of the flow patterns at the two cross-sections $\theta = 30°$ and $150°$ for different Reynolds' number are represented.

When the flow is laminar ($R_e = 246$), and at the early region of the bend ($\theta = 30°$) (Fig. 3), there exist a number of vortices (three or four) in the cross-section. At the developed region of the bend ($\theta = 150°$) (Fig. 4), these vortices adjust themselves to show a predominant cell near the middle of the channel width. There is no sign of the single large cell usually assumed to occupy the whole cross-section.

For higher Reynolds' number ($R_e = 2{,}000$), the two vortices existing at $\theta = 30°$ in the narrow channel (there are fewer vortices when the channel width is narrower) (Fig. 5) are also adjusted to show a main vortex at $\theta = 150°$, as represented in Fig. 6.

When the Reynolds' number attains a higher value ($R_e = 6{,}160$), as shown in Fig. 7, the turbulent velocity fluctuations destroy the structure of the spiral motion; in this last case, the radial velocity very near the channel



Illuminated cross section with light projected from the top.

Camera

Fig. 2. Plan of curved channel showing arrangements for photography of secondary currents.

bed and water surface is relatively strong and the effect of turbulence fluctuations in these regions is weak. In the remainder of the flow cross-section, Fig. 7 shows the rather random direction of the secondary flow due to turbulence effects.

For a yet higher value of R_e ($=7{,}910$) and wider channels ($b/h \gg 1$) (Fig. 8), the entire flow cross-section can be considered as a turbulent flow near a flat solid surface, and in this case the turbulent fluctuations have the predominant effect everywhere in the cross-section and no very clear spiral motion exists.

Despite several studies on turbulent flow in straight channels[3], the combined effect of secondary currents due to turbulent fluctuations and those due to channel curvature has not yet been analysed. At this stage, however, the present study (and further investigation which will be published later) concludes that when the aspect ratio of the flow (b/h) increases, the strength of secondary currents, as represented by the flow deviation from the circumferential direction, decreases. In this case the flow pattern in the cross-section tends to break into a large number of spirals and eventually, when $b/h \gg 1$, the

effect of turbulence fluctuations gives the flow pattern a random structure and no spiral motion appears.

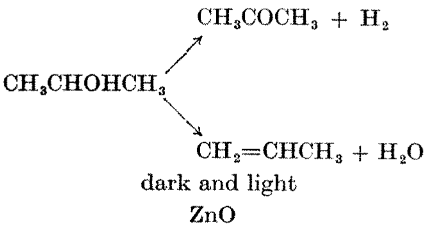
Decomposition of Isopropyl Alcohol photosensitized by Zinc Oxide

In previous investigations the activation energy of a catalytic reaction at the surface of a semiconducting oxide has been shown to depend on the strength of the metal oxygen bond in the surface of the semiconductor[1-8]. In a study of the oxidation of carbon monoxide on NiO, ZnO and Co_3O_4, the density of the bond electrons and the distribution of the electrons in the quantum states of the semiconductor surface bonds had been varied by supporting small grains of the oxides (1000 Å in diameter) on metals of different work functions (Ag, Au, Pd, Pt) and by excitation of the bond electrons by ultraviolet irradiation. The rate determining step of the reaction was found to be the transition of an oxygen atom from the potential valley of a metal oxygen bond (Ni—O, Zn—O, Co—O) in the semiconductor surface into the potential valley of the oxygen carbon bond of the newly formed CO_2 molecule. Because a semiconductor surface bond is destroyed during the rate controlling oxygen transition, the dependence of the activation energy on the strength of the metal oxygen bond is easy to understand.

In order to find out whether this dependence is valid also for a reaction in which no oxygen transition occurs we have investigated the decomposition of isopropyl alcohol vapour on a ZnO catalyst in dark and light conditions.

A dynamic reaction system with an all-quartz reaction vessel was used, containing a ZnO catalyst powder (ZnO colloidal extra, Zinkweiss-Forschungsgesellschaft, Oberhausen, grain diameter 1000 Å) supported on a quartz frit of 50 mm diameter. The catalyst could be illuminated by a high pressure mercury arc (220 V a.c., 300 W, Deutsche Quarzlampengesellschaft Hanau) mounted 50 mm above the catalyst bed. A constant flow of helium (99·995 per cent, Linde) at atmospheric pressure saturated with isopropyl alcohol vapour at 16° C (partial pressure of isopropyl alcohol 26·7 torr) passed continuously through the catalyst powder and was then analysed by a Perkin–Elmer F6/3T gas chromatograph with a Siemens recorder (2·5 mV) and a three column valve (molecular sieve 5 Å, silicagel, carbowax).

In the temperature range from 250° C to 340° C isopropyl alcohol is decomposed in two parallel reactions



$$CH_3CHOHCH_3 \begin{array}{l} \nearrow CH_3COCH_3 + H_2 \\ \searrow CH_2{=}CHCH_3 + H_2O \end{array}$$

dark and light
ZnO

The reactions are observable in both dark and light environments. Both reaction rates are increased on illumination, the dehydrogenation to a smaller extent than the dehydration. No wall reaction is detectable in this temperature range.

By varying the flow rate in the reaction vessel, we have measured the reaction isotherms of both reactions over a wide range of conversion of isopropyl alcohol (up to 80 per cent) in order to establish the kinetics of the reaction. The dehydration was found to be a zero order reaction, the dehydrogenation to be a first order reaction with a strong inhibition by water. Illumination was found to produce no change in the kinetics.

Table 1

	Activation energy, kcalories/mol		Pre-exponential factor, log *A*, torr/s	
	Dehydration	Dehydrogenation	Dehydration	Dehydrogenation
Dark	39	80	15	30·5
Light	31	65	13	25·7

As is seen from Table 1, the activation energy and pre-exponential factor are affected in the same way. The activation energy of both reactions shows a marked decrease due to illumination. The activation energies of the dehydration, a zero order reaction, are "true" activation energies, whereas the activation energies of the dehydrogenation, a reaction with a strong inhibition, are "apparent" activation energies. Because the heat of adsorption of water on ZnO (25–30 kcalories/mol)[9,10] is incorporated into these values, the "true" activation energies of the dehydrogenation may be smaller.

The main conclusion from the experimental results is that although no transition of oxygen atoms of the ZnO surface bond occurs during the decomposition reactions, the excitation of the surface bonds by light decreases the activation energy of both reactions. The activation energy is again found to depend on the strength of the ZnO surface bond. This may be understood by considering the mechanism. The isopropyl alcohol molecule forms a transition state at the surface with two hydrogen bridges to adjacent oxygen and zinc atoms. The products are then formed by a cyclic electron shift of the transition state (Fig. 1). The formation of the H bridges and the subsequent electron transition depend on the electron distribution in the ZnO surface bond. The surface bonds may be described by a resonance model

$$\mathrm{Zn}^{2+}|\overline{\underline{\mathrm{O}}}|^{2-}\leftrightarrow\mathrm{Zn}^{+}-\overset{\cdot}{\overline{\underline{\mathrm{O}}}}|\leftrightarrow\mathrm{Zn}^{\circ}|\overline{\underline{\mathrm{O}}}|^{\circ}$$

and the bond strength results as a linear combination of the resonance forms[8]

$$\psi_{\mathrm{ZnO}} = a\psi_{\mathrm{Zn}^{2+}\,\mathrm{O}^{2-}} + b\psi_{\mathrm{Zn}^{+}\,-\,\mathrm{O}^{-}} + c\psi_{\mathrm{Zn}|\overline{\underline{\mathrm{O}}}|}$$

Increasing the bond strength (decreasing c) must cause an increase in the activation energy; decreasing the bond strength (increasing c), as, for example, excitation by light,

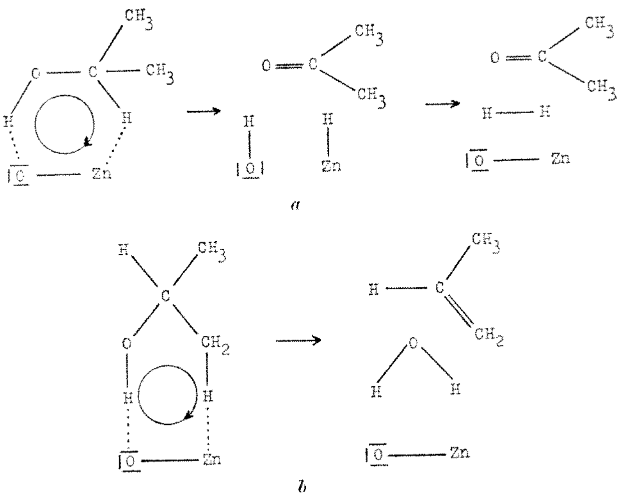


Fig. 1. *a*, Dehydrogenation; *b*, dehydration.

must cause a decrease in the activation energy. The last equation also shows that oxygen desorption from the ZnO surface decreases the bond strength (that is, increases *c*). Because the catalyst is constantly in contact with inert or reducing gases during the reaction, a continuous oxygen desorption from the ZnO surface is observed. This should cause a decrease of the activation energy which in fact is observed. We are now studying this in more detail.

We thank the Deutsche Forschungsgemeinschaft for sponsoring this investigation.

Hückel-level Calculations on the Band Structure of Poly-AT

THE linear combination of molecular orbitals (LCMO) approximation (ref. 1 and unpublished results of R. L. F.) has been suggested as a feasible method for studying the electronic properties of random biopolymers[2]. In the course of some preliminary Hückel-level calculations on random polymers of adenine and thymine we found some interesting behaviour in the energy bands of the polymer, which we report here.

The method[1,2] approximates the wave function of the polymer as a linear combination of the molecular orbital functions of the components. A further simplification is achieved by including only a few of the molecular orbitals from each component in the basis set for the polymer. The Hückel-level calculations reported here were based on the Hückel-level LCAO band theory calculations on regular, single-helix polymers by Hoffmann and Ladik[3]. Our method gives essentially the same results as the direct band theory calculations for the bands considered in homopolymers. The key point is that, in the homopolymers, the energy bands have a small spread about the values for the corresponding levels in the isolated components. The energy spread for the highest occupied band of an infinite polymer of either adenine or thymine is approximately 0·10 Hückel β units. The spread for the lowest vacant band is 0·06 β for adenine and 0·02 β for thymine. The result is similar if a heteropolymer is constructed with a regular alternation of units. The band spreads in this case are even smaller. The two highest occupied bands in an infinite polymer of alternating poly-AT have a spread of 0·15 β while the two lowest vacant bands have a spread of only 0·0002 β. This is also confirmed by the band-theory type calculations of Avery *et al.*[4].

When the order of the units in the polymer is random, no such grouping of the energy levels occurs. The energy bands quickly spread so that there is overlapping between the occupied bands. In the present case, the spread in the unoccupied bands is more gradual as the polymer is built up, because of the very small off-diagonal elements between these; there is every indication, however, that these too could overlap for an infinite polymer. Figs. 1 and 2 show this effect. In Fig. 1 a thirty-two unit random polymer is built up. In Fig. 2, four different eight-unit subpolymers are combined in various ways to give larger random polymers of up to thirty-two units. Fig. 3 presents an integrated energy density plot for the bands arising from the highest occupied orbital of adenine and of thymine for an alternating A–T–A–T- - - - - structure and for several different random polymers containing equal numbers of A and T. In such a plot, a band of closely spaced energy levels yields a nearly vertical region on the graph while an energy gap is represented by a horizontal line. This is the behaviour observed for the alternating structure. Perfect crystals also yield this type of plot for energy bands and gaps. A straight sloping line would indicate a uniform energy distribution over the range considered. The points for the random polymers approximate to such a straight line over much of the band. The behaviour found for the random polymers is very similar to that for the energy bands of a one-dimensional, one-component liquid[5] or for those of a one-dimensional, random binary alloy[6].

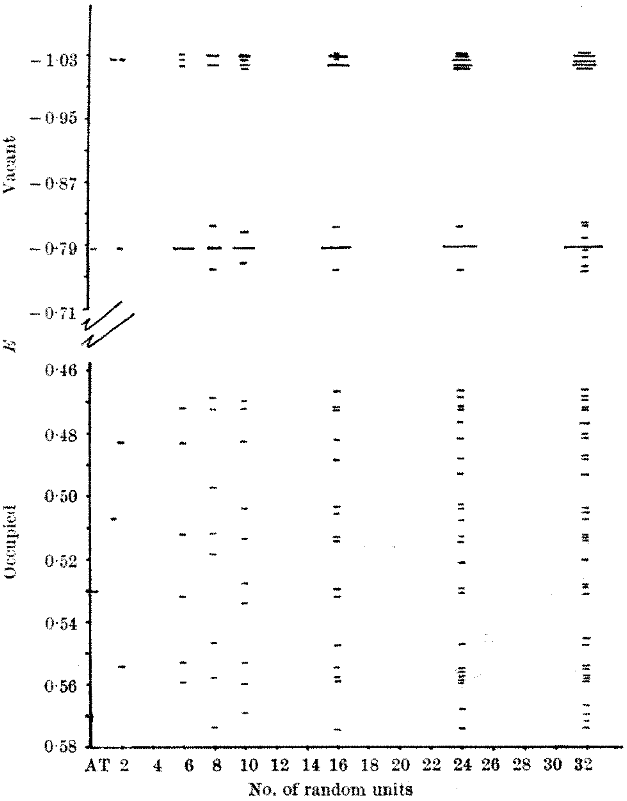

Fig. 1. Energy levels as a function of number of units in a random polymer. Energy unit, standard Hückel β_0. Lengthened lines indicate degeneracies. Order of units (starting at the bottom): ATTAAATTT-ATTATTATTTAATAATTATAAAA.

It has often been suggested that there should be extensive electron delocalization along the chain in biological polymers[7]. This suggestion has previously been justified theoretically by the calculations of Ladik *et al.*[3,4] and Yomosa *et al.*[8]. Such delocalization should have important effects on the electrical and magnetic properties, the optical properties, energy transfer and many other properties of the system. Qualitative discussions of these phenomena can be based on any model that allows delocalization along the chain, and, in many cases, on a perturbation theory treatment of the individual components. The available computational techniques are probably not refined enough to warrant any serious attempt at quantitative predictions of the properties of large polymeric systems. The band shapes we have obtained, however, suggest some ideas that should be considered even in qualitative discussions.

Calculations of optical properties are usually based on perturbation theory or exciton theory. Perturbation theory calculations involve summations of terms that have differences in energy or in powers of energy in the denominator.

$$\text{Property} \propto \sum_{j \neq i} \frac{1}{E_i^n - E_j^n}$$

The terms with energies near the specific energy under consideration are in general most important. Calculations for polymers show that a given electronic energy level occurs within a band of closely spaced energy levels. In a periodic polymer, these bands are narrow and near the energy levels for the isolated components, so that a perturbation theory calculation based on the isolated components should be a fair approximation of such a calculation on the polymer. For a random polymer, on the other hand, the bands are much more diffuse; consequently, the calculated properties should be significantly different from either the isolated component or the periodic polymer. For an infinite polymer, the summation should be replaced by an integration over the energy bands. Because the energy under consideration lies within the energy bands, such integrations would require the use of Dirac delta functions in order to eliminate the singularities as E_j approaches E_i.

Electrical conduction is theoretically described by band theory. Systems having partially filled energy bands are intrinsic conductors. Those with only totally filled and totally vacant bands are insulators or semiconductors. Polymers of the type under consideration fall into the latter category. They can, at most, be semiconductors. If a few electrons are placed in a normally vacant energy band, they can be moved through the system by an external field to achieve conduction. The charge carriers are the electrons. This is said to be n-type conduction. If, however, a few electrons are removed from a filled band, conduction can again occur. The net effect in this case is that the vacancy is the charge carrier. This is said to be p-type (or hole) conduction. In band theory calculations, the electrical conductivity of a system, for a given number of charge carriers, is proportional to $d^2E/d\mathbf{k}^2$ (via the effective mass of the carrier) where $\mathbf{k}$ is the propagation vector in the system. A plot of $E(k)$ against $\mathbf{k}$ (the energy dispersion curve) has the same form as Fig. 3 but with the axes interchanged. The quantity $d^2E/d\mathbf{k}^2$ is equal to the curvature of the dispersion curve. An estimate of the curvature near the band edges of the occupied and vacant bands should thus give a rough indication of whether the system should behave as a better n-type or p-type conductor, assuming an equivalent population or depopulation of the bands could be achieved. From a consideration of our data, it seems that random poly-AT should be a better n-type conductor than p-type.

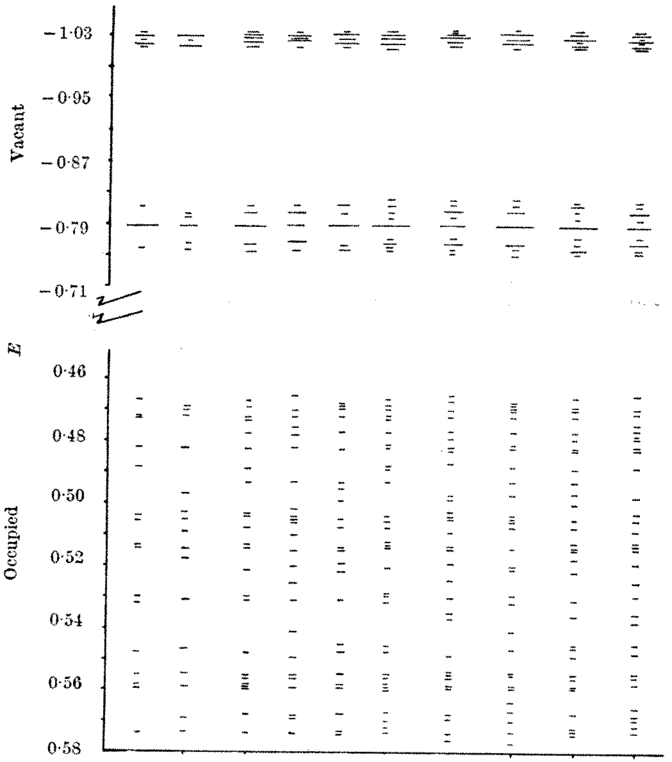

Fig. 2. Energy levels of several different 16, 24 and 32-unit random polymers made from different combinations of basic random 8-unit subpolymers. Energy unit, standard Hückel β_0. Basic subpolymers: (1) ATTAAATT; (2) TATTATTA; (3) TTTAATAA; (4) TTATAAAA.

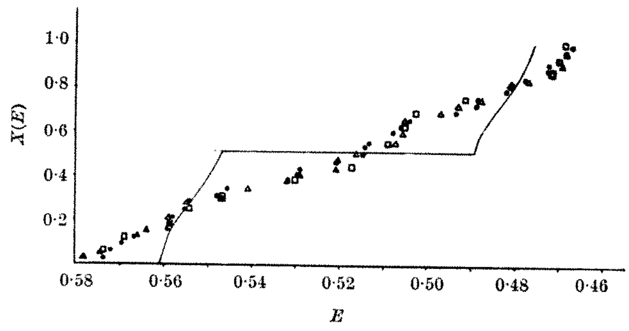

Fig. 3. Integrated energy density for an alternating AT polymer and several random polymers. $X(E)$ is the fraction of levels having an energy less than or equal to E. Energy unit, standard Hückel β_0. Solid curve, alternating AT (32 units); closed circles (1234); triangles (2341); squares (21).

Similar arguments to these can be applied to the theories of energy transfer, magnetic properties, and so on. Work is under way in our laboratory to obtain better wave functions for random polymers so that such discussions can be put on a more sound basis.

One further point. The calculations reported here are for a random ordering of the polymer units, but assume a fixed, rigid geometrical arrangement. Similar results would be obtained for ordered polymer units, but a randomized geometrical arrangement[5]. The forces holding biopolymers in their helical conformations are so weak that it would be expected that, at any instant, there would be a great deal of randomization of the positions of the constituent molecules. The considerations we have presented should thus be valid even for polymers with regular recurrence monomer units.

BIOLOGICAL SCIENCES

Induction of Immunity and Tolerance *in vitro* in the Absence of Phagocytic Cells

In previous reports on the induction of immunological tolerance *in vitro*[1,2] we presented evidence suggesting that specific unresponsiveness is mediated by the direct encounter of antigen molecules with immunocompetent cells. The kinetics of the antigen-dose response *in vitro*[1,2] to H-antigens of *Salmonella adelaide* (polymerized flagellin, POL)[3] suggested that in this antigen system not only tolerance, but also immunity, may result from such direct interaction. This assumption, however, contradicts certain current concepts which regard the macrophage as an essential participant in the induction of humoral immunity to all antigens. In this report, we will describe experiments which help to elucidate some aspects of this situation.

Peritoneal macrophages treated with antigen are thought to participate in immune induction[4–7]. In certain conditions, however, such cells can act as inhibitors of the immune response *in vivo*[1–8] and of antigen induced DNA synthesis *in vitro*[1–9]. This has been substantiated in the following way.

CBA male mice aged 80–120 days were used for all experiments. 10×10^6 peritoneal exudate cells (PEC) containing on the average 60 per cent macrophages as tested by carbon uptake were cultured together with 20×10^6 syngeneic spleen cells using the *in vitro* system described previously[10]. The cells were stimulated with immunogenic levels of POL (20 ng POL/ml.) and sheep erythrocytes (SRC) (2×10^6). Control cultures contained $25–30 \times 10^6$ spleen cells only and both antigens. Cultures were harvested after 4 days and assayed for numbers of antibody forming cells (AFC) to POL and SRC. Inhibition of the *in vitro* immune response by PEC was obtained with both POL and SRC antigens (Table 1).

Table 1. EFFECT OF ADDING PERITONEAL EXUDATE CELLS (PEC) TO CULTURES OF MOUSE SPLEEN CELLS ON *in vitro* AND *in vivo** IMMUNE RESPONSES

	In vitro (4 days of culture) Antibody forming cells per culture (mean ± *S.E.M.*)		*In vivo* (1 day *in vitro*, 7 days *in vivo*) 5×10^6 viable lymphocytes injected Antigen reactive cell foci (mean ± *S.E.M.*)	
Antigen *in vitro*	SRC	POL	None	POL
30×10^6 spleen cells	2,745 ± 245	3,490 ± 787	3·0 ± 0·5	3·3 ± 0·4
20×10^6 spleen cells 10×10^6 PEC	132 ± 37	135 ± 37	1·2 ± 0·3	3·9 ± 0·4

* Adoptive immune responses of mouse spleen cells cultured *in vitro* for 24 h in the presence or absence of peritoneal exudate cells were measured at the level of the antigen reactive cell (ARC). An antigen reactive cell focus produced in the host's spleen is taken as an indication that an ARC has produced a clone of cells secreting specific antibody to polymer of *S. adelaide* flagellin[11].

To test the effect of this inhibitory mechanism on antigen reactive cells (ARC), similar cultures were harvested after 24 h and cells injected intravenously together with 25 μg POL into lethally irradiated syngeneic recipients. Seven days later, recipient spleens were assayed for the number of ARC foci as described elsewhere[11]. Control groups received spleen cells cultured for 24 h in the absence of PEC. The results showed that the presence of PEC during a 24 h period of *in vitro* culture of spleen cells did not irreversibly diminish their content of immunocompetent cells to POL (Table 1).

The inhibition of the immune response *in vitro* could be due to (*a*) competition of macrophages and immunocompetent cells for antigen, (*b*) the secretion of inhibitory substances by PEC, or (*c*) a mechanism requiring direct contact between PEC and spleen cells. Antigenic competition and the secretion of inhibitory substances were excluded by the fact that a normal immune response could be induced by spleen cells cultured with the supernatant from cultures containing spleen cells, PEC and antigen. By culturing PEC and spleen cells in compartments physically separated from each other by a 'Nucleopore' membrane it was further established that PEC did not secrete inhibitory substances but required direct contact with spleen cells to inhibit the immune response.

Because of basic differences in experimental design, our findings on the inhibition of antibody formation *in vitro* by added PEC cannot be regarded as contradictory to other results which showed that these cells[6,7] or their cytoplasmic content[4,5] mediate immunity after exposure to antigen *in vivo* or *in vitro*. They do agree well, however, with the following experiments on the capacity of spleen cells to be immunized or rendered tolerant *in vitro* after removal of phagocytic cells.

Table 2. EFFECT OF REMOVAL OF PHAGOCYTIC ELEMENTS FROM MOUSE SPLEEN CELL SUSPENSIONS ON THE INDUCTION OF IMMUNITY AND TOLERANCE *in vitro* TO POLYMER OF *S. adelaide* FLAGELLIN

	Level of phagocytic cells per cent nucleated cells ± *S.D.*		Immune response in culture (AFC/culture ± *S.D.*)	
	Morphological assessment (macrophages + polymorphs)	Functional assessment (^{125}I-POL labelled cells)	Immunogenic dose (20 ng POL per culture)	Tolerogenic dose (3 μg POL per culture)
Original suspension	5·7 ± 1·9	1·41 ± 0·07	1,835 ± 605	25 ± 9
Filtrate fraction	0·05 ± 0·05	0·05 ± 0·04	1,390 ± 118	20 ± 9
Adherent fraction	13·3 ± 3·3	1·55 ± 0·12	905 ± 110	75 ± 75

Cell suspensions were assayed for the number of antibody forming cells (AFC) after 4 days of culture.

Phagocytic cells were separated from spleen cell suspensions by a modification of the active adherence column of Rabinowitz as described elsewhere (ref. 12, and K. S., in preparation). The separation procedure was monitored by differential cell counts which showed that 99 per cent of macrophages and polymorphonuclear cells had been removed by the separation, and by functional tests for phagocytosis based on the uptake of ^{125}I-labelled POL *in vitro* (Table 2). The small proportion of radiolabelled cells present in the filtrate were lymphocytes and polymorphonuclear cells, but never macrophages. The adherent fraction eluted as described elsewhere[13] comprised polymorphonuclear cells, macrophages and lymphocytes. Cultures containing 12×10^6 viable cells were incubated for 4 days in the presence of either 20 ng or 3 μg POL/ml. culture fluid. An antigen dose of 20 ng is optimal for the induction of immunity *in vitro*, while a concentration of more than 1 μg POL/ml. induces immunological tolerance[1,2]. The cell fractions cultured comprised: (*a*) the filtrate, depleted of phagocytes, (*b*) the adherent fraction, consisting of phagocytes and lymphoid cells, and (*c*) the original unseparated spleen cells as a control. Results in Table 2 gave clear evidence that both normal immunity and immunological tolerance to POL occurred in the absence of phagocytic cells.

These findings provide strong evidence in favour of the hypothesis that both immune induction and immune tolerance to POL are initiated by the direct recognition of antigen molecules by antigen-reactive cells. This recognition is presumably mediated by specific cell surface bound recognition sites and does not require the participation of phagocytic cells. The only parameter which decides whether immunity or tolerance to POL is induced *in vitro* is a quantitative one, the antigen dose. This does not conflict with the possibility that, *in vivo*, the binding of antigen on reticular cells in germinal centres may counteract immunity by tolerance induction, as was suggested by Ada and Parish[13]. Rather it suggests that macrophages may act as a "buffering system" to reduce the concentration of free antigen within the organ to levels too low to induce tolerance in order to favour immunity rather than tolerance.

Our results on immune tolerance contrast with those of Fishman's group[5] and others[6,7,15] who regard the phagocytosis of antigen by macrophages as an essential step in immune induction, and with those of Mosier[16], who demonstrated that the removal from mouse spleen cell suspensions of a macrophage-rich cell population resulted in the loss of immunocompetence on subsequent culture. As we have demonstrated in another article, however[13], and as recently pointed out by others[17], these apparent discrepancies are in fact a reflexion of different cellular mechanisms of immune induction depending on the type of antigen used.

Properties of Protective Malarial Antibody

PROTECTIVE malarial antibody has been demonstrated by passive transfer tests in monkey[1] and human[2] infections and, to a lesser degree, in rodent malaria[3-8]. Such tests have not, however, provided a suitable basis for detailed studies on the mechanism of malarial immunity. It has been shown recently that serum from monkeys immune to *Plasmodium knowlesi* specifically inhibits the cyclical proliferation of this simian parasite maintained *in vitro*[9]. This technique has now been used to obtain information about levels of protective antibody in immune sera, the distribution of such antibody among the major immunoglobulin classes and its mode of action on the parasite. Cultures of *P. knowlesi* were initiated with trophozoites and taken through a 24 h cycle of maturation, division, red cell reinvasion and renewed growth[9]. The average multiplication rate was six-fold in flasks containing normal serum. The course of parasite growth was followed as before by measurement of ^{3}H-leucine incorporation into parasite protein[9].

In the presence of normal rhesus sera, trophozoites and schizonts incorporate ^{3}H-leucine at an approximately linear rate for about 4 h. During parasite division (schizogony) the incorporation diminishes, becomes stationary for about 2 h after red cell reinvasion, and is renewed during the succeeding cycle of parasite development (Fig. 1). Immune serum has little effect on initial intracellular growth, but inhibits the second cycle of development which follows schizogony (Fig. 1). Normal and immune preparations were assayed in flasks containing 0·25 ml. of washed red blood cells with an initial parasitaemia of 0·5–1·0 per cent. The dose-dependent nature of parasite inhibition for one pool of antiserum from monkeys immunized for 17–20 months (Table 1, pool 1) is shown in Fig. 1. In flasks containing less than 0·3 ml. of antiserum increasing proportions of parasites enter a second cycle of development (Fig. 1).

Table 1. DATA CONCERNING IMMUNE SERUM POOLS ANALYSED

Pool No.	No. of donors	Duration of immunization	No. of challenges	Final challenge
1 (27.5.69)	4	17–20 months	11–12	10^8 parasites
2 (17·9.69)	4	17–23 months	10–14	10^8 parasites

For comparison of different immune preparations, dose-response data relating to inhibition of the second cycle of *in vitro* growth were derived from radioactivity measurements at 24 h. The standard inhibitory dose of immune serum was taken as 0·4 ml. of pool 1 (Table 1) because this consistently produced complete suppression of the second cycle of development. The normal increment was the difference between 24 h radioactivity values in flasks containing 0·4 ml. of the immune serum and those containing normal serum (Fig. 1). Radioactivity increments in other flasks expressed as a percentage of the normal showed an approximately linear relationship to dose on a logarithmic plot (Fig. 2). The mean data from four experiments for immune pool 1 (Table 1) and one experiment for pool 2 (Table 1) indicate that both these sera contain titres of protective antibody near the threshold required for inhibition of progressive parasite growth when red cells (0·25 ml., parasitaemia 0·5–1 per cent) and immune serum (0·3 ml.) are mixed in physiological proportions.

Malarial immunity in many species, including the rhesus monkey, develops slowly and is associated with persistence of the infecting organism as shown by periodic low-grade parasitaemia in clinically immune subjects, and the induction of malarial relapse by splenectomy in immune animals. This form of relative immunity, described as "premunition" or "tolerance"[10], may be a consequence of the fact that the intracellular plasmodium has limited access to immunologically competent cells so that protective antibody levels may remain inadequate for

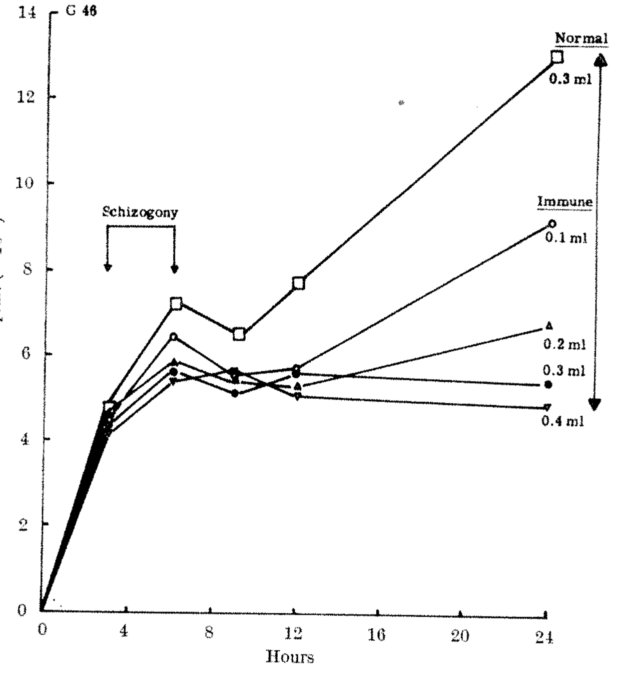

Fig. 1. Incorporation of ^{3}H-leucine by cultures of *P. knowlesi* in the presence of normal serum and various doses of immune serum (pool 1, Table 1). The vertical arrow on the right shows the normal growth increment (see text). The initial parasitaemia was 1·0 per cent and the multiplication rate in flasks containing normal serum was × 6·5. Schizogony denotes the period of parasite division.

Table 2. IgG AND IgM LEVELS IN VARIOUS RHESUS MONKEY PREPARATIONS TESTED FOR ANTIMALARIAL ACTIVITY (SEE FIGS. 2 AND 3)

Preparation	Fractionation method	IgG (mg/ml.)	IgM (mg/ml.)
Normal serum	—	13	0·7
Immune serum pool 1	—	13	0·8
Immune serum pool 2	—	13·5	0·3
Whole Ig	0·4 Saturated $(NH_4)_2SO_4$	13	0·4
$IgG_{(2)}$	DEAE-cellulose—0·015 M phosphate (*p*H 8·0)	13	< 0·1
$IgG_{(1)}$	DEAE-cellulose—0·02 M phosphate (*p*H 8·0)	13	< 0·1
IgM	'Sephadex *G*-200', first peak	< 0·1	0·8
Normal IgG	DEAE-cellulose—0·04 M phosphate (*p*H 6·0)	11	< 0·1

Ig fractions were isolated from pool 1 immune serum.

complete suppression of parasite multiplication even after long infection. This concept is supported by evidence of relatively low titres of protective antibody in serum from monkeys repeatedly immunized for about 2 years. Protective antibody levels are probably also low in human adults exposed to lifelong malarial infection, for passive immunization of African infants required doses of immune adult γ-globulin equivalent to about half the total circulating immunoglobulin pool of the recipient[2].

Various immunoglobulin fractions were prepared from immune rhesus serum by standard methods (Table 2). The IgG and IgM content of these was adjusted to that of the original immune pool (Table 2). Whole Ig (0·4 saturated $(NH_4)_2SO_4$ fraction) simulated the inhibitory effect of the original immune serum (Fig. 3), whereas IgG fractions of fast or slow electrophoretic mobility and IgM had significantly less inhibitory action (Fig. 3). The antimalarial effect of whole immune serum or salt precipitated Ig can be accounted for by the additive effects of IgG and IgM. In accordance with this finding, the inactivation of either IgA or IgE by addition of an excess of specific anti-IgA or anti-IgE sheep sera (the latter serum is known to react with monkey IgE[11]) had little effect on the inhibitory action of the immune serum. Similarly, attempts to inactivate IgE by heating at 56° C for 2 to 4 h produced little change in the activity of the immune serum.

The association of protective antibody with IgM in chronically immunized animals could be attributed to antigenic variability of the parasite. Variants of *P. knowlesi*, distinguishable by a schizont agglutination test[12,13], appear during the course of chronic infections and each might induce a primary immune response associated with IgM antibody[13]. The *in vitro* response to both IgG and IgM was, however, linear over the range investigated and at the highest doses tested IgM produced 40 per cent and IgG 80 per cent inhibition of normal parasite growth. These results suggest that, in regard to the parasite population analysed, IgG and IgM contained protective antibodies of comparable specificities. Persistence of IgM antibody after prolonged immunization has been observed with other particulate antigens[14]. The failure to demonstrate antimalarial activity in monkey IgE is of interest because IgE levels are high in human[15] and monkey[16] parasitic infections and this had suggested a possible protective role for the class of antibody known to be associated with immediate hypersensitivity reactions.

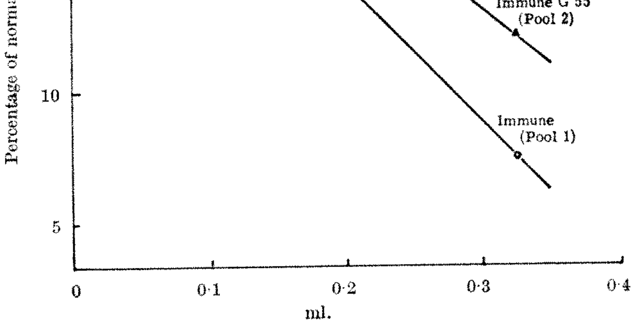

Fig. 2. Dose-response data (see text) for immune sera pools 1 and 2 (Table 1).

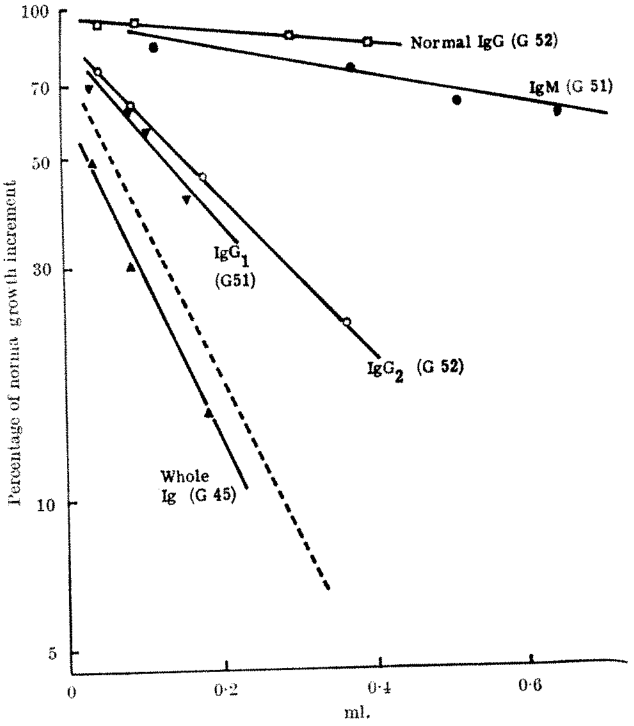

Fig. 3. Dose-response data for immune preparations of whole Ig, IgG and IgM and for normal IgG. Fractions were tested at concentrations corresponding to those of the original immune serum (see Table 2). The broken line shows the response for immune serum—pool 1 (Fig. 2).

Studies on the enzymatic splitting of γ-globulin have provided a means for investigating the molecular basis of various antibody reactions[17]. The role of bivalence and the importance of the Fc fragment in malarial antibody were studied by comparing papain fragments (univalent Fab together with Fc) and peptic fragments (bivalent $F(ab')_2$)[18] of IgG. The immune papain digest had no demonstrable effect whereas divalent $F(ab_1)_2$ fragments simulated the antimalarial action shown by equivalent concentrations of the original IgG (Fig. 4).

It is concluded that protective malarial antibody has many features in common with viral neutralizing antibody[19]. Both seem to inhibit cell reinvasion, act independently of complement, require at least two combining sites to exert their protective action and do not affect the behaviour of organisms already within cells. In the bacteriophage neutralization system, the effectiveness of bivalent as compared with monovalent antibodies[20-22] is not attributable to differences in size[21,22], but apparently reflects the considerably greater affinity of molecules carrying two combining sites[23]. In malaria the agglutinating capacity of bivalent antibody may also be significant for microscopical observation has shown that merozoites liberated into normal serum during schizogony remain discrete before reinvading red cells, but in the presence of immune serum the free parasites tend to agglutinate and fail to penetrate erythrocytes (unpublished data of G. A. B.).

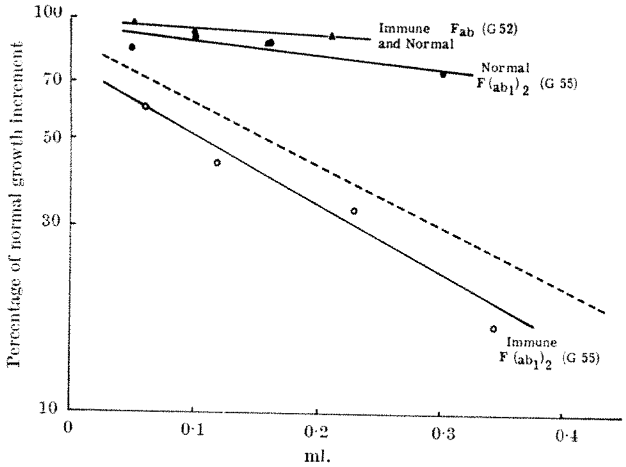

Fig. 4. Dose-response data for papain (Fab and Fc) and pepsin F(ab′)$_2$ fragments of normal and immune IgG. Concentrations of fractions tested were Fab + Fc 13 mg/ml., F(ab$_1$)$_2$ 8·7 mg/ml. Broken line shows the response for the original whole IgG (13 mg/ml.).

Evidence against the Presence of H2 Histocompatibility Antigens in Ehrlich Ascites Tumour Cells

The use of a hybrid between Ehrlich ascites tumour and hamster cell lines to immunize mice against the tumour has been reported[1]. We report here the use for the same purpose of a hybrid line between Ehrlich ascites tumour cells and cells derived from mouse embryo cells obtained from an inbred strain of mice (CBA). This hybrid is less immunologically foreign than the hamster × Ehrlich hybrid for the randomly bred Swiss mice used in the immunization experiments; it differs antigenically only in histocompatibility antigens, in particular in its H2 antigen, which, for CBA mice, is the H2^k antigen. Such a hybrid gave the opportunity of investigating whether the immunity arising after injection of Ehrlich × hamster hybrids[1] was the result of strong histocompatibility antigens (of H2 type) in the Ehrlich cells.

A primary culture of mouse embryo cells was obtained by trypsinization of minced, two-week-old embryos of a CBA mouse. The disaggregated cells were maintained in Dulbecco's modified Eagle's medium for one week before fusion. They were fused with Ehrlich ascites tumour cells as described previously[1], and the fusion mixture was incubated in a plastic bottle (area 25 mm^2, Falcon Plastics) for 24 h, when non-adherent cells were removed by pouring off the medium and repeatedly washing with Earle's balanced saline. Fresh medium (5 ml.) was then added, and incubation continued. One week later the bottle was shaken to suspend cells which were in mitosis, and the medium, with the suspended cells, was placed in a fresh plastic bottle. The medium was changed after 24 h incubation at 37° C, and incubation continued for another week. After four repetitions of this process the cell population obtained consisted of rapidly growing cells resembling morphologically the hamster × Ehrlich hybrid cells previously described[1]. Chromosome counts on this population showed a range of 95 to 114 chromosomes, with a model value of 110 chromosomes. All the chromosomes were telocentric or acrocentric with the exception of one large metacentric chromosome characteristic of the Ehrlich ascites tumour line[2]. The expected modal number of chromosomes in a hybrid line between mouse diploid cells and Ehrlich cells would be about 117. The cell population seemed therefore to consist of hybrids formed by the fusion of one mouse embryo cell and one Ehrlich cell, with reduction in the number of chromosomes. The karyotype of the population remained the same over several months cultivation *in vitro*, which was carried out by transfer of 10^5 to 10^6 cells at each passage. The CBA cells had no marker chromosomes of use in this cross, but the behaviour of the cells *in vivo* and their growth *in vitro* support the idea that they were, in fact, hybrids.

10^6 hybrid cells were injected intraperitoneally or subcutaneously in 0·2 ml. of Earle's saline into groups of five Swiss (randomly bred) or CBA (inbred) mice, with the following results. (1) Swiss mice, intraperitoneal injection : The mice developed an ascites tumour indistinguishable in time of first appearance, time of death, and cell concentration (determined at daily intervals) from that developing after injection of Ehrlich ascites tumour cells. The karyotype of the population ten days after injection differed, however, from the karyotype of the *in vitro* population. In one experiment the range of chromosome numbers at ten days was 73 to 83, with a mode at about 80 chromosomes, and in another experiment the range was 85 to 107, with a mode at about 95 chromosomes. (2) Swiss mice, subcutaneous injection: About one week after injection a small tumour developed at the injection site in all the mice. This increased slowly in size to a maximum never greater than 5 mm in diameter. From about 15 days after injection the tumours began to regress, and there was no trace of a tumour in any mouse three weeks after injection. Ehrlich cells, on the other hand, produced progressive tumours which reached 2 to 3 cm in diameter, often became ulcerated (the mice were then killed), and finally caused death with no sign of regression. (3) CBA mice, intraperitoneal injection: The mice developed a moderate degree of ascites. The total volume of exudate—which was in all cases heavily bloodstained—was never more than a few ml. and the cell concentration was always low, never more than 10^5 cells per ml. Multiple solid tumours were present on the mesentery, intestines and at the site of injection. The mice died between 10 and 12 days after injection. Ehrlich cells in these mice, on the other hand, produced a more marked ascites, also bloodstained, with cell concentrations reaching more than 10^7 cells per ml. A few small solid tumours were present in the peritoneal cavity. The mice died between 10 and 13 days after injection. The hybrid cells therefore seem to have been as malignant as Ehrlich cells in CBA mice. (4) CBA mice, subcutaneous injection: Hybrid cells by this route behaved in the same way as Ehrlich cells. Tumours were first detected six days after injection, and progressively increased to a size of 2–3 cm, often with ulceration. The mice died between 60 and 70 days after injection.

Immunization experiments were all carried out in randomly bred Swiss mice. The mice were immunized by subcutaneous injection of 10^6 cells into the flank, and challenged by intraperitoneal injection three to four weeks later. This time interval was adopted in order to allow the small tumours arising from subcutaneous injection of hybrid cells to regress completely. In several experiments the mice which survived the first challenge were rechallenged with 10^5 cells thirty days later. The results are summarized in Table 1. All the mice which died developed a massive ascites.

Table 1. IMMUNIZATION OF SWISS MICE AGAINST EHRLICH ASCITES TUMOUR (EAT)

Immunizing cells (10^6 subcutaneously)	Challenge cells (10^6) intra-peritoneally	Challenge dose	Mice surviving 30 days (no ascites)	Mice surviving rechallenge at 30 days with 10^6 cells
None	CBA × EAT	10^5	1/4	—
None	CBA × EAT	10^6	0/5	—
None	EAT	10^4	0/5	—
	EAT	10^5	0/5	—
	EAT	10^6	0/5	—
CBA × EAT	CBA × EAT	10^5	5/5	5/5
CBA × EAT	CBA × EAT	10^6	4/4	4/4
CBA × EAT	EAT	10^4	11/11	9/11
CBA × EAT	EAT	10^5	3/4	3/3
CBA × EAT	EAT	10^6	0/5	—
CBA mouse embryo fibroblasts	CBA × EAT	10^5	5/5	5/5
CBA mouse embryo fibroblasts	EAT	10^5	1/5	0/1

The results provide evidence against the presence of H2 antigens in Ehrlich cells, for the following reasons: Suppose Ehrlich cells possess a strong histocompatibility antigen of type "$H2^a$". If the strong antigens are co-dominant, CBA × Ehrlich cells should have antigens $H2^k$ and "$H2^a$". The rejection of the hybrid after subcutaneous injection into Swiss mice can be attributed to its $H2^k$ antigen, and possibly also to its "$H2^a$" antigen. The failure of CBA mice to reject the hybrid after subcutaneous injection, however, indicated that the "$H2^a$" antigen is either not expressed in the hybrid or is identical with $H2^k$. The fact that CBA × Ehrlich immunized against Ehrlich indicates that it is probably expressed. "$H2^a$", on this hypothesis, must therefore be identical with $H2^k$. Fibroblasts from CBA embryos immunized against CBA × Ehrlich, as would be expected, because both have $H2^k$. They failed, however, to immunize against Ehrlich ascites tumour cells which could mean that the Ehrlich $H2^k$ is in a "masked" form, insusceptible to immunological attack. Because CBA × Ehrlich was effective in immunizing against Ehrlich, the antigen cannot exist in such a "masked" form. It is therefore impossible to explain these results on the hypothesis that an antigen comparable in strength with H2 antigens is present in Ehrlich cells. Immunity after injection of Ehrlich × hamster (1) or CBA × Ehrlich hybrids must therefore have been directed against "weak" antigens of unknown nature.

Aberrant Karyotypes and Spontaneous Abortion in a Japanese Family

CHROMOSOME aberrations involving trisomy, monosomy and translocations may be aetiologically related to spontaneous abortion in humans[1-3]. We describe here a family in which translocations seem to be associated with repeated spontaneous abortions.

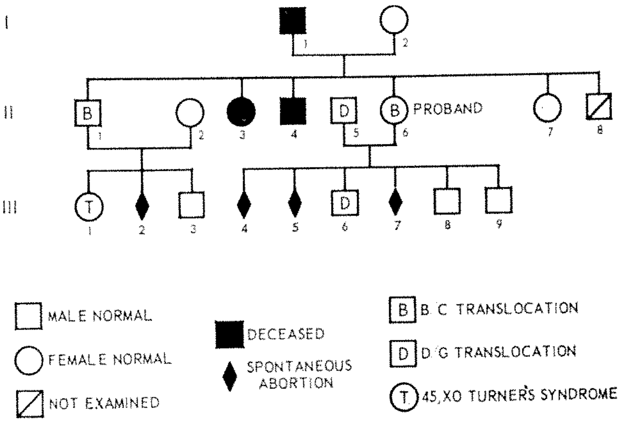

Fig. 1. Pedigree of family with *B/C* and *D/G* translocations, *XO* (Turner's syndrome) and multiple spontaneous abortions.

The proband was a female, aged 43. Her husband was 45 years old and all the family (Fig. 1) are physically and mentally normal with the exception of one with Turner's syndrome (III–1). In twenty-one years of married life, the proband has had three live births (III–6, 8, 9) and three spontaneous abortions (III–4, 5, 7) each at three months gestation. An elder brother of the proband (II–1) has two children: a normal son and a daughter with Turner's syndrome. His wife had one miscarriage at three months gestation.

Chromosome studies were carried out on leucocyte cultures according to a modification of the method of Moorhead *et al.*[4]. For each individual, the chromosomes in sixty to one hundred cells were examined, and at least ten metaphases were karyotyped. In cases with chromosome abnormalities, twenty to thirty cells were karyotyped.

The proband (II–6) and her elder brother (II–1) had chromosome counts of 46. Two chromosomes were missing, one each from group *B* and group *C*. Further, two unusual extra chromosomes were present: a large submetacentric element corresponding in length to the *A2* autosomes, and a small metacentric resembling *E16* (Fig. 2). It is likely that a distal part of the long arm of a *C* chromosome had been translocated to a distal portion of the short arm of a *B* chromosome. The abnormal chromosomes are tentatively regarded as heteromorphic partners of the *B5* and *C11* chromosomes in Fig. 2.

The husband of the proband (II–5) and one son (III–6) consistently had 45 chromosomes. Two were absent, one from group *D* and the other from group *G*, and in their place was one medium-sized submetacentric, the long arm of which was nearly the same length as that of the *D* chromosomes, whereas its short arm corresponded to the long arm of the *G* chromosomes. It is thus probable that this abnormal autosome was formed as a result of a translocation between a *D* and a *G* chromosome. A niece of the proband (III–1) was diagnosed as having Turner's syndrome. Her karyotype had 45 chromosomes with one element missing from group *C*, which was consistent with the diagnosis of *X* monosomy.

The pattern of chromosome replication was investigated autoradiographically in cultured leucocytes from the proband with the *B*/*C* translocation (for procedure, see Sofuni and Sandberg[5]). In thirty-eight out of fifty metaphase cells, one chromosome of group *C* was especially heavily labelled. Karyotype analyses of twelve labelled cells indicated that the late replicating *X* chromosome was probably not involved in the translocated chromosomes (Fig. 2).

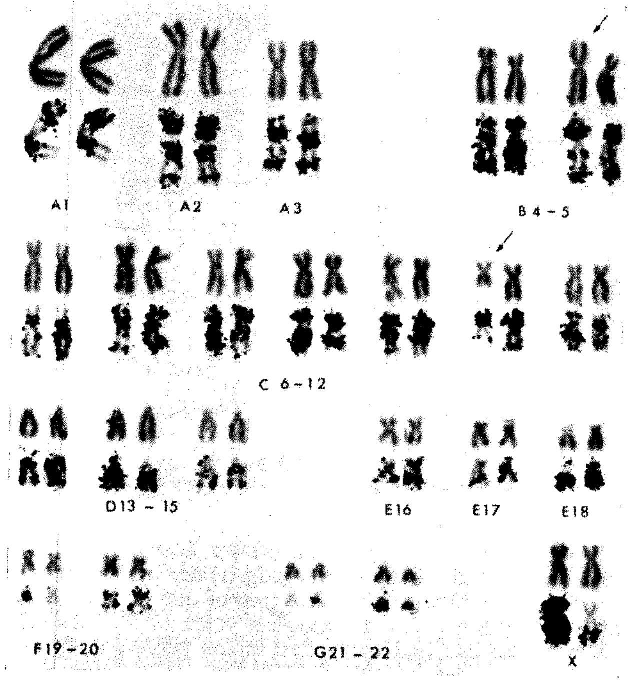

Fig. 2. Karyotype from the proband with *B*/*C* translocation. The chromosomes were photographed before and after autoradiography. Arrows indicate translocation chromosomes. Note the usual pattern of heavy labelling of one *X* chromosome, interpreted as showing that it is not involved in the translocation. One of the translocated chromosomes shows a labelling pattern similar to that of the normal *B*5 chromosome, except for the translocated segment (see text).

In group *B*, where one chromosome was missing, two of the remaining three chromosomes were relatively late replicating, and were identified as *B*4 chromosomes. The remaining chromosome in this group exhibited the expected labelling pattern of the normal *B*5 chromosome: generally early replicating but with a late replicating short arm. One of the translocated chromosomes had a labelling pattern similar to that of the *B*5 chromosome, except for the translocated segment which was early replicating (Fig. 2). The identification of the missing element in group *C* was difficult, for individual elements of the *C* chromosomes are not readily identifiable on the basis of the labelling pattern. The autoradiographic findings support the interpretation derived from karyotype analysis that the translocation probably occurred between a *B*5 and a *C* chromosome.

Recent cytogenetic studies have shown that translocations such as those represented by *G*/*G*, *D*/*G*, *D*/*D*, *C*/*E*, *C*/*D* and *B*/*C* can be transmitted through several generations and, moreover, are often evident in women who have repeated abortions[6-11].

Many individuals with balanced translocations seem to be phenotypically normal[6-12]. In gametogenesis (without nondisjunction) in these carriers, four types of gamete are theoretically possible: (1) normal, (2) balanced, (3) unbalanced with excess genetic material or (4) unbalanced with a deficient amount of genetic material. These four types of gamete from the proband with the *B*/*C* translocation and her spouse with the *D*/*G* translocation are shown in Fig. 3, along with the zygotes that would be formed by fusion of the various gametic types from each parent. Fusion of gametes I and II from the *B*/*C* parent with V and VI from the *D*/*G* parent would produce zygotes with a normal karyotype (A), one balanced translocation (B,C) and two balanced translocations (D). A, B and C are viable, but whether D would be is questionable, because presumably the double translocation would impair the genetic apparatus of the cell, perhaps eventually producing a non-viable foetus that would be lost by spontaneous abortion. The zygotes produced by a trisomic gamete from one parent and a normal gamete from the other (I and VII or III and V) would be partially trisomic for either the *G* chromosome (G) or the *C* chromosome (E). The former, with excess *G* material, might be a translocation Down's syndrome. Whether the trisomic gamete from the *B*/*C* translocation parent is viable, and if so, able to produce a viable foetus, in view of the large amount of reduplicated *C* material, is highly questionable. Most combinations of balanced and unbalanced gametes (F, H–P), together with the products of nondisjunction between the translocation chromosomes and their homologous partners, would be lethal[8,13].

We conclude that the frequent spontaneous abortions probably result from parental translocations. The occurrence of abortions in the first trimester indicates that the abortuses were probably chromosomally abnormal, although we do not have karotypes to support this view directly. Other studies have shown that the average length of gestation for abortuses with abnormal chromosomes is significantly shorter than for chromosomally normal abortuses[14-16].

It has recently been reported that the frequency of spontaneous abortions in sixty-three families with Robertsonian translocations (*D*/*D*, *D*/*G*, *G*/*G*) did not differ significantly from that in a general population[17], that some translocation carriers give birth to normal children and never experience abortion, and that even abortuses in families with translocations may be karyotypically normal[18]. It is therefore possible, in families where only one parent has the translocation, that abortions may result from some factor other than the chromosome aberration. In the family studied by us, however, both parents have different translocations, and it seems likely that these were responsible for the abortions.

In the case of *X* monosomy (III–1), the presence of the translocation might somehow predispose to nondisjunction of other normal chromosomes—in this case the sex-determinants—resulting in either trisomy or monosomy. Such an effect has been suggested by others where a *D*/*D* translocation was associated with *G*-trisomy Down's syndrome[19,20].

Presence of an Additional Metacentric Chromosome in AKR/T1ALD Leukaemic Cells

THE cells of human and murine leukaemias are usually either diploid or very close to diploidy, even when their karyotypes show some specific morphological abnormalities. In a study of spontaneous and transplanted AKR leukaemias, Wakonig-Vaartaja and Stich[1] found that most of the mitoses had a normal diploid set of forty chromosomes although there were forty-one chromosomes in one-third of the cases. Identical observations have been reported by Kurita and Yosida[2].

In 1967, Leonard and Deknudt[3] isolated and established an AKR substrain with only thirty-eight chromosomes (AKR/T1ALD). We maintain this substrain in our laboratory. The apparent decrease in the genetic content of AKR/T1ALD is the result of the rejoining of the acrocentrics of pair 4 with pair 13. Thus the chromosome set has thirty-six acrocentrics and two submetacentrics. This Robertsonian translocation which appeared spontaneously in the AKR strain does not change the chromosomal content and does not involve any gross phenotypic change, and in our animal colony the percentage of leukaemias in the AKR/T1ALD substrain does not differ significantly from the incidence of this disease in the AKR strain.

There is accumulating evidence that cells with a chromosomal imbalance are very sensitive to the chemical and physical agents which induce chromosomal abnormalities[4]. Radiation experiments were thus carried out with the T1ALD substrain and it was discovered that an additional metacentric chromosome frequently occurred in the cells of spontaneous and radiation induced leukaemias. This article describes the various patterns in the chromosome alterations.

All mice used in the experiments belonged to the AKR strain (forty chromosomes) and to the AKR/T1ALD substrain (thirty-eight chromosomes). An X-ray machine was used in the following conditions: 225 kV peak, 11 mA, through 2 mm Al and 0·3 mm Cu added filters. The dose rate at 35 cm was about 100 rad per min. Male and female T1ALD were exposed either to an acute whole body irradiation of 900 rad or to four weekly exposures of 175 rad each. In the first case, the mice were 60–70 days old and in the second they were 33–36 days old at the time of the first exposure. All the mice which had received 900 rad were restored with 0·7–1 × 10^7 bone marrow cells which had been obtained from young AKR or AKR/T1ALD donors. The animals exposed to fractionated sublethal irradiation were divided into three groups: the first was not treated with bone marrow; the second was given 0·7 – 1 × 10^7 AKR bone marrow cells; and the third received the same amount of AKR/T1ALD cells. Control and irradiated animals received water and food until they showed obvious leukaemic symptoms. They were then injected intraperitoneally with 125 mg of colchicine and were killed 1·5 h later. Thymus and femoral marrow cells were suspended in saline and were given a hypotonic shock (1 per cent sodium citrate) and processed[5]. The slides were stained with Giemsa. Metaphases were either photographed or analysed directly under the microscope. For each mouse, fifty metaphase plates of the thymic and bone marrow cells were analysed for chromosome counts. The thymus, spleen, lymph nodes and liver were examined histologically and bone marrow smears were examined cytologically.

Table 1 summarizes our findings. The percentages of extra metacentric chromosomes and acrocentrics in leukaemic cells were established exclusively from the thymic lymphosarcomas which are characteristic of these lymphoid leukaemias.

Ten of the fourteen leukaemic T1ALD had a third metacentric chromosome. One extra acrocentric chromosome was found in 3 per cent of T1ALD and in 40 per cent of AKR; more than one acrocentric appeared in 0·7 and 17 per cent of each substrain. In T1ALD mice which had received 900 rad and in isogenic T1ALD marrow, the frequency of cells with three metacentric chromosomes was the same as in the controls (24 per cent), but the number of cells with one or more extra acrocentric chromosome increased up to 14 and 4·8 per cent respectively. After restoration by AKR bone marrow, all leukaemias were of the donor (AKR) type as identified by the absence of metacentric chromosomes. But an extra acrocentric chromosome was seen in 32 per cent of the cells and more than one extra occurred in 6 per cent; this percentage was lower than in spontaneous AKR leukaemias.

Table 1

Strain	X-ray dose in rads	Origin of marrow	No. of mice Total	No. of mice With third meta-centric	Percentage of mitosis with extra Meta-centric	Percentage of mitosis with extra Acrocentric 1	Percentage of mitosis with extra Acrocentric 1
T1ALD	—	—	14	10	24·2	3·1	0·7
AKR	—	—	6	0	—	40	16·6
T1ALD	900	T1ALD	15	10	24	14	4·8
T1ALD	900	AKR	11	0	—	32	6
T1ALD	175 × 4	—	17	7	26·7	24·6	2·9

After fractionated irradiation (4 × 175 rad), the percentage of leukaemic cells with a third metacentric was 27 per cent in T1ALD and only 6 per cent in the animal restored with T1ALD bone marrow. It should be noted that in these four experimental groups, samples from different animals correspond to frequencies of additional metacentric chromosomes ranging from 2 to 100 per cent. No matter which group they belonged to, all the mice with a third metacentric chromosome in their thymic cells showed the same abnormality in their bone marrow cells; but in this last tissue the presence of normal cells of another haemopoietic series meant that an accurate estimate of their frequency could not be made, but if the bone marrow is completely invaded by leukaemic cells, the incidence of this abnormality in the marrow seems to be similar to the thymic one. In all the fourteen control T1ALD mice, and in the ten T1ALD mice irradiated with 900 rad and restored with T1ALD bone marrow, the relative length and the centromeric indices of the third metacentric were identical with those of the normal metacentric pair, but in the animals which had received 4 × 175 rad this third metacentric was normal in only two cases and was shorter than normal in all other instances.

This third metacentric chromosome was only found in leukaemic cells, and it was never seen in normal mice of the same age. But it must be noted that its presence in leukaemia is not usual because only 59 per cent of the animals in our experiment had this abnormality in their leukaemic cells and when it occurred it was often in very few of the cells. The influence of irradiation seems negligible because the percentages were the same in the controls (24 per cent), in mice which had received 900 rad (24 per cent), and in mice which had received 4 × 175 rad (27 per cent). In the radiation induced chimaeras which were obtained by the injection of AKR cells after a 900 rad exposure, all the leukaemias were of the donor type. It can therefore be assumed that this also occurs when the restoration is carried out with T1ALD cells, and in those cells which have not been irradiated, the third metacentric chromosome is as frequent as in the controls. Moreover, the incidence of this abnormality is similar in the controls and in animals in which the leukaemic process has either been stimulated by four irradiations or inhibited by 900 rad with subsequent restoration[6]. Thus there seems to be no direct correlation between the leukaemogenesis and the presence of an extra marker although it is a characteristic of most leukaemic cells.

The age of mice at which leukaemia develops does not influence the frequency of the abnormality. The mean survival time of the mice with a third metacentric chromosome was not statistically different from the survival time of the mice which did not show it; it was respectively 229 and 216 days for controls, 263 and 259 for the animal irradiated with 900 rad and 209 days in the group exposed to 175 × 4 rad.

The mechanism of formation of the third metacentric chromosome is at present unknown. But, because the extra metacentrics are identical with the normal pair in the controls and in the lethally irradiated animals, it can reasonably be assumed that they originate from a non-disjunction or a duplication. This assumption, however, does not explain why many of these extra metacentrics are shorter than normal in the irradiated groups and the radiation seems to be responsible for this structural change of the third metacentric chromosome.

It is striking that the frequency of extra acrocentric chromosomes is significantly higher in AKR than in T1ALD and comparable with the frequency with which the third metacentric marker is observed in T1ALD. The presence of such isolated extra chromosomes in specific pairs may be ascribed either to non-disjunction or to selective duplication. The theory of selective duplication has been substantiated by Lejeune *et al.*[8] using a leukaemic patient and using *in vitro* organ cultures[9]. These results may be extended to the production of a third metacentric chromosome in the T1ALD leukaemic cells. The reported findings do not support the theory of selective duplication more than the theory of reciprocal clones induced by non-disjunction, but with respect to this last possibility, no cells were observed with only one metacentric chromosome. Such monosomic clones, however, are at such a selective disadvantage that they are unlikely to show up. Finally, it is worth noting that this trisomy selectively applies to a chromosomal pair which has been previously modified by a translocation.

We thank Professor P. C. Koller for his help and advice in the preparation of this manuscript. This work was supported by a grant from INSERM.

Probable Occurrence of Infectious Bovine Rhinotracheitis Virus in Tanzania in Wildlife and Cattle

INFECTIOUS bovine rhinotracheitis (IBR), first described in the United States as a respiratory disease of feedlot cattle[1,2], has been identified in many countries including Tchad[3] and South Africa[4]. Serological evidence suggests that the virus is widespread in the Cameroons, the Central African Republic[5] and Nigeria[6]. There are, however, no published reports of the disease in East Africa.

At these laboratories we have therefore started to investigate the possible occurrence of IBR virus in Tanzania and its significance in animal disease in this country. A serological survey for the detection of IBR neutralizing antibody against the Oxford strain of IBR virus (provided by Dr J. H. Darbyshire of the Central Veterinary Laboratory, Weybridge, Surrey) has been started on sera of cattle and wildlife. This study began in the Masailand area of Tanzania.

Serum-virus neutralization tests based on the technique of Mohanty *et al.*[7] were carried out at a final serum dilution of 1/8 against 100 $TCID_{50}$ IBR virus in the inoculum; for each serum two tubes of primary calf kidney monolayers were used as the indicator system. Final readings were carried out when control cultures showed a maximum cytopathic effect, usually 5–6 days after inoculation, using a cytopathic effect scoring system[8] whereby neutralization is indicated by a quantitative estimation of inhibition of cytopathic effect. Neutralization titres were calculated according to the method of Reed and Muench[9].

Table 1. DISTRIBUTION OF IBR NEUTRALIZING FACTOR IN WILDLIFE AND CATTLE OF TANZANIA

Species	No. tested	No. positive	Per cent positive
Buffalo calf	3	1	33
Buffalo	52	38	76
Eland	46	0	0
Elephant	5	0	0
Giraffe	3	0	0
Impala	21	0	0
Thompson gazelle	29	0	0
Warthog	1	0	0
Wildebeeste	56	2	3·4
Cattle	61	52	85

Neutralization titres expressed as reciprocals.

Table 2. RESULTS OF THE TITRATION OF THE IBR NEUTRALIZING FACTOR IN SERA OF BUFFALO AND CATTLE

Reciprocal *S/N* titre	Nos. of positive sera Buffalo	Cattle
8–16	0	5
> 16–32	4	8
> 32–64	12	3
> 64–128	3	2

The results of the neutralization tests against the species tested so far are summarized in Table 1. Almost all positive sera were obtained from buffalo, but two wildebeeste also gave positive reactions. Eighty-five per cent of the sera collected at a local abattoir from cattle from the Ngorongoro area also gave positive neutralization for IBR virus. In buffalo and cattle the neutralization titre of positive sera was as high as 1/128 (Table 2). Rabbit hyperimmune serum collected after five serial intravenous inoculations of IBR virus during 4 months showed a titre of 1/180.

The neutralization factor thus detected is probably specific antibody against IBR virus or an antigenically closely related virus; this is indicated by the fact that it is stable to heat and trypsin and seems to be associated with the γ-globulin fraction of the serum protein. (Serum γ-globulins were precipitated by ammonium sulphate[10].)

This work indicates that IBR probably occurs in the wild life of Tanzania. This is very important, especially where the buffalo (*Syncercus caffer*) is concerned. Whether the antibody detected in buffalo is associated with any definite clinical disease in this species has yet to be determined.

Effect of Foetal Hypophysectomy on Catecholamine Levels in the Lamb Adrenal during Prolonged Gestation

DESTRUCTION of the pituitary gland of the foetal lamb *in utero* results in an indefinite prolongation of pregnancy[1]. This seems to be caused by a reduction in the secretion from the foetal adrenal cortex, for parturition can be induced in either post-mature hypophysectomized lambs or premature normal foetuses by infusions of ACTH or of large doses of cortisol into the foetus[2]. There is, however, a close association between the adrenal cortex and the concentration of adrenaline in the adrenal medulla[3-6]. In the lamb the rapid growth of the adrenal cortex immediately before birth is accompanied by a slight rise in the proportion of adrenaline in the gland[7]; absence of growth of the adrenal cortex after hypophysectomy might therefore affect catecholamine content, or more specifically the ratio of adrenaline to noradrenaline in the medulla, particularly during the period of prolonged gestation. This possibility has been investigated in the present experiments in which foetal hypophysectomy *in utero* was carried out at 93–105 days gestation in sixteen Welsh ewes.

The technique for electrocoagulation of the foetal pituitary[8] was modified so that the electrode could be inserted stereotaxically. The ewes were anaesthetized with sodium pentobarbitone and the foetal head was held rigidly within the uterus by means of a simple head-holder. The horizontal bars were inserted into the temporal fossae which could be palpated behind the post orbital processes through the uterine wall, while the vertical movement was controlled by a clamp over the upper jaw. The coordinates for positioning the electrode with the micro-manipulator mounted on the head-holder were determined from foetal skulls. The completeness of hypophysectomy was checked by histological examination of the contents of the pituitary fossa and adjacent tissues.

Postoperative recovery was uneventful in all sixteen animals. Ten of the hypophysectomized foetuses were examined 7–33 days after the normal date of parturition (147 days) and two were used 25 and 30 days after hypophysectomy, that is, at 128 and 131 days of gestation. Four animals were born spontaneously at the usual time despite electrocoagulation of the pituitary region. The adrenal glands were removed as rapidly as possible from all animals, under sodium pentobarbitone anaesthesia. The right gland was used for catecholamine determinations according to the method described previously[7] and the left gland was examined histologically. The results were compared with data from previous work on the same breed[7] and on a further series of normal foetuses near term, at birth and at 2–3 weeks of age.

The percentage of adrenaline in the post-mature foetuses was extremely low compared with that from normal unoperated foetal and postnatal lambs (Fig. 1*a*). The wide individual variation found in normal foetuses and the increase in the percentage of adrenaline shortly before term or soon after birth was not present after hypophysectomy; indeed, the percentage of adrenaline (20 per cent) was lower than that found early in gestation. Even 25–30 days after the operation the percentage of adrenaline had fallen and was below that at 90–100 days.

The contrast between the adrenal weights of the two series was most striking (Fig. 1*b*) and the changes were parallel to those in the percentage of adrenaline in the glands. Owing to the steep rise in adrenal weight in the control animals near term, due to growth of cortical tissue, parallel to those in the percentage of adrenaline in the gland rather than the concentration per g of adrenal tissue have been used as a basis for comparison (Table 1). The total catecholamine content of the gland after prolonged gestation was remarkably similar to the mean value found in the normal animals at term. In the hypophysectomized

Table 1. EFFECT OF HYPOPHYSECTOMY ON THE DEVELOPMENT AND CATECHOLAMINE CONTENT OF ADRENAL GLANDS

Animals	Age	No.	Mean adrenal wt (mg)	Mean catecholamine content (μg/gland ± *S.E.*) Adrenaline (A)		Noradrenaline (N)		Total	Mean percentage A
Hypophysectomized foetuses	154–180 days gestation	10	135 ± 3·8	108 ± 10·3	$P < 0.01$	414 ± 21·0	$P < 0.01$	522 ± 59	20·8
Control lambs	145 days gestation or newborn	6	328 ± 31·9	248 ± 27·8		281 ± 36·5		526 ± 28	47·0
	2–3 weeks after birth	3	397	391		260		651	60·0
* Unsuccessfully hypophysectomized foetuses	Newborn	4	200 ± 11·2	235 ± 52·0		250 ± 61·0		485	48·5

* Some anterior pituitary tissue attached to stalk (parturition 147–150 days).

animals, however, the mean noradrenaline levels were much higher and the adrenaline levels correspondingly lower than the values obtained from control lambs at birth or 3–4 weeks later.

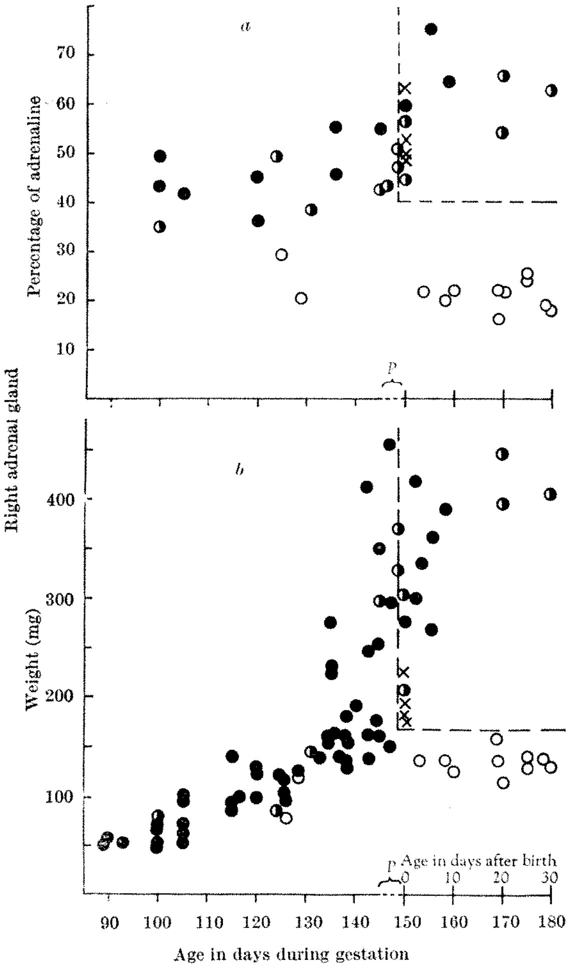

Fig. 1. Changes in (*a*) percentage of adrenaline in adrenal glands and (*b*) adrenal weights of hypophysectomized and control lambs during gestation and early post-natal life. ●, Unoperated control animals[7]. ◐, Unoperated control animals, present series. ○, Foetuses hypophysectomized at 93–105 days gestation, in which gestation was prolonged and germinated artificially. ×, Incompletely hyphophysectomized foetuses in which parturition (*P*) occurred at the normal time (147–150 days gestation). All points within the interrupted lines were obtained from lambs after birth.

In the four lambs in which parturition occurred spontaneously at the usual time in spite of electrocoagulation of the pituitary, the adrenal weight reached the minimum found after normal birth, largely because of growth of the cortex. The proportion of adrenaline in the adrenal medulla of these foetuses (Fig. 1) and the catecholamine content (Table 1) did not differ significantly from the control animals at term. Histological examination of the pituitary region in these animals showed that although the major part of the anterior pituitary had been destroyed the pituitary stalk was invariably present and had a small amount of anterior pituitary tissue attached to it.

The present findings suggest that after hypophysectomy the foetal adrenal medulla becomes unable to methylate noradrenaline; synthesis apparently continues and the stores of noradrenaline increase while those of adrenaline fall. These changes are intimately associated with the lack of adrenal cortical growth, but whether the adrenal medulla as well as the cortex is involved in the termination of gestation remains to be elucidated.

Gonadotrophin Inhibition by the Synergistic Action of Vasopressin and Oxytocin

GONADOTROPHIN inhibitory activity has been demonstrated in urine[1,2], serum[3] and in pineal extracts[4-6]. The similarity between the inhibitors from urine and the pineal gland[4,5], and the absence of inhibitory activity from urine from patients with sexual precocity resulting from pinealoma[7], suggests that the urinary factor is derived from the pineal gland. There are, however, several substances with gonadotrophin-inhibitory activity in the pineal gland. Melatonin prevents growth of the ovary and inhibits oestrus in rats[8], but in short term experiments, this substance differed from urinary extracts in having no effect on exogenously administered gonadotrophin[4]. Serotonin and adrenaline are gonadotrophin-inhibitory[9] and are present in the pineal gland[10]. But these substances could not be detected in potent pineal and urinary extracts[6]. A polypeptide, identified as arginine-vasotocin, has been found in the bovine pineal bland[10]. This compound inhibited the uterine weight response to pregnant mare serum gonadotrophin[11]. Because arginine-vasotocin has both pressor and oxytocic activities[10], it was thought that useful information might be obtained by studying the gonadotrophin inhibitory properties of vasopressin and oxytocin individually. I report here the results of such experiments, in particular, a synergistic effect between the two substances to produce gonadotrophin inhibition similar to that observed with urinary extracts.

The experimental procedure has been described[2,9]. The gonadotrophin-inhibitory properties of vasopressin and oxytocin were evaluated by the mouse uterus method using immature, albino mice from an inbred colony. They were 20–22 days old and initially weighed 8–11 g. Although the mean body weights of the groups in each experiment were the same, they varied from experiment to experiment and therefore responses to the same treatment in different experiments cannot be compared. Food and water were given *ad libitum*. The experimental groups consisted of six to eleven animals. All injections were given subcutaneously in aqueous solution except oestrone which was administered in oil. The total dose of human chorionic gonadotrophin ('Pregnyl', Organon) was 0·4 IU and that of follicle-stimulating hormone (FSH-P, Armour) was equivalent to 400 μg NIH—FSH—S1. The animals of further groups were injected at different sites with HCG (0·4 IU) and FSH (50 μg equivalents), while oestrone was given to a total dose of 0·3 μg.

Vasopressin ('Pitressin', Parke Davis) and oxytocin ('Syntocinon', Sandoz) were used in preliminary experiments to determine the minimal effect dose of each. This was found to total 15 IU for vasopressin and 6 IU for oxytocin. Some mice were given a mixture of 0·3 IU vasopressin and 0·3 IU oxytocin. These substances were tested for HCG inhibitory activity after they had been boiled for 1 h under reflux. Injections were at the same time but at a different site from those of the gonadotrophins or oestrone.

Treatment was given for 3 days using the following volumes: HCG, 0·2 ml., 0·1 ml. and 0·1 ml.; FSH, 0·2 ml., 0·2 ml. and 0·1 ml.; vasopressin and oxytocin, 0·2 ml. daily; and oestrone and vasopressin–oxytocin mixture, 0·1 ml. daily.

On the fourth day, the mean body and uterine weights from the test groups were compared with those given gonadotrophins (or oestrone) and distilled water, using the Student *t* test.

Table 1. EFFECT OF VASOPRESSIN (15 IU) ON THE MOUSE UTERINE WEIGHT RESPONSE TO GONADOTROPHINS AND OESTRONE

Experiment	No. of animals	Mean uterine weight (mg + *S.E.*)	*P*
HCG 0·4 IU + water	11	31·9 ± 4·6	= 0·05
HCG 0·4 IU + vasopressin*	11	21·3 ± 2·8	
HCG 0·4 IU + boiled vasopressin	10	23·8 ± 3·9	> 0·1
FSH 400 μg + water	10	14·1 ± 0·9	> 0·1
FSH 400 μg + vasopressin	9	15·1 ± 1·2	
Oestrone 0·3 μg + water	11	22·5 ± 1·5	> 0·1
Oestrone 0·3 μg + vasopressin	11	21·7 ± 0·9	
HCG 0·4 IU FSH 50 μg } + water	9	37·9 ± 4·3	> 0·1
HCG 0·4 IU FSH 50 μg } + vasopressin*	8	29·4 ± 4·2	

* Significantly lower final body weight than group given distilled water.

Table 2. EFFECT OF OXYTOCIN (6 IU) ON THE MOUSE UTERINE WEIGHT RESPONSE TO GONADOTROPHINS AND OESTRONE

Experiment	No. of animals	Mean uterine weight (mg ± *S.E.*)	*P*
HCG 0·4 IU + water	11	32·5 ± 1·5	
HCG 0·4 IU + oxytocin*	11	15·7 ± 1·4	< 0·001
HCG 0·4 IU + boiled oxytocin*	11	22·7 ± 3·3	< 0·02
FSH 400 μg + water	10	11·7 ± 1·0	> 0·1
FSH 400 μg + oxytocin	10	14·3 ± 1·3	
Oestrone 0·3 μg + water	11	27·2 ± 1·9	> 0·1
Oestrone 0·3 μg + oxytocin*	11	29·2 ± 1·8	
HCG 0·4 IU FSH 50 μg } + water	10	28·2 ± 3·3	> 0·1
HCG 0·4 IU FSH 50 μg } + oxytocin	10	27·4 ± 2·8	

* See Table 1.

The results are shown in Tables 1–3. Vasopressin and oxytocin, given separately or as a mixture, did not affect the uterine weight response to FSH or oestrone. On the other hand, they reduced the potency of HCG although this reduction was only just significant with vasopressin. Boiling removed the inhibitory activity from vasopressin but not from oxytocin or from the vasopressin–oxytocin mixture. HCG could, however, be protected from the inhibitory effects of the materials by administration of FSH. It was noted that some of the treatment groups failed to gain weight normally.

The urinary gonadotrophin inhibitor (GIM) is heat stable and reduces the potency of HCG but not of FSH or oestrone in the mouse uterus assay[2,7]. Similar results were obtained with crude extracts of bovine pineal glands[4,6]. In the present investigations, pharmacological doses of vasopressin and oxytocin (15 IU and 6 IU, respectively) were also found to inhibit gonadotrophin activity. In the case of vasopressin, this inhibitory effect was destroyed by boiling (Table 1). When the neurohypophysial hormones were mixed, there was a synergistic effect, and inhibition could be demonstrated with a dose as low as 0·3 IU (Table 3). This dose of arginine vasotocin has been found to be gonadotrophin-inhibitory[11]. As mentioned earlier, arginine–vasotocin is a polypeptide isolated from the pineal gland with both pressor and oxytocic activities[10]. The results of the present investigation suggest that the inhibitory properties of arginine–vasotocin, and therefore of the pineal extract, result from the combined effect of its pressor and oxytocic activities rather than from the polypeptide specifically. A further possibility is that the synergistic effect is caused by an altered rate of absorption of oxytocin from the injection site following vascular changes induced by vasopressin.

Table 3. EFFECT OF VASOPRESSIN–OXYTOCIN (V–O) MIXTURE (0·3 IU) ON THE MOUSE UTERINE WEIGHT RESPONSE TO GONADOTROPHINS AND OESTRONE

Experiment	No. of animals	Mean uterine weight (mg ± *S.E.*)	*P*
HCG 0·4 IU + water	10	46·7 ± 4·5	
HCG 0·4 IU + v–o mixture	10	31·9 ± 3·7	= 0·025
HCG 0·4 IU + boiled v–o mixture*	10	25·2 ± 3·7	< 0·005
FSH 400 μg + water	10	15·3 ± 0·7	> 0·1
FSH 400 μg + v–o mixture	10	14·0 ± 0·6	
Oestrone 0·3 μg + water	9	27·7 ± 2·9	> 0·1
Oestrone 0·3 μg + v–o mixture	10	30·6 ± 1·8	
HCG 0·4 IU FSH 50 μg } + water	10	44·0 ± 3·6	> 0·1
HCG 0·4 IU FSH 50 μg } + v–o mixture	10	47·0 ± 5·2	

* See Table 1.

The inhibitory properties of the neurohypophysial hormones are very similar to those of the urinary gonadotrophin inhibitor, suggesting that their modes of action are related. There is some evidence that the latter inhibits the endogenous gonadotrophin secretion necessary for the mouse uterine weight response to HCG and PMS[2,12]. This hypothesis could also be applied to the neurohypophysial hormones because of the protection afforded to HCG by giving exogenous FSH. Brinkley and Nalbandov have also reported inhibition of endogenous gonadotrophin secretion by oxytocin[13]. The similarity between the neurohypophysial hormones and urinary gonadotrophin inhibitor is also found when ovarian ascorbic acid is studied: vasopressin[14] and gonadotrophin inhibitor[6] both cause its depletion.

Several interpretations of the similar activities of neurohypophysial hormones and urinary gonadotrophin inhibitor are possible. First, their effects may be independent and both may produce a non-specific response to the injection of toxic material. This has been proposed as the mode of action of urinary gonadotrophin inhibitor[9] and in this investigation some of the animals given vasopressin and oxytocin failed to gain weight normally. Second, endogenous vasopressin secretion is part of the response to noxious stimuli[15] and it is likely that this is accompanied by oxytocin release[16]. Urinary gonadotrophin inhibitor activity may be mediated by this mechanism, but it is difficult to compare a physiological response with the effect of the pharmacological doses used in this investigation. Finally, it is possible that urinary gonadotrophin inhibitor contains neurohypophysial hormones. It will be necessary to demonstrate the presence of both vasopressin and oxytocin because it has already been shown that the amount of the former is less than 0·1 IU per l. urine[17].

Eight Types of Bisalbuminaemia

As our knowledge of human albumin variants increases, their description as electrophoretically "slow", "faster" and so on is becoming inadequate for classification. The largest comparative series[1] found five different migration rates in sera from nineteen families. Electrophoretic mobility is not the only criterion, and an earlier classification[2] used eight, variations of mobility in different electrophoretic media and dye-binding properties among them. Such observations will not establish the identity of two albumins but may prove their non-identity.

We have attempted a fuller description of bisalbuminaemia in eight unrelated families. Four are published variants, albumin Reading[3] (No. 4 in this series), albumin Naskapi[4] (No. 7), No. 5 (A.D.M. of Cooke, Cleghorn and Lockey[5]) and 6 (Payne and Dickinson[6]), one (No. 8) is awaiting publication (Rawstron and Mellor, to be published), and three are unpublished. No. 7 is North American Indian, No. 8 is Spanish, and the rest are British.

All sera were examined by three electrophoretic methods, on Whatman 3*MM* filter paper at pH 8·6 with bromophenol blue staining[7], on cellulose acetate at pH 8·6 and staining with Ponceau-*S* (ref. 8), and by disc electrophoresis in 7 per cent acrylamide gel in a discontinuous system of pH 8·3→8·9→8·3 with Ponceau-*S* staining[9]. These techniques of electrophoresis were also used with sera pre-stained with a quantity of bromophenol blue sufficient only to bind the albumin. Specificity of binding was achieved by incubation with 200–250 μg dye per ml. of serum at 37° C for 10 min shortly before filter paper or cellulose acetate electrophoresis, or by adding 2 μg to the 300 μg of serum protein used as the sample in disc electrophoresis, but omitting to add the tracking dye usual in this method. Sera 1–7 were also separated by horizontal starch gel electrophoresis in Poulik's pH 8·65 buffer, with naphthalene black staining[10]. Disc electrophoresis results are given in the 0–100 mm notation[9] (see Fig. 1), and relative mobilities in cellulose acetate are expressed in the same terms.

As Table 1 shows, all of the eight variants are distinguishable. All differ in several particulars, though the results of some tests show parallel tendencies and suggest that a short list of tests will serve to characterize variants. Only half the albumins resolve on filter paper; where they do, their type (fast or slow) follows that of cellulose acetate. The albumin of serum 2 gives two bands in acrylamide but does not resolve in starch gel; for the other sera, resolution in starch follows that in acrylamide. Generally, it seems that for each double albumin the difference

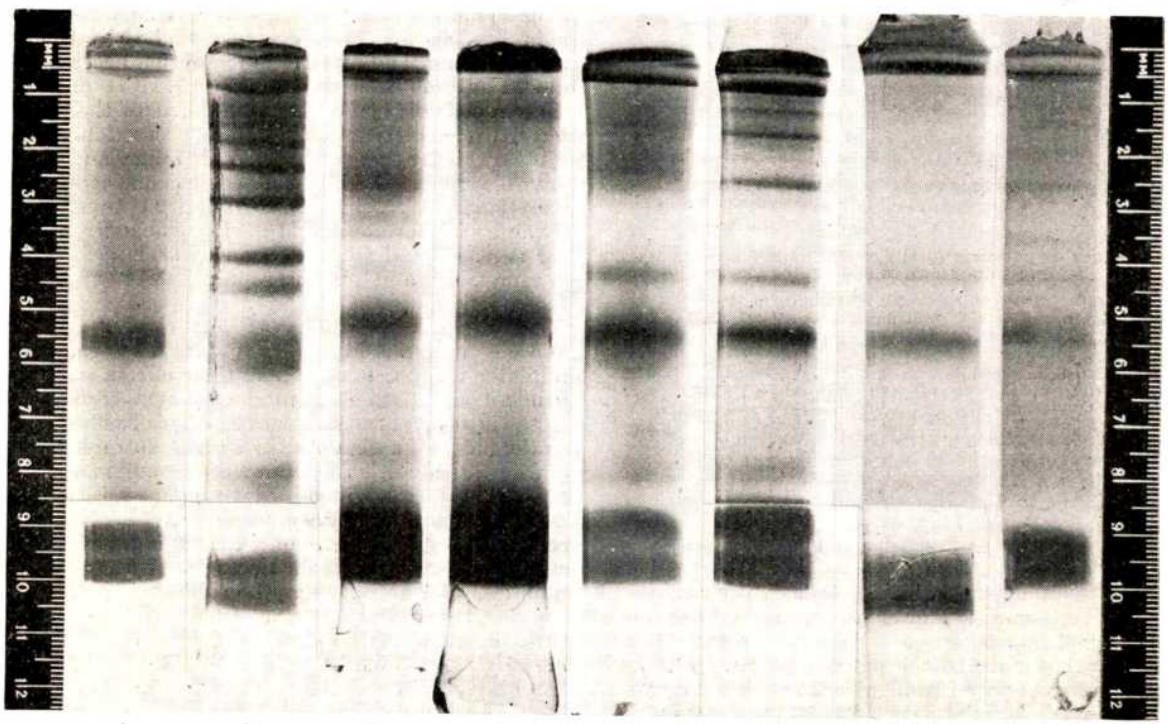

Fig. 1. Disc electrophoretic protein patterns of sera from eight families with different albumin variants. 0, Cathode end of pattern; 100, advancing edge of normal albumin band. Where the photographic contrast between the albumins and the rest of the pattern is too great, single negatives are printed by two processes and the prints joined at 85 mm.

Table 1. CHARACTERIZATION OF EIGHT ALLOALBUMINS

Serum No.	1	2	3	4[3]	5[5]	6[6]	7[4]	8[7]
Name of alloalbumin				Al Reading			Al Naskapi	
Electrophoresis:								
C.A.	85	113	107	108	86	86	110	90
F.P.	S	F	1	1	S	S	1	1
ACR.	89–95, 96–100	95–100, 101–105	85–100	82–100	86–92, 94–100	85–91, 94–100	94–100, 101–105	89–95, 95–100
ST.	2	1	1	1	2	2	2	
Bromophenol blue uptake:

F.P.	A > S	F > A	—	—	A > S	A > S	—	—
ACR.	A, S	F sl. > A	—	—	S	A, S	F (Na)	A, S

Electrophoresis: C.A., position of alloalbumin in cellulose acetate pattern (> 100 is faster, < 100 slower than normal albumin A). F.P., type of alloalbumin in filter paper pattern (F, fast; S, slow; 1, no separation of bands). ACR., position of albumins in acrylamide gel pattern (type assumed identical with C.A.). ST., number of bands in starch gel pattern. Bromophenol blue uptake: presence of stain on fast (F), slow (S) and normal (albumin A) bands.

of dye uptake between bands is in the same direction in all three media. But while on cellulose acetate and filter paper the slow alloalbumins take up less bromophenol blue than the normal band and fast variants take up more, acrylamide does not show this regularity.

The present tests may be developed to give more precise information. Millimetre positions in the cellulose acetate separations tend to be higher for shorter lengths of pattern, and this variation (within ±5 per cent) would be eliminated by adopting a standard running length. 0–100 mm values for filter paper separations could be obtained from replicate runs. Our starch gel separations have not generally been clear-cut enough for this notation (only serum 1 could be assigned band measurements, at 90–95, 96–100), and Ashton and Braden's lithium buffer[4] may be preferable for these separations.

Our results suggest a greater variety of human albumins than can be classified on published data. A set of tests, both electrophoretic and of the dye-binding type, gives more information and may enable variants to be equated with some degree of confidence. This would require agreement on a rational choice of tests and on standardized conditions for carrying them out.

Nuclear Relaxation in Phospholipids and Biological Membranes

ATTEMPTS have recently been made to apply high resolution proton magnetic resonance spectrometry to the problem of molecular association in biological membranes and in dispersions of phospholipids in water[1–4]. On the high resolution scale, line broadening gives the appearance of weak absorption by protons of fatty acid molecules. Because broad lines could result from restricted molecular motion and might indicate that fatty acid chains are immobilized in these systems, a central problem in the interpretation of spectra is the relationship between molecular mobility and linewidth. In steady-state absorption nuclear magnetic resonance (NMR) the apparent transverse relaxation time, T_2, is given by the reciprocal of the linewidth. Often the T_2 thus obtained is an inverse measure of correlation time and reflects molecular mobility. This interpretation is valid for isotropic solutions of small molecules, where rapid motion produces line narrowing and large values of T_2.

The interpretation of linewidths in terms of correlation times is also valid for isotropic solutions of detergent micelles[5] and for serum lipoproteins[4–7], but extension of these ideas to anisotropic particulate systems such as cell membranes or phospholipids dispersed in water may not be justified. Other line broadening mechanisms can introduce spurious results in the sense that measured linewidths do not truly reflect the state of molecular mobility. Field-dependent broadening has already been demonstrated in phospholipids in the lamellar phase[8]. The observed linewidths are several hundred Hz, but the values extrapolated to zero external field are approximately 10–20 Hz. Similar field-dependent broadening also occurs with sonicated phospholipids in water and is more accentuated for the absorption lines of the fatty acid methylene protons than for those of the polar ends of the molecules[9]. Such phenomena most likely arise from internal magnetic field gradients caused by local variations in diamagnetic susceptibility[9].

Field-dependent and susceptibility-dependent line broadening is well known in other materials, both particulate and liquid, and is especially pronounced with particulate systems[10–14]. As with phospholipids, the linewidth is a linear function of field strength. Local internal magnetic field gradients have been shown to be present, and in some cases diffusion within these gradients plays a part. In such conditions, broadening due to field inhomogeneities occurs and short transverse relaxation times obtained from linewidths are erroneous.

Values of T_2 independent of field inhomogeneities can be obtained by pulsed spin-echo methods[10]. It would be expected, then, that for phospholipids the equivalent linewidths calculated from spin-echo measurements of T_2 would be considerably smaller than those determined by other methods. If broadening mechanisms similar to those in phospholipids are also present in biomembranes, they, too, should yield narrow equivalent lines by spin-echo techniques.

We have examined, without using sonication, erythrocyte ghosts and total ghost lipids by two kinds of pulsed NMR: free induction decay and the Meiboom–Gill modification of the Carr–Purcell spin-echo method[15,16]. In the first approach, the decay of the transverse magnetization is observed after a 90° pulse (a 90° pulse is one which rotates the magnetization vector by 90°). T_2 measured by this technique is similar to that calculated from linewidths, and is subject to the same broadening mechanisms. In the second method a 90° pulse is followed by a train of 180° re-focusing pulses, and T_2 is obtained from the envelope of resultant echoes. This latter T_2 is independent of field inhomogeneities, whether from the external laboratory magnet or from gradients within the particles. The results show that line broadening arising from field

Table 1. RELAXATION TIMES DETERMINED BY THE FREE INDUCTION DECAY (FID) AND CARR-PURCELL (CP) METHODS

	T_2 (ms)	$\Delta\nu$ (Hz)
Ghost lipids	0·56 ± 0·3 (FID)	1,100
	110 ± 10 (CP)	5·8
Ghosts	1·4 ± 0·2 (FID)	460
	75 ± 1 (CP)	8·4

inhomogeneities occurs with both membranes and extracted lipids. The transverse relaxation times obtained with the spin-echo technique are long, suggesting a high degree of molecular mobility.

Erythrocyte ghosts were prepared from fresh citrated beef blood by lysis in phosphate buffer[17], and were then lyophilized from distilled water and resuspended in deuterium oxide containing 0·1 M NaCl. Lipids were extracted from lyophilized ghosts with chloroform–methanol (2 : 1), lyophilized from benzene, and also suspended in 0·1 M NaCl-^2H_2O. For both systems the concentrations were approximately 25 per cent w/v. Measurements were made at 60 MHz and room temperature with a 'Magneon SE-30' high-power spin-echo spectrometer; 5 mm tubes were used for free induction decay, and 12 mm tubes for Carr–Purcell runs. Oscilloscope traces were photographed on 'Polaroid' film, digitized with an Autotrol Corp. Model 3400 digitizer, recorded on paper tape, and fitted by a computerized least-squares routine. One dominant relaxation time was present in each case. Relaxation times determined by the two methods are listed in Table 1, together with equivalent full linewidths at half-height calculated from the relation $\Delta\nu = 1/\pi T_2$.

As expected, linewidths calculated from free induction decay experiments are several hundred Hz, in agreement with published steady-state absorption spectra. Those obtained from the Carr–Purcell programme, however, are only a few cycles and are typical of liquid-like systems. These narrow lines are similar to those obtained by extrapolation of phospholipid absorption spectra to zero field. The true correlation times appear to be short and are approximately the same in both lipid dispersions and membranes. We interpret these results to mean that in both systems absorption lines are inhomogeneously broadened by magnetic field gradients. Interpreted in terms of molecular motion, broad lines obtained by absorption NMR are misleading.

Preliminary experiments with intact ghosts which were not lyophilized and with sonicated ghosts also show disparities between free induction decay and Carr–Purcell results. Minor changes are caused by freeze-drying; and these are under investigation. The phenomena described are not confined to erythrocyte ghosts: membranes of *Mycoplasma laidlawii* and *Escherichia coli* also appear to exhibit broadening due to internal magnetic field inhomogeneity.

We thank Dr R. H. Lawler, Dr R. Kedzie and Mr D. Longland for discussions and technical aid. This work was supported by a grant from the US Public Health Service.

Formation of Epithelial Basement Membrane is restricted by Scurvy *in vitro* and is stimulated by Vitamin C

ALTHOUGH scurvy was probably the first clearly defined nutritional disease and active antiscorbutic material was the first of all the vitamins to be crystallized and synthesized, the biochemical function of ascorbic acid in synthesis of collagen has only recently been identified. Some of the proline residues of the collagenous polypeptide are hydroxylated to form hydroxyproline, and ascorbic acid is a cofactor for the hydroxylating enzyme[1]. Most pathological findings in scurvy can be attributed to a restriction in ability to synthesize collagen of bone, teeth and other connective tissues. Some manifestations occasionally found in infantile scurvy are more prominent in adult scurvy and are difficult to explain by a restriction in ability to synthesize collagen of connective tissues. For example, the cutaneous haemorrhages or "scorbutic spots" appearing spontaneously about hair follicles are one of the cardinal signs of adult scurvy[2].

Epithelial and vascular basement membrane contains a protein similar or identical in composition to collagen of bone and connective tissue[3]. The purpose of this report is to present evidence that the synthesis of epithelial basement membrane is dependent on ascorbic acid and to suggest that some of the manifestations of scurvy may be attributed to a restriction in synthesis of basement membranes.

Cell cultures were initiated from explants of a transplantable parietal yolk sac carcinoma of the mouse, LS402A VI, shown to synthesize epithelial basement membrane both *in vivo* and in cell culture[4,5]. The cultures were grown at 37° C in Dulbecco and Vogt's modification of Eagle's medium supplemented with 10 per cent foetal bovine serum and equilibrated with 10 per cent CO_2 in air. In these conditions the cells do not form a confluent monolayer in the culture vessel, but grow as separated colonies on the glass surface. After the cells within a colony proliferate and become densely packed, spherical masses of cells approaching a millimetre in diameter detach and float in the nutrient medium. These cellular masses enlarge further while floating. A "stationary phase" of growth is difficult to identify.

From histological evidence, epithelial basement membrane is more abundant in the cellular masses that are detached or nearly detached than in the cells attached to the glass substrate. It was therefore decided to examine the influence of ascorbic acid on the ability of the detached cellular masses to synthesize hydroxyproline of protein.

The cell masses were removed from the nutrient medium by centrifugation, were resuspended in fresh medium and two aliquots were reincubated at 37° C in the presence of 5 μCi/ml. of ^{3}H-L-proline (304 mCi/mmole, obtained from Nuclear Chicago, Chicago, Illinois). One aliquot was incubated with 125 μM sodium ascorbate and the other aliquot without. After incubation for 3 h the cells were again separated by centrifugation, washed with 0·01 M L-proline in ethanol, and an aliquot taken for analysis of cellular protein[6]. The remainder was hydrolysed for determination of radioactivity in proline and hydroxyproline in the cells[7]. In order to estimate the amount of radioactively labelled proline and hydroxyproline secreted

Table 1. EFFECT OF ASCORBIC ACID ON APPEARANCE OF RADIOACTIVITY IN PROLINE AND HYDROXYPROLINE OF PROTEIN IN CELLS AND MEDIUM OF CULTURED PARIETAL YOLK SAC CARCINOMA

		Without ascorbate	With ascorbate
Cells	mg protein	32·1	31·5
	DPM in proline	$8{\cdot}6 \times 10^6$	$7{\cdot}9 \times 10^6$
	DPM in hydroxyproline	$1{\cdot}2 \times 10^5$	$1{\cdot}8 \times 10^5$
Medium	DPM in proline	$2{\cdot}7 \times 10^4$	$2{\cdot}8 \times 10^4$
		$3{\cdot}3 \times 10^4$	$2{\cdot}8 \times 10^4$
	DPM in hydroxyproline	$1{\cdot}5 \times 10^3$	$2{\cdot}6 \times 10^3$
		$1{\cdot}5 \times 10^3$	$3{\cdot}0 \times 10^3$

by the cells into the nutrient medium, protein was precipitated from aliquots of nutrient medium by adding 4 volumes of absolute ethanol. The precipitate was washed with 0·01 M L-proline in ethanol and was hydrolysed for determination of radioactivity in proline and hydroxyproline[7].

The results of this experiment (see Table 1) indicate that ascorbic acid stimulates the appearance of hydroxyproline in cellular protein by about 50 per cent. Hydroxyproline secreted by cells into the nutrient medium was stimulated nearly two-fold by the vitamin. Ascorbic acid did not, however, affect the amount of radioactive proline in either cells or medium. Additional experiments indicated that the effects of the vitamin were reproducible. Thus ascorbic acid enhances the synthesis of hydroxyproline by cultured parietal yolk sac carcinoma cells making basement membrane. The enhancement by ascorbic acid is quantitatively similar to that reported for cultured fibroblastlike cells during collagen production[8]. Only about 1·5 per cent of the radioactive proline incorporated into protein of parietal yolk sac carcinoma is, however, hydroxylated to form hydroxyproline, whereas a much larger fraction is reported to be hydroxylated by fibroblast-like cells.

In order to determine whether the antigenic components of basement membrane are increased by ascorbic acid, the tumour cells were grown on 22 × 40 mm coverslips in medium devoid of ascorbic acid or supplemented with 125 μM sodium ascorbate. The medium was changed on alternate days. One week later the coverslips were removed and rinsed in phosphate-buffered saline. They were then exposed for 30 min at room temperature to antibasement membrane rabbit globulin conjugated with fluorescein isothiocyanate, were again rinsed with saline and were then mounted. These conjugated antibodies were prepared to basement membrane of the same parietal yolk sac carcinoma grown in ascitic form[4]. The antibodies thus prepared react with epithelial basement membrane, vascular basement membrane and reticulin. These preparations have been previously used in the study of epithelial basement membrane[5]. The mounted coverslips in my experiments were randomized and coded, then examined independently by two observers who did not know the coding. The amount of fluorescence over cell masses producing epithelial basement membrane was scored on a scale of 0 to 4+ and the results are recorded in Table 2. A substantially greater fluorescence was recorded by both observers for the cultures grown in the presence of ascorbic acid.

Table 2. EFFECT OF ASCORBIC ACID ON FLUORESCENCE IN CULTURES OF PARIETAL YOLK SAC CARCINOMA EXPOSED TO ANTIBASEMENT MEMBRANE RABBIT GLOBULIN CONJUGATED WITH FLUORESCEIN ISOTHIOCYANATE

Without ascorbate		With ascorbate	
Observer No. 1	Observer No. 2	Observer No. 1	Observer No. 2
0	0	+ +	+ +
+	±	+	+
+ +	+	+ + +	+ +
+	±	+ + + +	+ + +
+ +	+	+ + +	+ +
±	±	+ + + +	+ + +

These observations suggest that the ability of cells to form a basement membrane is restricted when they are grown in medium devoid of vitamin C. Addition of the vitamin stimulates synthesis of hydroxyproline, a component of basement membrane protein, to an extent quantitatively similar to the stimulation of hydroxyproline synthesis by fibroblasts that form collagen. Antigenic components of epithelial basement membrane (presumably including basement membrane protein) produced in cell culture are also stimulated by the vitamin. Some of the pathological manifestations of vitamin C deficiency may well be explained by inability to synthesize epithelial and vascular basement membranes.

This study was supported by funds from the National Institutes of Health, US Public Health Service. I thank Paul Nakane and G. Barry Pierce for supplying the conjugated antibodies and for assistance with the immunofluorescence procedures.

Allosteric Interactions in $(Na^+ + K^+)$-ATPase

SODIUM and potassium ions are both required to activate the $(Na^+ + K^+)$-dependent–ATPase and each inhibits activation by the other[1]. The K^+ activates the turnover of enzyme hyperbolically at low Na^+ concentrations, but with increasing concentrations of Na^+ the activation curve becomes sigmoid[2]. Similarly at low concentrations of K^+, the Na^+ activation curve is hyperbolic but at high concentrations of K^+ it becomes sigmoid[1]. These data indicate the presence of at least two Na^+ and/or K^+ sites, respectively, but do not indicate the mechanism of interaction between these ions or sites[3]. Priestland and Whittam[2], and others, have suggested that direct competition between the cations for the activating sites can account for the sigmoidal activation curves in the presence of high concentrations of the other cation. Alternatively, Robinson[4] has argued that the sigmoidal activation curves, which are consistent with the heterotropic effects of an allosteric activator[5], are evidence for allosteric interactions in the $(Na^+ + K^+)$-ATPase. In support of this hypothesis he has presented evidence for a cooperativity in the K^+ activation of the *p*-nitrophenylphosphatase activity of the $(Na^+ + K^+)$-ATPase[4]. As Garrahan[6] has pointed out, however, these data are not conclusive.

In support of Robinson's interpretation we present more evidence for cooperative interactions between the Na^+ binding sites of this enzyme. In the presence of Mg^{2+} and P_i a readily reversible binding of ^3H-ouabain to this enzyme was observed[7,8]. The equilibrium level of this binding was lowered by the addition of Na^+, and zero in the presence of high Na^+. At low concentrations of ouabain ($2{\cdot}5 \times 10^{-7}$ M) the Na^+ inhibition curve was almost hyperbolic and the apparent K_m for Na^+ was 2·5 mM. A Hill plot of these data gave a slope of $n = 1{\cdot}11$. When the concentration of ouabain in the medium was increased, the apparent K_m for Na^+ increased and the inhibition curve became markedly sigmoid. At $2{\cdot}5 \times 10^{-5}$ M ouabain the apparent K_m for Na^+ was about 70 mM and n increased to 2·5. These observations suggest a cooperative interaction between the Na^+ sites and seem to represent a "standard example of a heterotropic allosteric interaction"[4,8].

This interpretation is strongly supported by the experiment in Fig. 1, which shows that the cooperativity of the Na⁺ sites is sensitive to a sulphydryl reactant. The (Na⁺+K⁺)-ATPase retains a considerable portion of its Mg^{2+} and P_i-dependent ouabain binding after treatment with ethacrynic acid[9]. After such treatment, however, the Na⁺ sites cannot cooperate as effectively as before, and this is indicated by the changed shape of the inhibition curve and the altered slope of the Hill plot in Fig. 1. Because Na⁺ accelerates inhibition of this enzyme by ethacrynic acid[10] and was used to accelerate inhibition in this particular enzyme, it is unlikely that ethacrynic acid acted directly at the Na⁺ sites. Further, the apparent affinity of the enzyme for Na⁺ was little changed. Thus it seems that ethacrynic acid, interacting with this enzyme at other than the Na⁺ sites, has reduced the ability of these sites to cooperate. The effect resembles the classical desensitization of an allosteric enzyme[11]. It shows that the interaction between the Na⁺ sites is effected by the protein (or lipoprotein) structure of the enzyme, and is therefore allosteric[12].

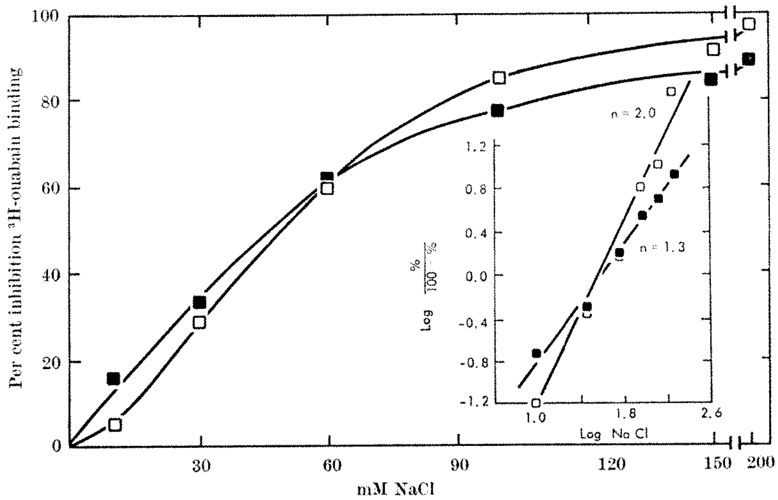

Fig. 1. (Na⁺+K⁺)-ATPase was treated with 10 mM ethacrynic acid for 40 min in 100 mM Na⁺ at 37° C, *p*H 7·6±0·1. The enzyme was then washed three times in buffer by alternate centrifugation and resuspension to remove unreacted ethacrynic acid. (Na⁺+K⁺)-ATPase activity was 79 per cent inhibited: Mg^{2+} and P_i dependent ouabain binding was 38 per cent inhibited. ³H-ouabain 2·5 × 10⁻⁶ M was allowed to bind to both untreated (□) and treated (■) enzymes in the presence of 4·0 mM Mg^{2+}, 1·0 mM H_3PO_4 and NaCl as indicated. Other conditions were as in ref. 8. Binding was plotted as a percentage of the value at 0 mM NaCl. Hill plot slopes were fitted by the method of least squares. In another experiment with a more inhibited enzyme the slope of the Hill plot shifted from 2·38 to 1·10.

Exchange Diffusion

C. and D. van Breeman have reported[1] that radioactive calcium passes more slowly through an artificial membrane when calcium is absent from the *trans* side of the membrane than when it is present. Following a general practice, they call the phenomenon exchange diffusion. Because the membrane was a porous structure they say that exchange diffusion was demonstrated in the absence of carriers, although exchange diffusion was previously regarded as evidence for the existence of carriers. I wish to point out that the apparent contradiction arises because "exchange diffusion" is currently used to name two different phenomena.

Consider a solute passing passively through a membrane. If the individual molecules of solute move independently of one another in the membrane, the ratio of the fluxes of solute in opposite directions must be equal to the ratio of the electrochemical activities of the solute on each side. This is the Independence or Ussing relationship[2-6] and is particularly valuable in non-equilibrium conditions: if experimentally the flux ratio should differ from the electrochemical activity ratio, there must be some interaction and exchange of energy between the solute molecules during passage.

Ussing[3] originally used "exchange diffusion" to describe what happens when the flux ratio is closer to unity than the electrochemical activity ratio, as, for example, when glucose passes through the human red cell membrane[7]. It means that when a solute molecule passes through the membrane it must assist the movement of one or more molecules of the same solute in the opposite direction. The "mobile" carrier[3,8] was proposed to explain this type of interaction. Because all the suggested mechanisms for exchange diffusion seem to be variants of the "mobile" carrier hypothesis, exchange diffusion in Ussing's sense is regarded as strong evidence for the existence of carriers.

But if there are interactions between different solutes within the membrane (sodium and potassium, for example), if there is an active pumping of the solute or if the solute molecules are moved by a flow of solvent, no conclusions about interactions between like solute molecules can be drawn from the flux ratio. In such conditions a fall in the flux when the solute is removed from the *trans* side of the membrane[8] has been taken as evidence for exchange diffusion. The magnitude of the fall was considered to be equal to the exchange diffusion flux before the solute was removed from the *trans* side of the membrane. This test requires that the membrane potential should remain unchanged if the solute is electrically charged. But it also assumes[10] (1) that any exchange diffusion is caused entirely by a carrier system in which the unladen form is immobile: the carrier system can thus only mediate a one-for-one exchange; (2) that removing the solute from the *trans* side of the membrane interrupts the one-for-one exchange but has no other effects on the membrane permeability. Neither of these assumptions is universally true, and so it is theoretically possible for the flux to fall when the solute is removed even though exchange diffusion of Ussing's type is not occurring; or there might be no change, even an increase, in the flux in the presence of exchange diffusion. Unfortunately, however, the limitations of the test have been overlooked, and many now talk of exchange diffusion as if it were synonymous with a fall in the flux when the solute is removed from the *trans* side of the membrane. The term thus describes two different phenomena which are not necessarily related.

I therefore suggest that "exchange diffusion" should be reserved for the appropriate deviation, in passive conditions, of the flux ratio from the independence relationship. The term seems to be justified by the thermodynamic significance of the observations. On the other hand, the fall in the flux of a solute when the solute is removed from the *trans* side of the membrane has of itself no clear thermodynamic significance; it need neither mean that exchange diffusion is taking place nor require the existence of carriers. One should therefore say simply that the flux decreased when the solute was removed from the *trans* side of the membrane.

Demonstration of Sodium and Potassium Conductance Changes during a Nerve Action Potential

WE wish to report a new method with which we have been able to measure the sodium and potassium conductance changes postulated by Hodgkin and Huxley[1] in the course of a single action potential. To measure the membrane conductance at any desired time during the course of the action potential, we have designed a membrane potential control system which can be turned on and off quickly with an electronic switch.

The electronic switch consists of two transistors (PNP and NPN). The emitters of these transistors are electrically connected together to the output of the control amplifier. The collector of the PNP transistor makes electrical contact with the current supplying wire, which is inside the axon. The collector of the NPN transistor is connected through a resistance to the input of the control amplifier. Both bases are electrically connected together and to a positive constant voltage which holds the PNP transistor "closed" and the NPN transistor "open"; application of a rectangular negative voltage pulse to the bases reverses this situation and the membrane potential control is turned on during the pulse.

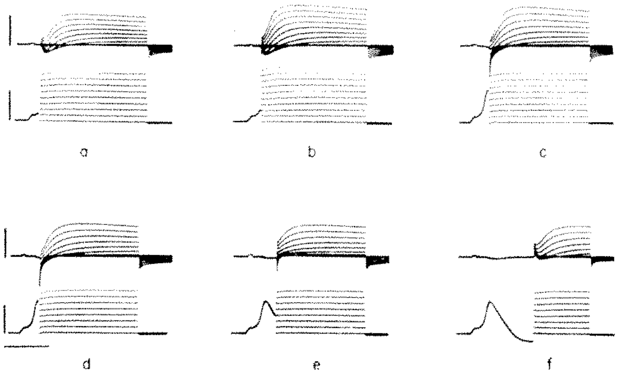

Fig. 1. Upper traces represent records of ionic currents; lower traces represent records of membrane potential before and during the period of membrane potential control. Compensated feedback was used to correct for the voltage drop through the resistance in series with the axolemma. It was set to compensate for only 4 Ω·cm². Ordinate for current traces: 2·68 mA/cm². Ordinate for membrane potential traces: 100 mV. Abscissa: 4 ms. The axon was internally perfused with 550 mM KF and externally perfused with potassium-free artificial seawater at 8° C. The resting potential was −60 mV.

Giant axon fibres from the squid *Dosidicus gigas* were used in this work (for details of the combined perfusion technique and voltage clamp procedure, see refs. 2 and 3).

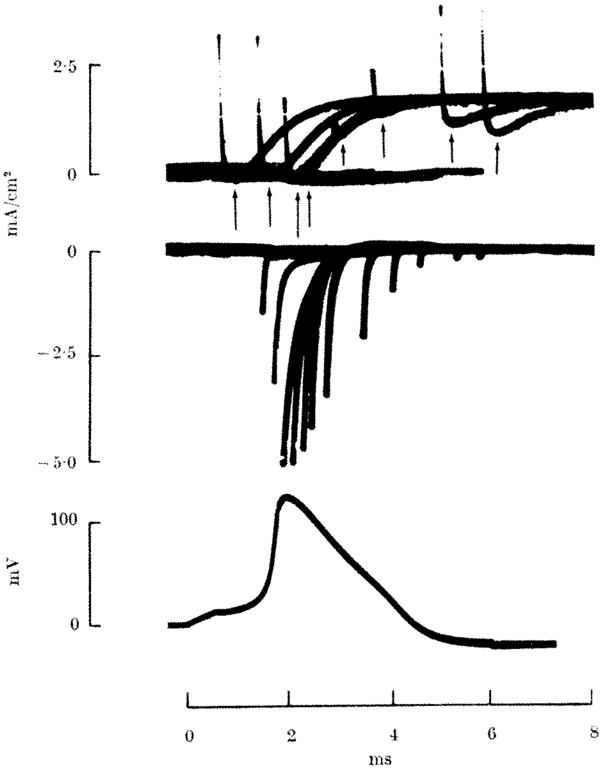

Fig. 2. Upper traces represent unretouched records of ionic currents when the membrane potential during the control period was 60 mV. Lower traces represent records of the ionic currents when the membrane potential during the control period was −80 mV. The capacitative current transients in the upper traces are apparent because a Z-input intensifier was used with the oscilloscope. No series resistance compensation was used. The resting potential was −60 mV. The temperature of the external seawater was 8° C.

Fig. 1 illustrates the results obtained with this switch. Membrane currents are shown in the upper traces; membrane potentials before and during the time in which the membrane potential was under control are shown in the lower traces. The individual traces were taken at intervals of 1 s for depolarizations from the resting potential to −40 through 80 mV in 20 mV steps. Capacitative current transients lasted for about 20 µs and are not apparent in these current records. From these records we have determined six (*a–f*) current–voltage relationships measured 50 µs after the control system was turned on. The slopes of these current–voltage curves were found to be approximately linear and represent the instantaneous conductance at various times during the action potential. The time course of the instantaneous conductance measured in this way is essentially the same as found by Cole and Curtis[4] utilizing bridge techniques and as calculated by Hodgkin and Huxley[1].

The total membrane conductance during a membrane action potential can be split into its "sodium" and "potassium" conductance by the following method. If the potential is switched to −80 mV, which is approximately equal to the potassium equilibrium potential, there is no potassium current, and the current is almost entirely in the sodium channel. Similarly by switching to 60 mV, which is approximately the equilibrium potential of the sodium channel, there is no sodium current, and the current is almost entirely in the potassium channel. Fig. 2 shows the current records obtained when the membrane potential during the control period was either the potential at the peak of the action potential (60 mV, upper traces) or the potential at the underswing of the action potential (−80 mV, lower traces). The points indicated by the arrows on the upper set of transients are proportional to the potassium conductance and show its time course. The beginning of each transient on the lower set of membrane current records is proportional to the sodium conductance and shows its time course.

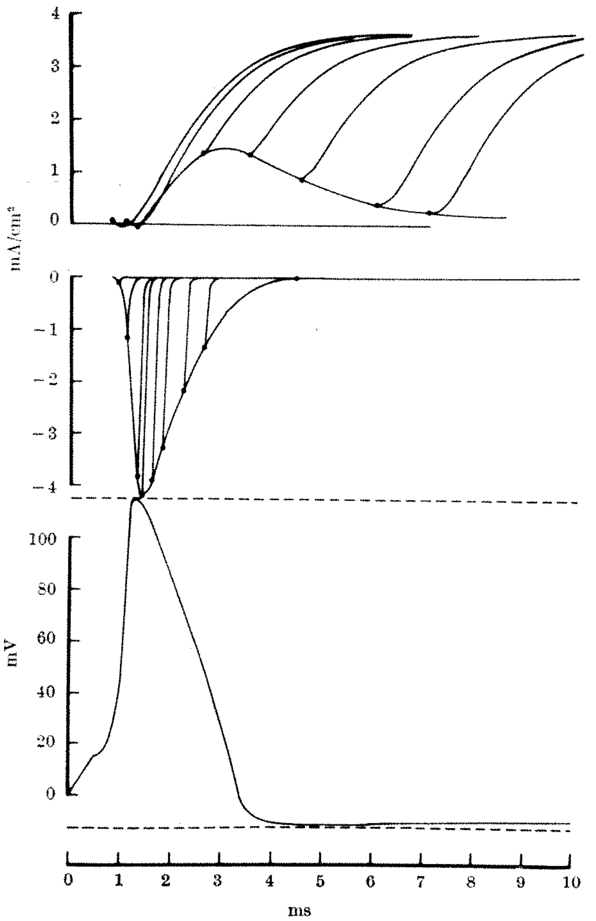

Fig. 3. Ionic currents and membrane action potential calculated utilizing the Hodgkin and Huxley equations[1]. The curve drawn through the points on the upper curves (initial potassium currents) is proportional to the potassium conductance change. The curve drawn through the points on the centre curves (initial sodium currents) is proportional to the sodium conductance change. Resting potential equal to −60 mV. The temperature was 6·3° C.

The results of a similar experiment performed on the model axon are shown in Fig. 3. Ionic currents were calculated utilizing the Hodgkin and Huxley equations[1], but some of the parameters used to compute the action potential were determined for a *Dosidicus* axon. The upper set of curves represents the total ionic currents when the potential during the control period is equal to 55 mV (peak of the action potential) and the lower set of curves represents the total ionic currents when the potential during the control period is equal to −71 mV. The calculated ionic currents are remarkably similar to those shown in Fig. 2 which were obtained on a real axon. Fig. 3 also shows the envelope curves drawn through the points of the initial potassium and sodium currents. The quantitative comparison will be published later, but it is clear that the calculated time course of the potassium or sodium conductance change agrees closely with the measured time course.

We thank Dr C. Armstrong for suggestions during the course of this work and Professor A. L. Hodgkin for comment.

Histochemical Differentiation of Motor Neurones and Interneurones in the Anterior Horn of the Cat Spinal Cord

The neurones of the anterior horn are a heterogeneous population of physiologically different cells. Alpha and gamma motor neurones, Renshaw cells and interneurones are recognized components[1]. Alpha motor neurones have been divided further into F and S types according to the fast and slow contractile properties of the muscle fibres that they innervate[2]. Anatomic investigations, largely by retrograde chromatolysis, have shown that the different neurones are intermingled, and that the larger are mainly alpha motor neurones while the smaller are a heterologous group of gamma motor neurones, Renshaw cells and interneurones[3,4]. Staining techniques selective for the Golgi body differentiate motor neurones from interneurones by the direction of their axons, but standard histological methods result in uniform staining without significant morphological distinction. We have used histochemical staining reactions to attempt neuronal differentiation in the anterior horn.

The histochemical techniques for phosphorylase, diphosphopyridine and triphosphopyridine diaphorases and α-glycerophosphate menadione-mediated dehydrogenase have been described previously[5]. Those for succinate, malate, lactate and glucose-6-phosphate dehydrogenases, with minor modifications, were performed as summarized by Pearse[6]. The tissue investigated was the lumbar seven spinal cord segment of the cat, fresh frozen and serially sectioned at 20 μm.

Marked differences in the activities of phosphorylase and succinate dehydrogenase were found among the neurones in the anterior horn (Fig. 1*a* and *b*). Consistent patterns of cell distribution for each enzymatic reaction were found according to cell size and area of grey matter (Fig. 2). In the ventrolateral pool the large (more than 50 μm) and medium (30 to 50 μm) neurones were high in phosphorylase and low in succinic dehydrogenase. The small (less than 30 μm) neurones were negative for phosphorylase but exhibited high activity of succinic dehydrogenase. These results were confirmed for individual neurones when identified in serial sections, histochemical staining providing clear separation of two types of neurones otherwise lying interspersed. The staining reactions were located in the perikaryon and, with succinate dehydrogenase, also in (or on) the dendrites. Neurones of the ventromedial grey matter were uniformly high in succinic dehydrogenase and negative for phosphorylase. This was true even in medium sized neurones. Exceptional medium and even small size neurones with high activity in both enzymes were found in the ventromedial area. The axon exit zone of the anterior grey matter (Fig. 2) demarcated the different histochemical features of the ventromedial and ventrolateral areas.

According to previous anatomical knowledge mentioned, the larger neurones in the anterior horn are alpha motor neurones and the smaller are gamma motor neurones, Renshaw cells and interneurones. The neurones of type "S" (slow) motor units are considered to be smaller than those of type "F" (fast) motor units[2,7]. Characterization of anterior horn neurones in the middle of the size spectrum has not been possible with current physiological techniques.

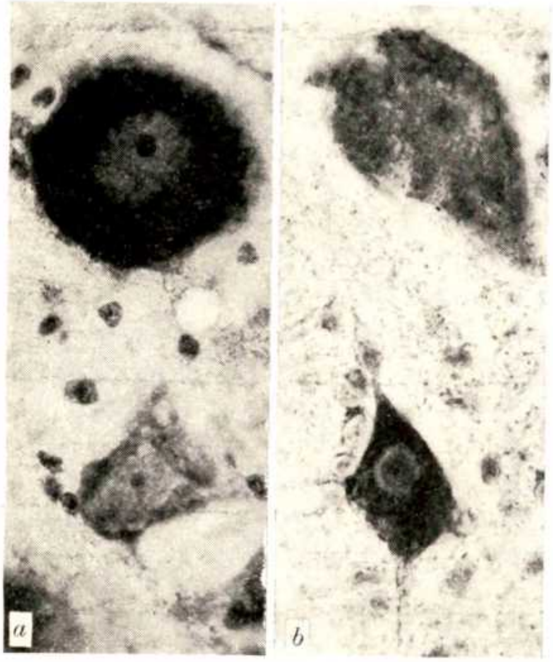

Fig. 1. Differences in the intensity of staining reactions ("darkness") for (*a*) phosphorylase and (*b*) succinate dehydrogenase in large and small neurones of the ventrolateral grey matter. Because in each reaction a counterstain of contrasting colour (gallocyanin for phosphorylase and saffranin for succinate dehydrogenase) was required to demonstrate enzymatically poorly reactive neurones, the marked contrast between strongly and weakly reacting neurones of the original slides and colour photographs could not be faithfully reproduced in black-and-white photographs. × 480.

These reactions for phosphorylase and succinate dehydrogenase separate the neurones of the ventrolateral grey matter into two groups with diameter larger and smaller than approximately 30 µm. It may be concluded that the largest type "F" alpha motor neurones belong to the group with high phosphorylase and low succinate dehydrogenase activities and the smallest gamma motor neurones, Renshaw cells and interneurones correspond with the reverse histochemical group with low or no phosphorylase and high succinate dehydrogenase activities. The type "S" alpha motor neurones and perhaps some interneurones of the ventrolateral grey matter could belong to either or both histochemical groups.

The histochemical demonstration of high level of phosphorylase in alpha motor neurones suggests that they are more dependent on glycogen metabolism than other spinal neurones.

Other histochemical reactions used in this study failed to show differences among the neurones of the L-7 cord segment. The activities of NADH and NADPH diaphorases, and of lactate and malate dehydrogenases, were equally strong in all neurones. The reactions for glucose-6-phosphate and menadione-mediated α-glycerophosphate dehydrogenases were uniformly negative.

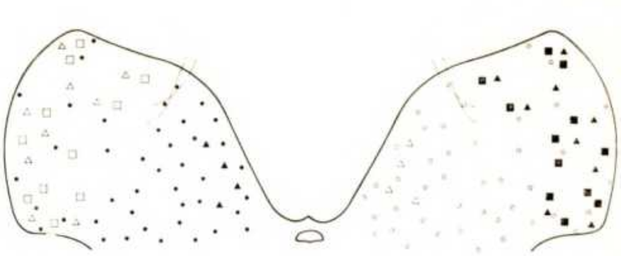

Fig. 2. Diagram of the anterior horns representing the histochemical reactivity (high = black, and low = white) for succinate dehydrogenase (left horn) and phosphorylase (right horn) in large (squares), medium (triangles) and small (circles) size neurones. The axon exit zone is represented by crossed lines.

Effects of Lithium on Amino-acids in Mouse Brain *in vivo*

LITHIUM exerts marked effects on the function of brain and peripheral nerve *in vivo* and *in vitro* and has been used successfully in the treatment of manic-depressive psychoses[1,2]. Although the effects of lithium treatments on monoamine metabolism have been studied[3,4], the relationships which may exist between lithium injections and the content of free amino-acids of brain remain unexplored. Recently, it was shown that injection of lithium directly into the amygdala of monkeys which were awake exerts very potent and reproducible effects on the EEG. After these effects had subsided they could be re-induced by direct injections of L-glutamate into the same sites[5]. It was therefore postulated that glutamate exerts its pharmacological action in animals which were awake by increasing the permeability of CNS neurones to sodium or to lithium (the latter not normally being present)[5]. Our experiments were conducted to show whether lithium injections affect the content of glutamate in the brain.

Young, male, Swiss albino mice (ICR strain), weighing about 20 g, were decapitated at various times after short-term intraperitoneal injections of LiCl (1·0 M) in doses of 0·1–2·0 ml. per mouse. Their brains were excised, homogenized in nine volumes of ice-cold ethanol (v/v) and centrifuged for 1 h at 20,000g (refs. 6 and 7). Aliquots of the clear supernatant fluid representing 10 mg brain tissue were subjected to an accelerated system of automated amino-acid analysis[8-10]. For studies on the effects of lithium on the synthesis of amino-acids in brain, 1·0 µCi/g

* Intraperitoneal injections of 1·0 M LiCl.

† Brains were removed within 1 min after mice were killed except when 1·0 and 2·0 ml./mouse of LiCl were injected; in the latter cases all mice died within 5–10 min after injection.

‡ $P < 0{\cdot}001$, by t test.

Results are means ± $S.E.$; numbers of mice are in parentheses.

(of mouse) of $^{14}C_6$-D-glucose (110 mCi/mmole) was injected intraperitoneally 30 min before mice were killed. Amino-acid analyses were carried out as described and in some cases the effluent from the analyser was coupled to a fraction collector so that radioactivity in the amino-acids could be monitored[9,10]. Radioactivity was measured with a Packard scintillation counter and corrections for quenching were made by a method of external standardization.

It is clear that cerebral glutamate is decreased with injections of 0·25 and 0·5 ml./mouse of LiCl and that this change occurs rapidly (see Table 1). When mice were given very large doses of LiCl (1·0 and 2·0 ml./mouse) and allowed to die from the toxic effects before their brains were excised, glutamate levels were not changed though the well known post-mortem increases in GABA[6] and α-alanine (for example, ref. 11) occurred. All mice became sedated within a few minutes after injection of 0·25–2·0 ml. of LiCl, but a detailed study of this behavioural change was not made. The total amount of radioactivity of $^{14}C_6$-D-glucose which was found in the brain was not significantly decreased by LiCl injections (0·25 or 0·5 ml./mouse) given either 10 min after or 30 min before glucose (four mice in each case and four control mice), but the radioactivity in all amino-acids was decreased by about 10–20 per cent. There was no selective action of LiCl on the synthesis of glutamate.

The significant decrease in cerebral glutamate caused by short-term LiCl treatments may be related to the mechanism responsible for the sedative action of lithium in animals and to its prophylactic effect on manic-depressive psychotics, but further and more detailed studies involving chronic treatments are required. The fact that glutamate was the only amino-acid affected by lithium treatment could lend support to its suggested role as an excitatory transmitter[12], although the possibility exists that the change is a result of, rather than the cause of, sedation.

Two Innate Releasing Mechanisms subserving the Same Motor Pattern System

ANIMALS respond to an external stimulus situation with the biologically appropriate motor pattern. The response is triggered by a filter system which is called here an innate releasing mechanism (IRM)[1,2] if it functions independently of any experience with the appropriate stimulus situation. The mobbing response of breeding pied flycatchers (*Ficedula h. hypoleuca*) to owls and shrikes is highly stimulus specific; moreover, it is independent of individual experience with these predators (ref. 3, and our unpublished results). The question, then, is whether these two predators are recognized by means of two different IRMs (first hypothesis), or whether a more general IRM is used (second hypothesis).

To decide between the two models, a number of special experiments were designed. In the course of 11 years, seventy different enemy dummies were shown to over 2,200 breeding pied flycatchers at a standard distance from their nest box (study areas in Berlin, around Frankfurt/Main, and near Brunswick). The mobbing response was measured by counting the calls during a standard period. Each bird was tested once only, to circumvent biasing after-effects. The results obtained will be stated here only in qualitative terms; the quantitative details will be published elsewhere.

The first method was to present dummies combining owl and shrike characters with releasing value. For the sake of comparison we selected enemies of equal size, the pigmy owl (*Glaucidium passerinum*) and the red-backed shrike (*Lanius collurio*). The total colour pattern of the male shrike or its most effective part was transferred to a wooden painted model of the owl, and vice versa. Experiments allowed for the fact that such transference of "donor" sign stimuli took place, in some cases, at the expense of sign stimuli of the "host" dummy. The behaviour capacity of the birds would have allowed an increase in response strength[4]. The visual change interferes, however, with the original appearance of the "host" object and thereby decreases its releasing value. At the very least it leaves it unchanged. According to the "law of heterogenous summation", the sign stimuli entering one and the same IRM should summate[5], though not necessarily in an algebraic manner[4]. The result therefore favours the first hypothesis by exclusion of the second.

The second method was to compare dummies of both predator species altered identically. The rationale behind this method is to modify both the shrike and the owl with respect to some character shared by both. If the amount and/or the direction of the resulting change in the strength of the response is different in each case, the first hypothesis would be supported. This follows because the two presumed IRMs could then be distinguished, at least, on the basis of their differential evaluation of that changed common character, depending on the accompanying stimuli[6]. For the comparison to be conclusive, it was essential that the scaling of mobbing motivation should be known, as reflected in the measured response[4]. The only character thus tested yielded a result that clearly favoured the first model.

The third method used stimulus specific habituation to either of the two avian predators. The response to both the owl and the shrike can be habituated by ineffective models of either type, thereby avoiding any possible change of the mobbing motor system as a consequence of the stimulation[7]. By this "reaction-free" habituation, the response to the shrike could be entirely eliminated without interference with the response to the owl, which maintained the full releasing value. This experiment reveals more directly than the two first methods the high degree of functional independence of the two channels under consideration, thus supporting the first hypothesis too.

The model of at least two IRMs converging before or on the mobbing motor system is in harmony with two other findings. First, there is interaction between the sign stimuli within both the owl and the shrike, the respective releasing values not being added algebraically (unpublished). Second, the recognition of both predators in two subspecies of the pied flycatcher matches closely the differential distribution of shrikes in the two areas concerned[3].

The organization of the IRM coping with the resting avian predator into operationally defined functional subunits outlined here shows that "the IRM" is not as unitary either as critics of the concept have propounded[8,9] or as many investigators using it believe it is.

Learning of Leg Position in Chronic Spinal Rats

Is the brain necessary for learning? Pavlov[1] concluded that the cortex is essential for conditioning; yet Culler and Mettler[2] reported conditioning a decorticate dog, while Shurrager *et al.*[3–5] report having conditioned dogs and cats caudal to spinal cord transections. Franzisket[6,7] believes that it is possible to condition the withdrawal reflexes of spinal frogs.

Such evidence has not been widely accepted. Other similar experiments have failed[8,9], and alternative interpretations can be made[10]. One difficulty has been the absence of appropriate control animals[10].

Chamberlain *et al.*[11] have studied a phenomenon that resembles learning in spinal rats; and the conditioning of foot withdrawal has been reported for chronic spinal kittens[12] and acute spinal cats[13]. A. A. B. and Dawson[14] discussed an effect akin to conditioning in chronic spinal kittens. Horridge[15,16] devised an ingenious paradigm for studying how insects learn leg position when their heads are removed or part of their nervous system is isolated. His method is particularly useful because it includes a yoked control, and we have used it in a modified form to study chronic spinal rats.

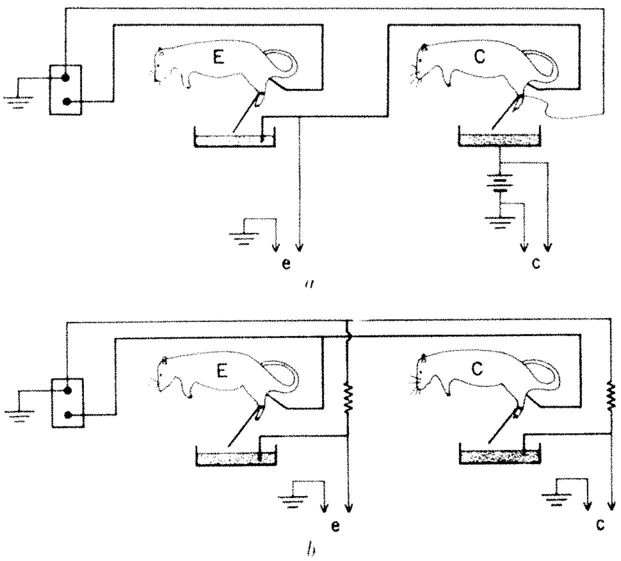

Fig. 1. *a*, The experimental situation; *b*, the testing situation.

In the first step (Fig. 1*a*) the experimental animal serves as an electrical switch for the control animal. The position of the experimental animal's leg determines whether it is shocked; there is no relation between leg position and shock for the control.

In the second step (Fig. 1*b*), the aim is to verify learning by testing for improved performance (savings) resulting from previous experience. Each animal is electrically independent of the other and the leg position of each animal determines whether it is shocked. If learning occurs, two effects would be expected. (1) In the training situation, the experimental animal should hold its leg so as to avoid shock, whereas the control animal should not change its normal leg position. (2) In the testing situation, the experimental animal should avoid shock before the control animal does. Horridge found these results with headless cockroaches and locusts; we have tried to obtain them for chronic spinal mammals.

The spinal cords of mature female rats were transected between L_1 and L_2 under barbiturate anaesthesia supplemented with atropine sulphate. The dorsal and ventral roots exposed by the transection were cut. The small amount of bleeding that occurred was controlled with saline-soaked cotton, thrombin solution or gelatine sponge. When the transection was complete, the bottom and sides of the vertebral canal were seen to be free of neural tissue at the site of the transection. This procedure was the first check that the cord was cut completely; the fact was verified at autopsy. Several days after surgery, two animals were fastened snugly in wire mesh tubes. Holes had been cut in the tubes so that their hind legs could hang freely. The same hind leg on each animal was extended dorsally and taped out of the way. On the contralateral feet, electrodes of fine silver wire were inserted under the skin over the dorsal surface of the metatarsal bones. They were then connected in the training situation as shown in Fig. 1*a*. All connexions except the foot electrodes were of insulated copper wire. The containers of electrolyte solution were filled with 10 per cent acetic acid. The shocks were then delivered by a commercially available stimulator. Sometimes the natural tonus of the leg muscles was so great that the legs were weighted slightly; if so, identical weights were always applied to both animals. A multichannel recording device of high input impedance was connected to the apparatus at points *e* and *c* for separate recordings of the withdrawals of each animal. Because the input impedance of the device was high, it did not influence the responses of either animal.

Pilot experiments convinced us that the phenomena we were looking for could not be obtained easily if the animals could remove their electrodes from the electrolyte by extension of the leg. Typically, the animals would extend the legs backwards about once a second for 10 to 20 min until habituation or fatigue occurred. We tried several methods designed to make the animals remove their electrodes by flexion. The simplest effective way we found was to tie a ligature firmly around the foot at the level of the tarsal bones and then to fasten it at a point in front of the animal such that the leg hung naturally but could not move caudally. All our animals' legs were tied in this way and levels of the electrolyte containers were carefully adjusted so that both animals' electrodes were inserted the same distance into the fluid. The exact distance varied between 1 and 3 mm.

Both experimental and control animals received the same pattern and intensity of current in the training situation. Any subsequent differences between animals therefore occurred because experimental animals always received shocks when their legs were in a particular position, whereas control animals received shocks unrelated to leg position. Rather, the control animals received shocks at times determined by the position of the experimental animal's leg. For these reasons, the exact stimulus parameters are not important because they could not have produced subsequent differences in behaviour. The stimulator was turned on and the stimulus parameters set so that both animals began flicking their legs out of the water. If the experimental animal stopped flexing its leg, the stimulus parameters were increased. After a training period of 10–30 min, the two animals were reconnected in the testing situation (Fig. 1*b*): each was shocked independently whenever its own foot was lowered far enough for the attached electrode to enter the conducting solution. The levels of the containers were again adjusted with each foot electrode an equal distance into the solution, and the stimulator was set to make both animals flick their electrodes out of the solution.

We had hoped to put each pair of animals through the procedure twice, using different pairs of legs, with a few days betweeen tests. We also planned to exchange the experimental and control animals the second time around. Chronic spinal mammals are, however, prone to sickness and we refused to start with a pair in which either animal showed any signs of disease or in which hind leg withdrawal reflexes did not appear normal. Only two pairs of animals stayed in good condition long enough to be used twice. They showed the desired results on both sets of rear legs: after exposure to the experimental situation using the right legs, the experimental animals held their electrodes out of the solution, whereas the control animals did not. During the testing situation, the experimental animals showed savings, that is, they held their electrodes out of the solution sooner and for a longer time than the controls. Finally, two days later, both pairs were tested with the left legs, using the former experimental animals as controls and vice versa. The results were the same as before. Five pairs of rats were put through the procedure once only, and they all gave similar results.

Our results are significant at the 0·01 level, according to the Fisher exact probability test[17]. They demonstrate that repetitive application of shocks when the leg is in a given position produces changes absent when the same shocks are applied without relation to leg position. It seems fair to conclude that the isolated spinal cord is capable of associating leg position with shock. In psychological terms, the phenomenon seems to be a form of escape and avoidance learning by an isolated and rather simple part of the nervous system. A physiological, anatomical or biochemical analysis of this phenomenon will probably be quite complex, in spite of the relatively small number of neurones involved.

Our research was partially supported by a fellowship from the US National Institute of Mental Health (A. A. B.), a traineeship grant from the US National Science Foundation to Harvard University, and by grants to C. G. Gross from the US National Institute of Mental Health and the US National Science Foundation. We thank the faculty and staff of the Department of Psychology at Harvard University for help and advice, especially Dr C. G. Gross for his discussion and support, and D. Bender and P. Rogers for technical assistance.

Movement Control in a Repetitive Motor Task

IN experiments that used a pencil and graph paper targets, we have been able to demonstrate what we believe to be the intermittency of visual feedback control in a simple motor task. The intermittency hypothesis was first advanced by Craik[1]. It was developed by E. R. F. W. Crossman and P. J. Goodeve in their theoretical analysis of movement control (unpublished), showing that an intermittent servo mechanism could produce results obtained by Fitts and others that related the speed of movement to the terminal accuracy.

We have attempted to show the intermittent nature of visual feedback in a simple speed and accuracy experiment by interrupting the visual feedback loop. In our experiment the subject aims with a pencil at a vertical line target about two feet in front of his face, from a home position near his shoulder. The accuracy of movement is registered by the root mean square of the distribution of pencil marks about the target. Various speeds are achieved by asking the subject to make repeated movements in time with a metronome.

The pencil has a "wing" of cardboard taped to it, near the point, and when the wing breaks an infrared beam the illumination of the target and the room is extinguished. It returns as the subject leaves the target. The infrared beam can be moved to various distances from the target.

We assumed that if error feedback were sampled, then a delay would occur while processing went on until a motor correction occurred. In this case the accuracy of hitting the target should depend on whether the light was turned off nearer or farther from the target than a distance corresponding to the corrective reaction time

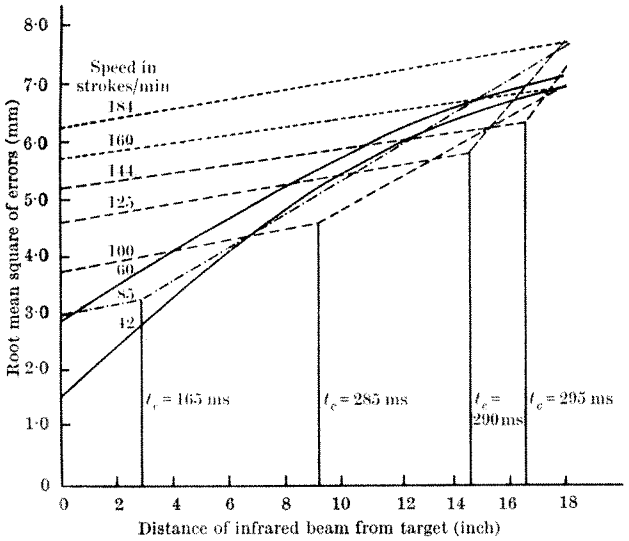

Fig. 1. Effect of extinguishing the light at different distances from the target at different speeds.

t_c. The effect on the accuracy should be greater when t_c is exceeded.

Fig. 1 shows the relationship we found between the root mean square of the errors on target at different speeds, and the distance of the infrared beam from the target. For the faster movements, 700 ms and less, the expected result is obtained. For the slowest speeds, with movement times of 1 s and more, the lines show no discontinuity and curve in the opposite direction. We believe the explanation is that the subject, in the very unnatural condition of aiming slowly in the dark, adopts a different strategy from the strategy he uses when working more quickly.

We have recorded the time from breaking the beam to hitting the target in all our experiments. These data yield a set of approach curves, giving the time to impact at any distance and speed. We can simply read off from them the time to impact corresponding to each break in the curves in Fig. 1.

Our estimates of t_c appear in Fig. 1. There seems to be an anomalous result at a speed of 700 ms movement time, but a mean corrective reaction time of 290 ms is found at the higher speeds. This value is of the order of that found by Keele and Posner[2] and Vince[3]. It thus seems reasonable to identify the discontinuities in three of our curves as evidence of delayed visual feedback processing.

The equal slopes in the non-visual parts of these curves look interesting, but we cannot yet explain them.

Our research is supported by a grant from the Medical Research Council.

Water Uptake from Subsaturated Atmospheres: its Site in Insects

Although the uptake of water from subsaturated atmospheres by some arthropods is well established, neither its mechanism nor its site has been conclusively established. Uptake may occur over the general body surface and the mechanism involve both cuticle and epidermis: much of the evidence is summarized by Beament[1-3]. Conclusive location of the site of uptake would be an important step in the elucidation of the mechanism. I deal here with a test of the assumption that uptake takes place over the general body surface, attempting to locate the site of uptake more precisely.

The firebrat *Thermobia domestica* (Packard) is capable of absorbing water from atmospheres down to 50 per cent relative humidity (RH)[4,5]. In my experiments, 2 days of desiccation in dry air at 37° C depleted the water content of the insects, and the mean weight loss of twenty-six insects was 17·1 ± 1·5 per cent (*S.D.*) of their initial weight. The experimental treatments were then carried out under carbon dioxide anaesthesia. After recovery from anaesthesia, subsequent gains were measured after 1 day of exposure to 83 per cent RH at 37° C.

Control insects were handled under anaesthesia as though being operated on, but given no further treatment. Gains were 17·1 ± 6·2 per cent of their initial weight, returning them almost exactly to their initial weight.

In a series of sham operations, paraffin wax, heated so that it just melted, was applied to different regions of the body. Subsequent gains were 18·2 ± 1·2 per cent after treatment of the mid-dorsal surface of the abdomen, 13·5 ± 3·2 per cent for insects with their mouths blocked, and 11·0 ± 4·7 per cent after treatment of the posterior ventral surface of the abdomen. These gains differ significantly neither from those of the control insects nor from one another (t tests, $P > 0·05$ in all cases).

The main operation was to block the anus with molten wax, with care to avoid damage to surrounding tissues as far as possible. No treated insect subsequently showed any gain. Losses amounted to a further 3·4 ± 1·5 per cent of the initial weight after 1 day and continued subsequently. Occlusion of the anus clearly prevents uptake of water from the atmosphere.

This was further confirmed by making continuous weight recordings at 20·5° C of individual insects given successive treatments. Gains in 84 per cent RH were recorded before and after treatment of the dorsal abdomen; but only losses were recorded when the anus was blocked.

These experiments point conclusively to the anal area as a localized site for the uptake of water from the atmosphere. The failure of oral blocking to prevent uptake precludes the reingestion of hygroscopic faeces as a mechanism of water uptake and confirms previous work[2,3]. Blocking of the anus does, however, cut off the rectum from the exterior, and it is probable that this explains the effect of this treatment. The rectum in *Tenebrio* equilibrates the air spaces in its lumen to 88 per cent RH[6], which is also the lowest humidity from which this insect can absorb water. Preliminary experiments with *Tenebrio* indicate that uptake is prevented when the anus is blocked, and recommences when the block is removed. Taken together with the results in *Thermobia* it would seem that the rectum is the site of uptake, being connected to the atmosphere through the valve-like anus. The rectum is known to be involved in the reabsorption of water from the faeces and is under physiological control in the insect[7-14]. Preliminary observations on *Thermobia* show that it has the complex fine structure associated with water-absorbing tissues. The involvement of the rectum in the uptake of water from the atmosphere could prove on further investigation to be of more general distribution.

One implication of these findings is that the general body surface does not take part in uptake, the cuticle of these areas being involved only in the restriction of transpiration. Lowered water potentials in the cuticle of living insects[15,16] may therefore not be of significance in the uptake mechanism, but may only reflect an added device for restricting transpiration. A further implication is that the site of uptake is separate from the site of restriction of transpiration, as foreshadowed in earlier work on *Thermobia*[5].

I thank the Agricultural Research Council for a grant in support of this investigation.

Alarm Pheromone and Avoidance Conditioning in Goldfish, *Carassius auratus*

WHILE the alarm reaction in fish is believed to be produced by a chemical substance (pheromone) secreted by specialized cells in the epidermis and released by epidermal damage, relatively little systematic research has been devoted to the extent, nature or essence of the reaction and its relationship to the relevant chemical substance[1]. Our investigation represents an exploration of the effect of alarm pheromone on avoidance conditioning. Fifteen 2 inch goldfish, *Carassius auratus*, were kept in a thirty gallon aquarium divided into thirds by wire barriers. In accordance with other reports, the fish were deliberately well fed[2]. Massed avoidance conditioning (all trials on one day) was studied in a Lafayette Instrument aquatic conditioning unit (volume of approximately one gallon; inside dimensions, 3·5 × 6 × 9 inches). Lights at each end of the conditioning tank served as the conditional stimuli (CS) and electric shock as the unconditional stimulus (US). Shock was adjusted for each fish and varied from 5 to 7 a.c.

A successful avoidance response involved swimming out of the lighted side of the tank into the dark side within the CS–US interval of 7 s. Following the 7 s CS, the CS remained on and shock was delivered through electrodes at the top and bottom of the tank on the lighted side only for 23 s. The next trial started 30 s after shock offset. Thus the intertrial interval was a constant 1 min. The experimenter manually switched the apparatus so that, regardless of the fish's position (if, for example, it swam through the divider during the intertrial interval), the CS (light) would be presented on the side of the tank that the fish was occupying at the start of each trial. In other words, this is a two-way shuttle avoidance paradigm.

Thus a typical avoidance paradigm was followed (delay procedure, CS–US interval of 7 s, 1 min intertrial interval) with trials continuing until a criterion of twelve successful avoidances out of fifteen consecutive trials was attained. Six of the fish received training trials in aquarium water, four were conditioned in aquarium water into which 50 ml. of pheromone solution had been thoroughly mixed, and five were left undisturbed in one end section of the aquarium. The alarm pheromone was prepared by scaling a freshly decapitated goldfish into 50 ml. of aquarium water.

Fish conditioned in plain water reached criterion in an average of 65·5 trials (range 49–84). Fish conditioned in water containing pheromone reached criterion in an average of 45·5 trials (range 12–94). Using the Wald–Wolfowitz Runs test, this was found to be a significant difference ($P < 0·05$). It should be pointed out that the extreme case in the pheromone group (ninety-four trials) was operating "near" criterion throughout, and all the other pheromone fish reached criterion in thirty-eight trials or less. To assess the effects of pheromone on activity and to observe the "fright" or alarm reaction more carefully (with video tape), 100 ml. of pheromone solution was prepared by scaling two freshly killed goldfish into 100 ml. of aquarium water. The solution was dumped into one corner of the section of the aquarium containing the five previously undisturbed fish. As soon as several of the fish happened to swim into the area in which the solution had been dumped, they displayed agitated, non-directional, jerky movements with fins fully erected. Soon afterwards, all the fish began doing this and within seconds all sank to the bottom of the tank in the corner farthest removed from the one into which the pheromone solution had been dumped. The form of the reaction agrees with other reports[2]. The fish remained clumped together in this fashion and did not resume their normal free-swimming patterns for several hours.

The pheromone's effect on avoidance conditioning cannot be explained from this brief experiment. It is probably not the result of an increase in general activity or reactiveness to stimuli in general as shown by the large tank experiment. Observation did not reveal any differential sensitivity to electric shock in the two groups. As shown by the large tank experiment, alarm pheromone seems to produce not only "fright" and "alarm" behaviour but also flight or withdrawal. In our apparatus, avoidance involved swimming from a lighted chamber on presentation of the CS into a dark one. Even though this is a somewhat unnatural situation for a fish to be in, it is probably similar enough to swimming into dark recesses and crevices, as many kinds of fish do when frightened or threatened. So perhaps the increased "fearfulness" resulting from the alarm pheromone in the water interacts with the CS–US pairing to result in an enhancement of avoidance conditioning.

Serum Lipids and the Death of Spawning Pacific Salmon

DURING a recent expedition of the R/V Alpha Helix (1968), we had the opportunity to compare blood serum lipids of pink salmon (*Oncorhynchus gorbuscha*) collected at two points in their spawning migration. Fish were sampled from commercial purse seines near Namu, which is located on the British Columbia coast at the entrance to the Burke Channel; and again 60 miles from the sea in a small freshwater stream (a tributary of Thornsons Creek) near Bella Coola, at the head of the same channel. The fish were spawning at this latter site and were obtained by dip net. The principal difference between the Namu and Thornsons Creek fish was that the latter had undertaken a migration of 60 miles under total fasting conditions. The Namu fish were in good condition while those in the freshwater stream had lost on average one-third of their weight and were close to death. Other studies[1-4] have demonstrated that salmon lose weight during the spawning migration. It is known that lipids are the principal substrate in the energy metabolism of fish and that 91 to 96 per cent of the fat reserve in the salmon is utilized during this migration[1]. Ultrastructural observations (to be published) confirmed that lipid deposits had disappeared from the back muscle of the salmon after migration.

By thin layer chromatographic analysis a large triglyceride component was consistently detected in individual as well as pooled serum samples for both male and female pink salmon from Namu whereas little or no triglyceride could be detected in similar serum samples of spawned fish. Because circulating triglycerides must be an important energy source in fasting fish, a more detailed analysis of the major classes of serum lipids for representative groups of fish from the two sites was undertaken.

Blood (10 to 15 ml.) was drawn from the caudal vein of freshly caught fish and allowed to clot for 30 min in 12 ml. conical centrifuge tubes. Serum was collected from above the sedimented clot after centrifuging for 15 min at 3,000 r.p.m. Lipids were extracted from 2 ml. serum samples by the method of Folch *et al.*[5]. The concentration of total lipid in serum was calculated from the weight of the extracted lipids which were made to 2·0 ml. in chloroform and stored at 2°–4° C. Aliquots of the chloroform solutions were analysed: total cholesterol by the method of Abell *et al.*[6] and phospholipid phosphorus by the procedure of Rouser *et al.*[7]. After separation by thin layer chromatography, triglycerides and free fatty acids were analysed by the methods of Stern and Shapiro[8] and of Duncombe[9], respectively. Thin layer chromatography was also used to separate the free and esterified cholesterol, the relative proportions of which were then calculated from data by the Abell method.

Table 1. AVERAGE CONCENTRATIONS OF MAJOR BLOOD SERUM LIPIDS IN PINK SALMON COLLECTED AT TWO POINTS ON THEIR SPAWNING ROUTE

	Lipids (mg/100 ml. ± *S.D.*)	
	Ocean coast	Spawning ground
	mg/100 ml. (± *S.D.*)	
Total cholesterol	267 (± 31)	237 (± 22)
Phospholipids	994 (± 139)	410 (± 56)
Triglycerides	375 (± 117)	71 (± 11)
Free fatty acids	26 (± 5·6)	16 (± 3·5)
Total lipids	1,986 (± 328)	640 (± 121)

Results are from duplicate analyses of eight representative fish at each location.

Table 1 includes data from four males and four females of the post-spawning specimens and two males and six females of the pre-spawning fish. For the variables which were particularly significant in this study, that is, serum triglycerides and total serum lipids, sex did not appear to be an important factor. The data for phospholipids were derived by multiplying lipid phosphorus in 100 ml. of serum by a factor of twenty-five. The free fatty acid values were calculated as stearic acid, the triglycerides as triolein. Only one or two of the serum lipid samples showed an even faintly detectable level of diglycerides and none showed monoglycerides by thin layer chromatography.

The cholesterol levels of the two groups of fish were fairly comparable. The ocean fish averaged 54 per cent esterified and 46 per cent free cholesterol; the post-spawning fish had 60 per cent esterified and 40 per cent free cholesterol. The serum free fatty acids of the ocean fish averaged somewhat higher than those for post-spawning fish, but this resulted primarily from two fish in the ocean group with higher levels (44 and 52 mg/100 ml.). Bilinski and Gardner[10] have shown that starvation of rainbow trout over a 70 day period brings about no marked change in plasma free fatty acids. The vanishing levels of triglycerides in the post-spawning fish may, however, signal a failing supply of energy to vital organs and muscles. This depression was confirmed for many fish in addition to the sixteen for which data are provided. There is no plausible food supply which could feed millions of mature salmon in the spawning streams. Our data regarding loss of weight and marked depression of serum lipids support the conclusion that these fish are starving.

Host Response of Tobacco to *Verticillium dahliae* (tob.) Kleb.—a Cytological Method of assaying Resistance

A WILT disease of tobacco caused by *V. dahliae* constitutes an economic problem in New Zealand. During a histological study of the progress of the pathogen inside the host tissue, the interplay of various mechanical defence mechanisms such as gummosis and tylosis was observed in the vessels of roots and stems. In the meristematic regions of the root-tips, however, a reduction in cell division was revealed by the number of metaphases in the infected resistant variety as compared with non-infected plants or infected susceptible plants. This observation was subsequently confirmed, and I report the findings here.

In the experiments, I used plants of two varieties of tobacco—a biotype of McNairs 121 (MN), which is a resistant type, and Virginia Gold (VG), a susceptible variety. The plants were grown to transplanting stage (6–8 weeks old), and after most of the fibrous root system had been severed they were washed, surface sterilized in 5 per cent sodium hypochlorite solution and transferred to a standard water culture solution in glass tubes. After 6–7 days in a growth chamber the roots emerged. A control sample of the extreme tips of 2–3 roots was fixed in 3 : 1 alcohol–acetic acid solution. The water culture solution was then replaced by a spore suspension (8×10^6 spores per ml.) of *V. dahliae*, grown on potato dextrose agar for 4 days. Samples of root-tips were taken at 4, 8, 16 and 24 h, and fixed for 2 h in the alcohol–acetic acid mixture. The plants were retransferred to water culture solution and further samples of root tips were taken on the third and fifth days.

After fixation, root-tips were transferred to a mixture of nine parts of acetic acid–orcein[1] (0·5 per cent orcein in 45 per cent (by volume) acetic acid) and 1 part of 1 M HCl and heated gently over a spirit lamp. The extreme tip of the individual root was squashed under a cover slip which was sealed with a rubber solution. The number of cells at the metaphase stage was counted under a microscope (×250). The thickness of the root-tips was taken into consideration in averaging the results, which are summarized in Table 1.

Table 1. EFFECTS OF SPORE SUSPENSION OF *V. dahliae* ON ROOT MERISTEM OF TOBACCO

No. of sample	Time	McNairs 121 (MN resistant) (No. of cells showing metaphase)	*Virginia Gold (VG susceptible) (No. of cells showing metaphase)
1	0 h	180 (control)	160 (control)
2	4 h	45 (spore suspension) †	170 (spore suspension)
3	8 h	50 ,, ,, †	150 ,, ,,
4	16 h	80, 15 ,, ,,	60, 15 ,, ,,
5	24 h	100, 10 ,, ,,	50 ,, ,,
6	72 h	200 (water culture)	180 (water culture)
7	120 h	260 ,, ,,	200 ,, ,,

Figures recorded here are an average of 20 experiments of 10 plants each.

* 5 Virginia Gold plants showed reduction in metaphase like that of McNairs 121.

† Significantly different from control: $P < 0{\cdot}01$.

Within 4 h of infection the rate of cell division had dropped by more than 50 per cent in the resistant (MN) variety, compared with the controls taken from the same plants or from non-infected plants. By contrast, in infected Virginia Gold (susceptible) the number of dividing cells remained unchanged. The phenomenon was consistent in all replicate experiments for up to 8 h in the spore suspension. After 16 h, however, variable cell counts were recorded for both resistant and susceptible varieties; some roots showed very low numbers and some high numbers. By this time, the spores were germinating, with a variable effect on the root growth. Once returned to water culture, however, all roots reverted to the normal rate of cell division, and, in fact, the number was much higher in MN than in controls. This experiment was repeated with two other varieties which gave similar results. Cell-free filtrates of a spore suspension of *V. dahliae* held for 4 h before filtration were as effective in reducing cell division as the spore suspension itself. The fluctuations resulting from germinating spores were thereby eliminated.

I suggest that the phenomenon of rapid repression of cell division after 4–8 h of immersion in a spore suspension could be used as a test for the resistance of plants before they are transplanted to the field. The technique is relatively rapid once the active root system has been formed. Care must be taken, however, to minimize contamination from other microorganisms. The same plants could be used in subsequent field trials.

As far as I know, this is the first report of the partial inhibition of cell division in root meristem of *Verticillium*-infected host. The view that host–parasite reaction results in a change in nucleic acid and protein synthesis is widely held[2-4]. Patil and Diamond[5] have reported a higher rate of protein synthesis in a resistant variety of potato infected with *Verticillium*. Hadwiger and Schwochan[6] proposed an induction hypothesis for host resistance responses on the basis of their own results and those of others. The observation of partial inhibition of cell division in the resistant McNairs is probably a part of this "induction" process. Fungal metabolites temporarily repress such of cells' differentiation processes as are shown by the rate of cell division in the roots. This hypersensitive reaction is possibly necessary for gene activation which results in a higher rate of protein synthesis. In the susceptible VG the reaction is either delayed or diminished. It must be emphasized, however, that resistance in tobacco is polygenic[7]. Variable resistance is therefore expected within a single variety until selection is complete.

I am now pursuing both biochemical studies to identify the chemical nature of the inhibitor and a comparison of the rate of protein synthesis.

Trends in Montane Grasslands in Snowdonia, expressed in Terms of "Relative Entropy"

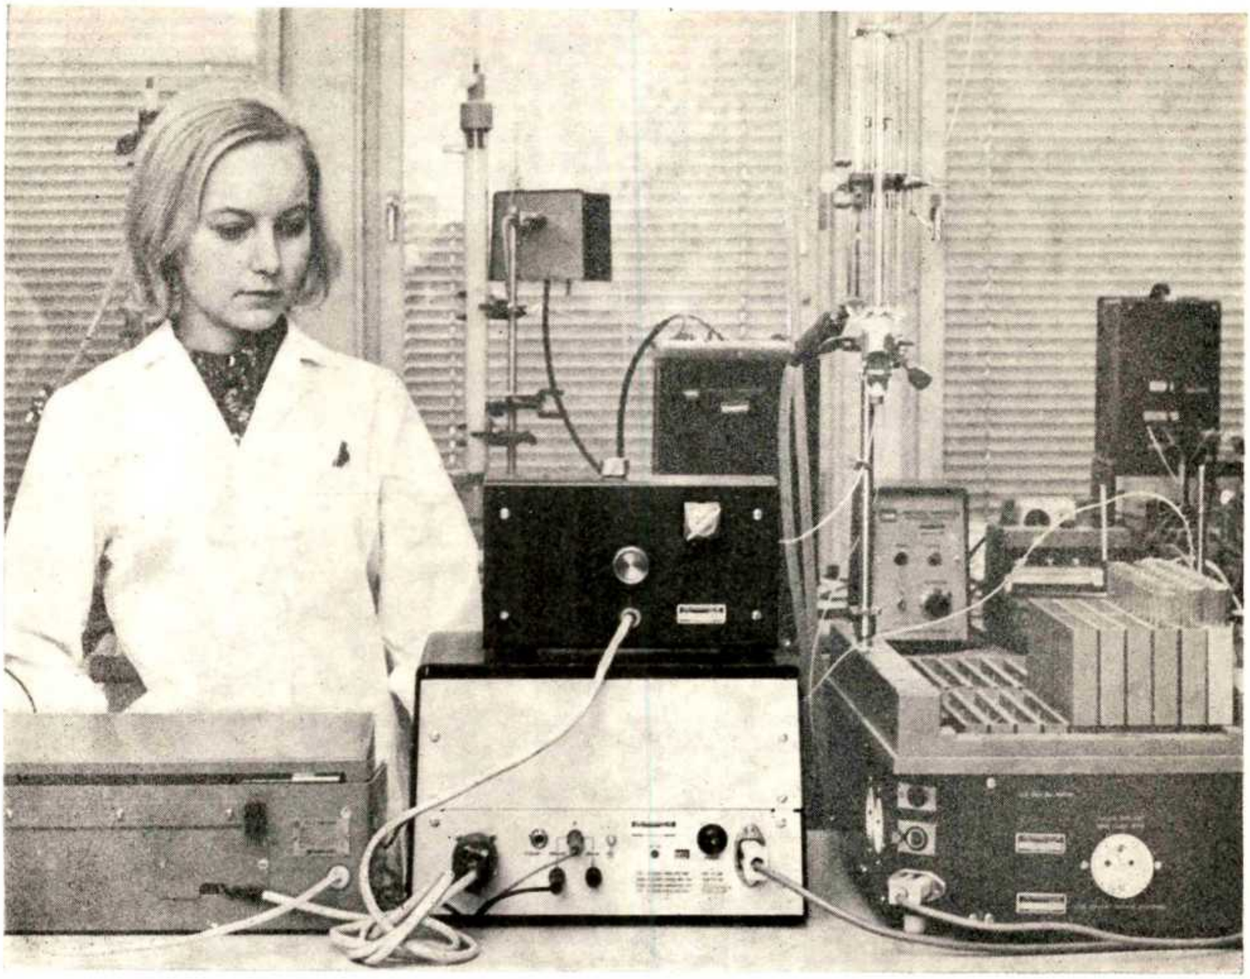
BETWEEN 1957 and 1960 a series of experiments was set up at four sites in Snowdonia, North Wales, to study the influence of sheep grazing on two widely distributed plant communities characterized by the dominance within them of *Nardus stricta* (on soils of peaty podsol/peaty gley character), and *Agrostis tenuis* and *Festuca ovina* (on soils of brown earth character), respectively. Some of the experiments were established by M. J. Chadwick[1]. The experimental sites cover an altitude range of 1,300–3,000 feet O.D. (396–914 m) and, at each site, three treatments are set out in a randomized design incorporating four replicates per treatment. The experimental treatments were: (i) Normal grazing: open to the sheep from the surrounding mountain pastures (most of the breeding ewes and yearling sheep are removed from the mountain in winter); (ii) winter protection from grazing: the plots were protected by fencing from October to April each year; normal grazing took place during the summer; (iii) no grazing; the plots were ungrazed throughout the period of the experiment. (The approximate densities of the sheep populations grazing the experimental plots, expressed in ewe units/acre (hectares), are set out in Tables 1 and 2.)

Each block of replicates covers 576 square yards (481 m²) and the individual replicates are 48 square yards (40 m²) in area. The vegetation has been sampled by means of point quadrats in all years except 1964.

One hundred randomly placed vertical point quadrats (each consisting of a pin 35 cm × 2 mm) are recorded within each replicate, so that the whole experimental block at each site contains 1,200 points. The individual point quadrats are located by coordinates given from tables of random numbers and each species hit at a particular point is recorded. The data are thus summarized as percentage hits of each species.

Changes in the species composition of the vegetation types have been recorded in this way for a period of ten years. Changes that have taken place in the absence or diminution of grazing have received particular attention. They may well be relevant to problems of managing the vegetation in the future. The detailed features of vegetational trends have been described by J. Dale and his results will be published elsewhere.

We have also followed changes with time and treatment in the pattern of species in the plant communities and used an "index" to summarize and order some of the information about the vegetational changes. We have applied the concept of "entropy" in the statistical sense to the study of multicomponent systems (as outlined by Miller and Kahn[2]) of which the plant communities are instances.



The other side of the UVICORD

Once an LKB Uvicord ultraviolet monitor has been installed people seldom look at the back—that's why we are giving you the chance to see it before yours is installed.
LKB designed the Uvicord to be fully compatible with all kinds of recorders; you will find three signal outlets on the back. One of these will fit your recorder, no matter what type it may be. A further example of the versatility of LKB instrumentation, which will operate in any system your laboratory may possess. A factor worth considering, when you weigh up the other features: stable base line, high sensitivity and sharply-defined bandwidth.

This is what your microscope would look like

if you were to use at one and the same time all of the reproduction methods offered by WILD.

Even then it would be incomplete, because we also offer:

- The **"Variomag" zoom adapter,** which can be used with our M 12 or M 20 microscopes. The scale of magnification can be steplessly altered, so that features of interest can be made to fill the format available.
- We also have an **image converter unit,** which will extend the wavelength range of the visible spectrum into the infra-red and ultra-violet regions. It can be used to make things visible which are normally invisible.
- There are some more accessories available for projection work with prisms and mirrors.
- We have a lot of different cameras; if desired they can be made fully automatic, or they can be used with our new exposure meter "S".

Miller and Kahn applied information theory to mapping multicomponent systems in geology, using an "entropy" function defined by Shannon[3] and developed by Pelto[4]. Pelto's function is

$$100\,H_r = \frac{-100 \sum\limits_{i=1}^{N} P_i \ln P_i}{H_m}$$

and

$$H_m = -\Sigma \frac{1}{N} \ln \frac{1}{N} = \ln N$$

where $100\,H_r$ = "relative entropy" on a percentage basis
H_m = maximum "entropy"
N = number of components or species
P_i = the proportion of the ith component or species

The "relative entropy" ratio is similar to Pielou's[5,6] and can be taken as a measure of the "evenness" of the population of species in the plant community.

Functions of similar derivation to Pelto's "relative entropy" have subsequently been used in several population studies[7-10]. In **1964** we considered the possibility of presenting our vegetational data (point quadrat data expressed as percentage hits) in terms of the "relative entropy" ratio. The ratio tended to decrease with time after grazing had ceased completely. Here the ratio is used not as an aid to mapping but to express a vegetational trend in relation to time and treatment.

Our data from Cwm Idwal National Nature Reserve, North Wales, illustrate the broad vegetational trends, expressed in terms of "relative entropy", that take place in relation to time and variations in grazing pressure. The data are closely paralleled at our other sites (Tables 1 and 2). Where no grazing occurs, the vegetation on the peaty podsol/peaty gley soil shows a trend over a period of 10 years from domination by *Nardus stricta* to ericoid shrubs (*Vaccinium myrtillus*, *Erica cinerea*, and *Calluna vulgaris*) and *Molinia caerulea*. On the brown earth soil the grasses *Holcus lanatus* and *Deschampsia caespitosa* tend to become prominent after the cessation of grazing in the vegetation previously dominated by *Agrostis tenuis* and *Festuca ovina*. Where grazing has been restricted to the summer months (April–October), and where normal grazing throughout the years has remained, there is little change in the vegetation.

Table 1 shows that in the absence of grazing, "relative entropy" has decreased with time, while there is no definite trend for the two other treatments. The total number of species present in the plant community does not show a parallel change with time, although there are seasonal fluctuations and an initial increase.

Table 2 covers three other experimental sites in Snowdonia. In each case there is a decrease in the "relative entropy" of the point quadrat data over a period of 8–10 years when the vegetation is not grazed.

In practical terms a decrease in "relative entropy" probably means that there is a movement from the "uncertainty" of the grazed sites to a state of greater "certainty" where they are ungrazed. So far the applica-

tion of the "relative entropy" or "evenness" ratio or index has promised to be valuable in analysing vegetational trends for experiments of the kind we have described, but it can probably be of wider use in ecological classification and mapping generally[10-12], as well as in the ordination of vegetational assemblages so that they may be related to environmental and other factors.

We thank members of the staff of the Nature Conservancy for their help and advice, particularly Mr M. Mountford (Biometrics) and Dr D. F. Ball (Pedology); and Mr K. B. Martin of the School of Plant Biology, University College of North Wales, Bangor, for his helpful criticism.

Extract of *Ipomoea pes-caprae* (Convolvulaceae) antagonistic to Histamine and Jelly-fish Poison

The creeper, *Ipomoea pes-caprae* (L.) Roth. of the family Convolvulaceae, which is found in abundance along the warmer seashores of both hemispheres, is used as a medicant in many parts of the world. The leaves are usually used—either boiled for external application as an anodyne in colic or rheumatism, or powdered and incorporated in an ointment said to have good local effects on bedsores—but they may also be used as an escharotic in the treatment of ulcers. Previous reports[1,2] suggest that the extracts of the plant have no pharmacological effects.

In the light of use of the plant by Thai fishermen as an antidote to jelly-fish stings and as an antipruritic agent, I examined various crude extracts and have found that there is an active principle (IPA) that is antagonistic to jelly-fish poison and is also mildly antihistaminic. This is of interest because there are no known specific antidotes for jelly-fish poison, described by Halstead[3] as toxic proteins; oral and topical antihistamine drugs are used for urticarial lesions and symptoms from contact with jelly-fish.

The water distillate from the dry ground leaves of the plant was extracted with ether. The residue was found to be slightly impure IPA and yielded about 0·05 per cent (dry basis). Infrared absorption and chemical analysis indicated that IPA is a volatile ester.

The antihistaminic activity of IPA compared with histamine dihydrochloride was evaluated *in vitro* by the Magnus method[4], in which measurement is made of the amount of the drug which relaxes histamine-induced spasm in an isolated ileum of guinea-pig immersed in Tyrode solution. The antagonistic effect of IPA compared with jelly-fish poison was evaluated by the same technique, but a dilute solution of jelly-fish poison (obtained by water extraction of the tentacles of a large jelly-fish, *Catostylus* sp.) was used to replace histamine dihydrochloride for inducing spasm in the isolated ileum of guinea-pig. (Compared with histamine dihydrochloride, the jelly-fish toxic material induced a slower contraction of the muscle, but the spasm remained much longer even after repeated washings. Moreover, an isolated guinea-pig ileum could stand many more experimental tests with histamine than with jelly-fish toxic material which paralysed the ileum after a few experiments.) The results of these experiments and similar experiments using two well known antihistamine drugs, diphenhydramine hydrochloride injection USP, BP ('Benadryl'), and antazoline methanesulphonate injection BPC ('Antistine'), are shown in Tables 1 and 2.

Table 1. DETERMINATION OF THE ANTIHISTAMINIC EFFECT OF IPA, COMPARED WITH OFFICIAL ANTIHISTAMINE DRUGS, AGAINST 2×10^{-6} HISTAMINE DIHYDROCHLORIDE ON THE ISOLATED ILEUM OF GUINEA-PIG

Description	Concentration	Antihistaminic effect (per cent)
Diphenhydramine HCl injection USP, BP	5×10^{-7}	Positive, 50
	1×10^{-6}	Positive, 99
Antazoline methanesulphonate injection BPC	5×10^{-6}	Positive, 80
	1×10^{-5}	Positive, 99
IPA	3×10^{-5}	Positive, 50
	6×10^{-5}	Positive, 99
Ethanol* (control sample)	0·3–0·6%	Negative

Table 2. DETERMINATION OF THE ANTAGONISTIC EFFECT OF IPA, COMPARED WITH OFFICIAL ANTIHISTAMINE DRUGS, AGAINST DILUTED GIANT JELLY-FISH POISONS

Description	Concentration	Antagonistic effect (per cent)
Diphenhydramine HCl injection USP, BP	4×10^{-7}	Positive, 25
	4×10^{-6}	Positive, 30
	1×10^{-5}	Positive, 90
	4×10^{-5}	Positive, 100
Antazoline methanesulphonate injection BPC	6×10^{-5}	Positive, 99
IPA	3×10^{-5}	Positive, 80
	6×10^{-5}	Positive, 99
Ethanol* (control sample)	0·3–0·6%	Negative

* The final IPA solution for this test experiment contained 0·3–0·6 per cent ethanol.

It is seen that although IPA is less effective in its antihistaminic effect than either of the two official antihistamines, it has about the same antagonistic effect against jelly-fish poison as the two drugs.

Dr Mongkol Mokkhasmit and Mr Prayuth Satrawaha of the Department of Medical Sciences, Thai Ministry of Public Health, have found that IPA has no toxic effect on mice after oral administration of 7·5 g per kg mouse.

Eustigmatophyceae—a New Algal Class with Unique Organization of the Motile Cell

Investigation of the cytology and ultrastructure of fifteen species drawn from twelve genera of coccoid Xanthophyceae (carried out in conjunction with a similar study of nineteen species drawn from four filamentous genera[1,2]) reveals that this algal class contains two structural series. The morphology of the motile cell in one series is unique in the plant kingdom and this series is here separated from the Xanthophyceae *sensu stricto* as a new class, the Eustigmatophyceae.

Diagnostic features of the new class are as follows:

(1) The eyespot (Figs. 1 and 3) is a large orange-red body at the anterior end of the motile cell, completely independent of the single chloroplast; it consists of an irregular group of non-membrane-bounded droplets, with no membrane around the whole complex.

(2) Zoospores of most species have only one emergent flagellum (Figs. 1–3) but a second basal body is present; the flagellum is inserted subapically, is always directed anteriorly during swimming and bears a bilateral array of stiff hairs (Fig. 2). Only one species, *Ellipsoidion acuminatum*, has the second flagellum developed as an emergent organelle; this flagellum is smooth and short, with a long hair-point, and is always directed laterally or posteriorly during swimming.

(3) A flagellar swelling (Fig. 3) is borne at the proximal end of the hairy flagellum; it consists of an expansion of the dilated flagellar sheath (see Fig. 2) and is always closely applied to the cell membrane in the region of the eyespot.

(4) The elongate chloroplast (Figs. 1 and 3) contains three-thylakoid lamellae but no girdle lamella; endoplasmic reticulum bounds the plastid but is not in direct association with the nuclear envelope.

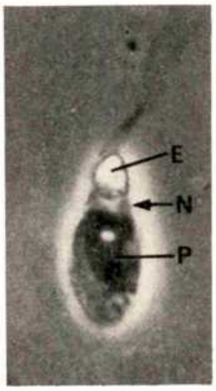

Fig. 1. Zoospore of *Vischeria stellata* (Eustigmatophyceae), showing the single flagellum with expanded sheath, the eyespot (E), the position of the nucleus (N) and the plastid (P). Light microscopy (×2,000).

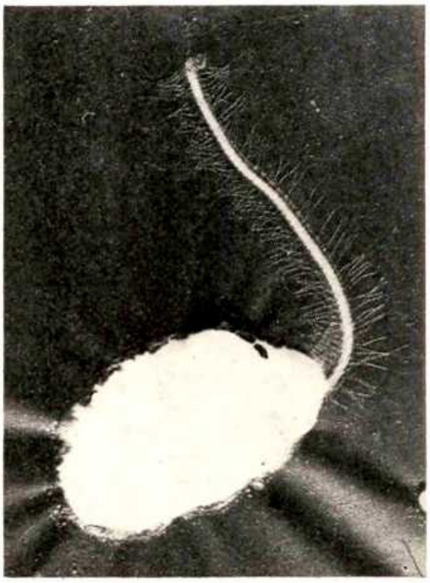

Fig. 2. Zoospore of *Vischeria punctata* (Eustigmatophyceae), showing the bilateral array of stiff hairs and the expanded sheath of the single flagellum. Electron micrograph of shadowcast whole cell, reversed print (×5,000).

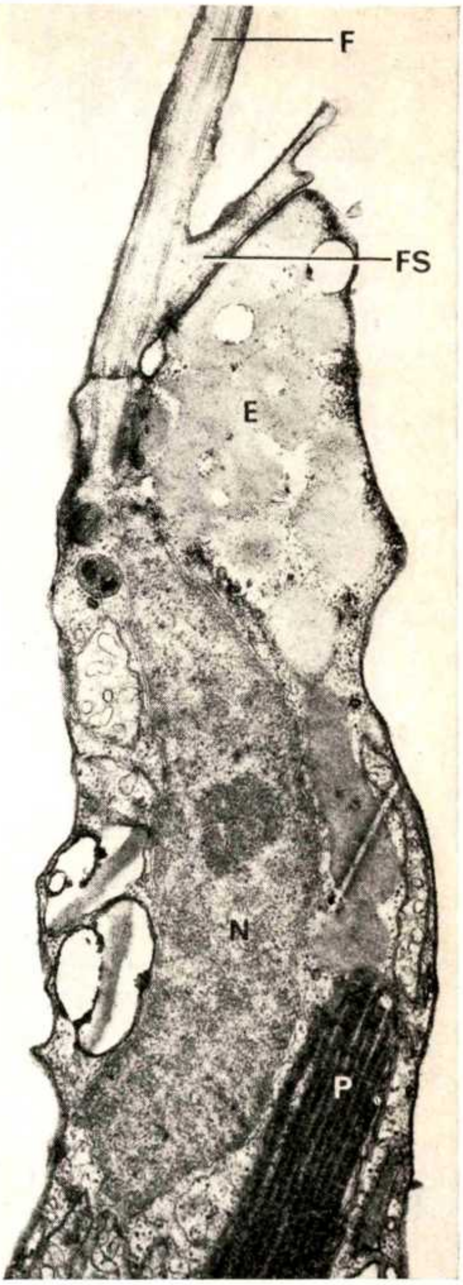

Fig. 3. L.S. anterior end of the zoospore of *Polyedriella helvetica*, showing the key features of eustigmatophycean structure: the extraplastidic eyespot (E) is separated from the plastid (P) by the nucleus (N); the single, anteriorly directed flagellum (F) bears a swelling (FS) which is adpressed to the eyespot and is an extended dilation of the expanded flagellar sheath; the plastid does not contain a girdle lamella. Electron micrograph (×20,000).

(5) Golgi bodies are absent from the motile cell but present in the vegetative cell.

(6) A unique form of pyrenoid is always present in the vegetative cell, never in the zoospore; the pyrenoid is polygonal, projects from the inner face of the lobed plastid on a narrow stalk and is surrounded by flat plates of an unidentified photosynthate which appears finely lamellate after fixation (and is not normal starch); thylakoids do not enter the pyrenoid matrix.

Species which can be placed with certainty in the Eustigmatophyceae are *Ellipsoidion acuminatum* Pascher, *Pleurochloris commutata* Pascher, *Pleurochloris magna* Boye Petersen, *Polyedriella helvetica* Vischer et Pascher, *Vischeria punctata* Vischer and *Vischeria stellata* (Poulton) Pascher; *Chlorobotrys regularis* West et West can probably be included on vegetative characters alone (no zoospores recorded). Coccoid forms which can be left with certainty in the Xanthophyceae *sensu stricto* are *Botrydiopsis alpina* Vischer, *Bumilleriopsis filiformis* Vischer, *Chlorellidium tetrabotrys* Vischer et Pascher, *Chloridella neglecta* Pascher, *Mischococcus sphaerocephalus* Vischer, *Ophiocytium majus* Naegeli, *Pleurochloris meiringensis* Vischer and *Sphaerosorus composita* Moewus, joining filamentous forms of the genera *Bumilleria*, *Heterococcus*, *Heterothrix* and *Tribonema*, and the siphoneous *Botrydium granulatum* Greville, which have all been investigated by modern techniques[1-4]. These true xanthophycean forms have the eyespot as part of a chloroplast; an anteriorly directed hairy flagellum and a posteriorly directed smooth one, the latter bearing the flagellar swelling; two or more plastids, typically with a girdle lamella; a sheath of chloroplast endoplasmic reticulum continuous with the nuclear envelope; Golgi bodies present in both motile and vegetative cells; and pyrenoids rare, but also in both zoospores and vegetative cells when present, semi-immersed, with no surrounding photosynthate (except lipid) and with normal three-thylakoid lamellae always entering the pyrenoid matrix. In addition, a pigment difference has recently been reported[5] between two true xanthophycean species (with antheraxanthin as the major xanthophyll) and two eustigmatophycean forms (with antheraxanthin replaced by a pigment corresponding to violaxanthin).

It is therefore clear that the Eustigmatophyceae possesses several unique features and is, in fact, less like the Xanthophyceae *sensu stricto* than the latter is like the other "heterokont" classes (the Phaeophyceae, Chrysophyceae *sensu* Christensen[6] and Bacillariophyceae) which share most of the features listed here for the Xanthophyceae. The possession of a typical "heterokont" anterior hairy flagellum by the Eustigmatophyceae does, however, raise a point of real taxonomic difficulty, necessitating a review of the whole concept of heterokont organization. The taxonomic status of the new class in relation to this problem will be discussed elsewhere, together with the detailed morphology of the motile cell and the ultrastructure of the individual organelles.

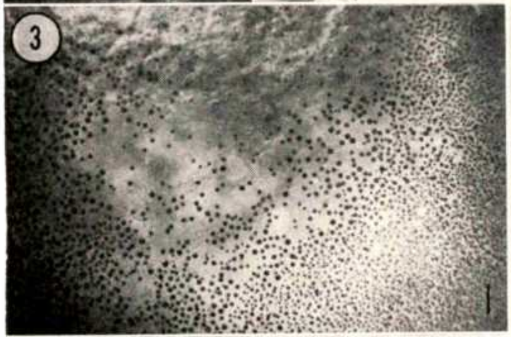
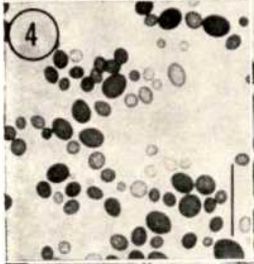
Proline in the Vesicles and Sporelings of *Valonia ventricosa* and the Concept of Cell Wall Protein

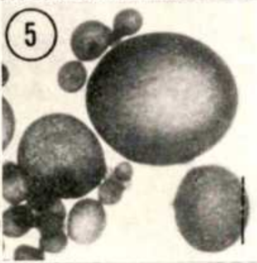
THE mature vesicle of *Valonia ventricosa* was an early source of information about the nature of cellulose[1] and the configuration of a cellulose cell wall[2,3]. Later it was used in one of the first investigations with the electron microscope of the way a plant cell wall develops at a naked protoplasmic surface[4]. The opportunity to make such a study was provided by the formation, at will, of aplanospores and by their subsequent development[5]. Aplanospores are small spherical masses of protoplasm, each with a nucleus, and they may form in very large numbers from the multinucleate, non-septate, protoplasm within a single vesicle. This system, therefore, has also provided an opportunity to allow sporelings to develop their cell walls while in contact with ^{14}C-proline in sea-water. Current methods of autoradiography and electron microscopy make possible determination of the distribution of the radioactivity fixed from ^{14}C-proline. This should test whether a developing cellulose cell wall incorporates substantial amounts of "cell wall protein" as indicated by radioactivity bound in the form of ^{14}C-proline. Also the cell wall of mature vesicles of *V. ventricosa* can easily be obtained free of cytoplasm so that it is possible to ascertain, by direct analysis, how much total protein each contains and its content of proline and/or hydroxyproline.

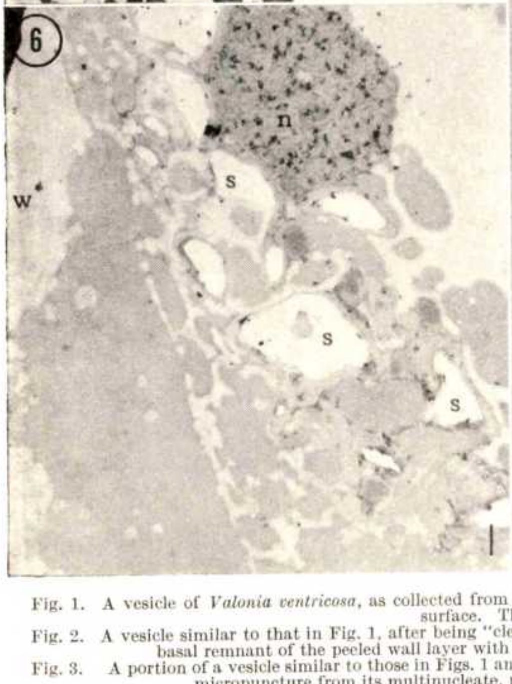
These observations are pertinent because of frequent claims that the combined hydroxyproline of higher plants is present, virtually exclusively, in a protein moiety present in their cell walls and which, in advance of its isolation and purification, was named extensin[6]. This claim has been extended to the presence of protein in cell walls of algae[7,8], along with speculations as to its function[9]. All such claims depend on proof that the analyses were performed on authentic preparations of pure cell wall, as it exists *in situ*, and with no cytoplasmic contamination. This has been demonstrated with preparations which behaved so as to indicate that as algal walls are more purified they may contain peptide but not protein[10]. A recent comprehensive study[11], of which note was taken in *Nature*[12], described the results of a combined electron microscopic and autoradiographic study which located the products of combined proline in the protoplasm, rather than in the wall of aseptically cultured cells of carrot. This work[11] had particular relevance because it involved the system which had furnished the original evidence that ^{14}C-proline absorbed by rapidly dividing cells was incorporated into a metabolically stable entity in which it was converted to hydroxyproline in the approximate overall ratio of 1 : 1[13,14]. Because of their relevance to these problems, certain findings on *Valonia* are being presented here, out of the context of the larger investigations from which they arise. Inasmuch as these observations concern a free cell culture that develops into a plant they relate to our work on morphogenesis; the evidence on the distribution of radioactivity from ^{14}C-proline between the cytoplasm and the developing cell wall is a sequel to the work on carrot cells[11]; the extent of the absorption of this solute contributes to other work on solute uptake[16], and all the results bear on continuing work on the metabolism of proline and hydroxyproline in plants (ref. 11 and communication to Amer. Soc. Plant Physiologists, August 1968, by F. C. S., R. L. M. and P. M. L.).

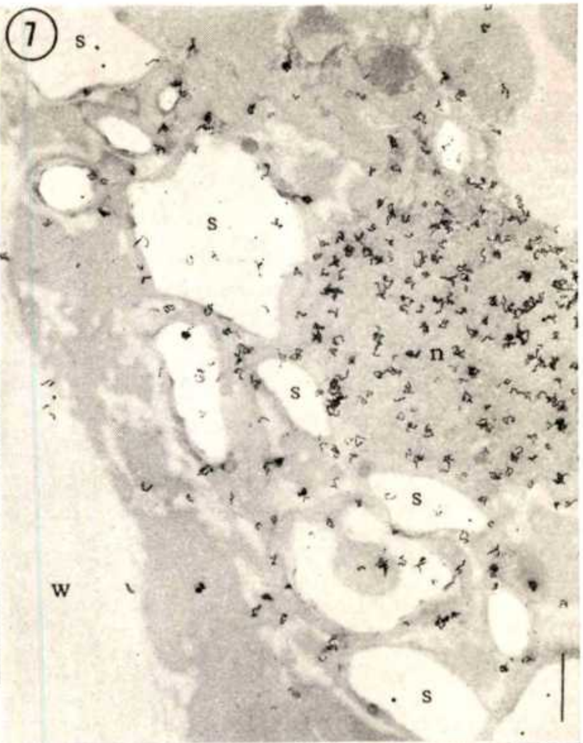
Our observations were of two kinds, being made either on mature freshly collected vesicles or on the aplanospores to which they may give rise. *Valonia ventricosa* vesicles, as they occur in their natural habitat, are commonly encrusted (Fig. 1) with calcareous material and minute organisms (including *Melobesia*) as well as other epiphytes. It has long been our practice to "clean" these vesicles before use in metabolic and cell physiological experiments. A layer of wall can be removed without irreversible damage to the vesicle (Fig. 2). The resulting "clean," iridescent wall can then be punctured and the entire cell contents washed out. In this way three fractions were obtained for analysis from each vesicle as follows. (i) The outermost layer of wall variously contaminated with other organisms from bacteria, protozoa, to other algae (Fig. 2); (ii) a relatively clean, thick, predominantly cellulosic cell wall, free of the gross contamination of the outer layers and which was washed free of cytoplasm; (iii) the whole living content of the vesicle. These various fractions were weighed, hydrolysed with acid, and submitted to amino-acid analysis by chromatographic and autoradiographic methods which











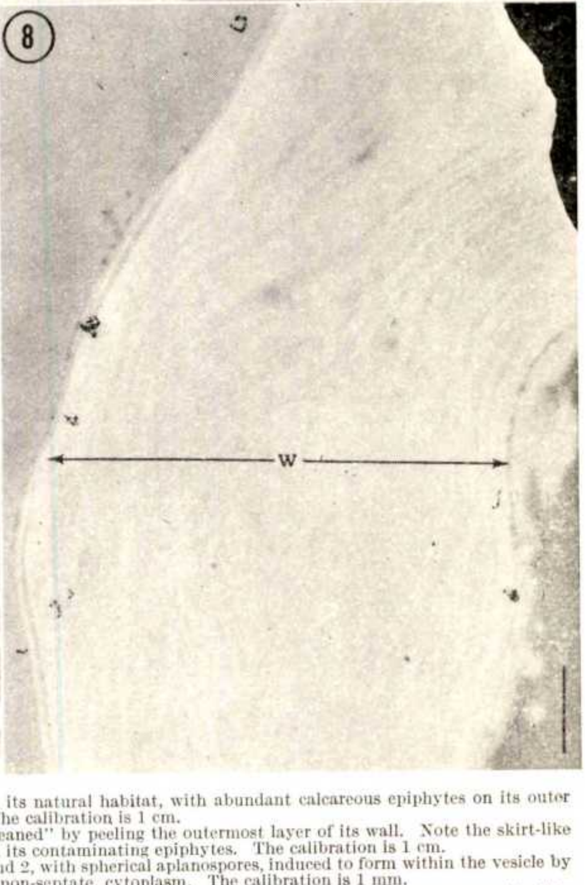


Fig. 1. A vesicle of *Valonia ventricosa*, as collected from its natural habitat, with abundant calcareous epiphytes on its outer surface. The calibration is 1 cm.

Fig. 2. A vesicle similar to that in Fig. 1, after being "cleaned" by peeling the outermost layer of its wall. Note the skirt-like basal remnant of the peeled wall layer with its contaminating epiphytes. The calibration is 1 cm.

Fig. 3. A portion of a vesicle similar to those in Figs. 1 and 2, with spherical aplanospores, induced to form within the vesicle by micropuncture from its multinucleate, non-septate, cytoplasm. The calibration is 1 mm.

Fig. 4. Newly formed aplanospores which were aseptically recovered from a mature vesicle, and which had been exposed to ^{14}C-proline seawater for approximately 8 h. At the time of first contact with ^{14}C-proline—7 h after puncture—the cellulose at the sporeling surface would be negligible[4]. The calibration is 1 mm.

Fig. 5. Sporelings from the population as in Fig. 4, but cultured for 19 days in ^{14}C-proline containing seawater. The calibration is 1 mm.

Figs. 6–8. The distribution of radioactivity in *V. ventricosa* sporelings after 19 days' growth in ^{14}C-proline seawater as revealed by electron microscope autoradiography. w, Wall; n, nucleus; s, starch grain. The calibration is 2 μm.

Fig. 6. A portion of wall and parietal protoplasm at very low magnification. Note the concentration of radioactivity in the nucleus.

Fig. 7. As Fig. 6, but at a somewhat higher magnification. Note the scattered radioactivity in the cytoplasm, the concentration in the nucleus and the virtual absence of radioactivity in the wall.

Fig. 8. A portion (area 100 μm^2) of a new cell wall conspicuously free of radioactivity although it developed during 19 days in contact with ^{14}C-proline seawater.

Table 1. THE PROTEIN CONTENT OF *Valonia ventricosa* VESICLES AND OF THEIR WALLS

	µg protein per vesicle
Total protein* in epiphytes and outer wall of a typical vesicle, 2·4 cm in diameter	551
Total protein in the wall† free of cytoplasm and of the outer layer of wall with its epiphytes	72
Total protein‡ in cytoplasm	565
Total protein in typical vesicle, free of epiphytes	637

* This protein contained 6 per cent of its weight as proline and 19 per cent as glycine but no detectable hydroxyproline.

† This protein contained 2 per cent of its weight as proline and 3·5 per cent as glycine but no detectable hydroxyproline.

‡ This protein contained 9 per cent of its weight as proline and 5 per cent glycine but no detectable hydroxyproline.

became standard after earlier work[13,14], and their content of combined amino-acids (especially of proline and hydroxyproline) was measured.

Table 1 shows that (i) the combined proline in the natural *V. ventricosa* cell wall is in its outermost contaminated layer; (ii) less than a 5 per cent residual contamination of the inner by the outer layer would have accounted for its proline content, even without regard to the known presence of minute hapteron cells at the base of the vesicle which, by "Uhrglaswande"[4], enclose some protoplasm; (iii) the small amount of proline recorded in the "clean" *Valonia* wall was not heavily accompanied by hydroxyproline, and (iv) virtually all of the combined proline of the intact, cleaned vesicle was present in its protoplasm. From this work an upper limit (< 2 per cent of its dry weight) can be placed on the content of protein in the mature *Valonia* wall in its habitat.

Intact living vesicles of *V. ventricosa* were induced to form aplanospores by making controlled minute punctures[5]. The green sporelings so produced survive and grow, either in the original vesicle (Fig. 3) or when isolated into seawater (Figs. 4 and 5). At their formation within the vesicle the aplanospores were free from other organisms and they were maintained in artificial or natural seawater in a unialgal, virtually bacteria-free, state for the duration of these experiments. During this time the entire growth of the sporelings was in the presence of ^{14}C-proline (10 µCi/ml.). Some conversion of ^{14}C-proline to ^{14}C-hydroxyproline by the sporelings could be detected but only in very limited amounts. Washed sporelings were also prepared for transmission electron microscopy by standard methods and then their thin sections so treated[11] (using the procedure there designated SP–1) that the distribution of radioactivity from proline became evident (Figs. 6–8). These figures are deliberately reproduced at low magnifications to show extensive fields.

The fine structure of the cytoplasm of *Valonia* presents problems to be taken up elsewhere. Nevertheless, Figs. 6–7 reveal the newly developed cell walls, the peripheral cytoplasm which contains abundant chloroplasts (up to 60–70 per cent of its volume)[18] with relatively large starch grains and, of course, very numerous nuclei. Fig. 8 shows a substantial area of wall which had developed on an otherwise naked surface of protoplasm and in contact with ^{14}C-proline.

The results are self evident. The radioactivity absorbed during the growth of these sporelings was not significantly present in the cell wall. Any radioactivity there detected did not exceed the expected background, or cross scatter, or the possibility of casual contaminations during cutting. Virtually all the radioactivity from ^{14}C-proline was present in the protoplasm; and, as in the case of cultured carrot cells, it was heavily concentrated in the nuclei.

A predominantly cellulose wall (up to 12 µm thick) comprising as many as twenty composite laminated layers may therefore develop during 19 days on an otherwise naked protoplasmic surface. Although this wall had direct access throughout to exogenous ^{14}C-proline, its content of combined proline was negligible. Thus because all proteins surely contain proline, these newly developed walls did not contain appreciable protein moiety. These data confirm the analysis of the walls of mature vesicles.

The choice of *V. ventricosa* to test the relationship between proteins in cytoplasm and wall was motivated by the relative ease with which cytologically recognizable cytoplasm and wall could be separated in the large vesicles, even without any grinding or killing. By contrast, the extensive work[7–9] referred to on various other algae, which purports to show that proline-containing proteins commonly exist in their walls, was based on the analysis of hydrolysates of fractions of homogenized preparations. The sharp distinction between wall and cytoplasm, as they exist *in situ*, has not been critically demonstrated in such homogenized preparations. In fact, the difficulties in so doing have been acknowledged[8,10,19]. Similarly, the analysis of plant materials for combined hydroxyproline, which is then considered to be the measure of cell wall protein[6,20], does not, in our view, yield meaningful results. Furthermore, those who earlier located the combined hydroxyproline in the wall of angiosperm cells[20] now recognize that it is also to be found extensively in protoplasm[21]. It is in this context that work on the protein content of a mature *Valonia* vesicle on the one hand, and on the incorporation of ^{14}C-proline into the vesicles growing from aplanospores on the other, as here demonstrated, has particular significance.

The concept that there is a major cell wall protein is clearly inapplicable to *Valonia* vesicles, even as it is inapplicable to cultured carrot cells. The protein moieties in cells which do contain combined proline and the hydroxyproline which arises from it *in situ*, and their relations to rapidly growing cells, undoubtedly retain their interest. Nevertheless, this interest is accentuated, not minimized, because these events seem to occur first in protoplasm, especially in nuclei (Figs. 6 and 7) and even more so in nucleoli[11]. These observations are reiterated in spite of a recent report[22] which, in our view, is quite inadequate in its microscopy and autoradiography.

The walls of different senescent, or even dead, plant cells frequently incorporate many non-cellulosic substances (from lignin to tannins and even some special nitrogenous compounds), but such events, interesting as they may often be, should not be allowed to confuse the relative roles of cytoplasm and walls in still viable growing cells. Furthermore, the extrusion by a sort of "reversed pinocytosis" of isolated, membrane-bound proteinaceous "pockets" into the walls of such highly specialized, often protein-secreting cells as pollen, should be recognized as highly interesting but very special cases[23]. Such examples do not require that protein is a necessary integral part of unspecialized plant cellulose walls, nor that the normal mechanism of wall growth requires a protein moiety such as that which has been called extensin[6,24].

Lack of Synergy of EDTA with Antimicrobials in Resistant Enterobacteriaceae

ETHYLENEDIAMINETETRAACETIC acid (EDTA) is known to increase the permeability of Enterobacteriaceae to certain compounds such as actinomycin[1] and to make *Escherichia coli* susceptible to lysozyme lysis[2]. Presumably, this is related to the disruption of the cell wall characterized by loss of lipopolysaccharide[3]. Weiser, Asscher and Wimpenny[4] reported that EDTA increases the sensitivity of certain organisms resistant to penicillin, ampicillin, chloramphenicol and tetracycline presumably by overcoming their permeability barrier to these antimicrobials. Resistance to ampicillin, penicillin and chloramphenicol has been demonstrated to be the result of an inactivation of the drugs by penicillinase[5,6] and chloramphenicol acetyl transferase[7]. The mechanism of resistance to tetracycline is unclear although Franklin[8] suggested a change in permeability in *E. coli* with transferable resistance.

We sought to determine whether EDTA is synergistic with ampicillin, chloramphenicol and tetracycline in strains in which resistance is either chromosomally or episomally determined.

Bacteria were grown overnight in 'Penassay' broth (Difco). Tubes containing serial dilutions of the drug and EDTA were inoculated with approximately 10^5 cells/ml. The tubes were incubated at 37° C for 16 h. The lowest concentration which prevented visible turbidity was considered the minimal inhibitory concentration (MIC). Each experiment included a determination of the MIC of EDTA and drug alone.

Tables 1, 2 and 3 give the MIC of several test organisms with and without EDTA. As can be seen, the maximum increase in sensitivity found with the concentration below the MIC for EDTA was four-fold. This does not represent a synergistic effect of EDTA but can be attributed to an additive effect as well as variation inherent in the method.

Table 1. ABSENCE OF SYNERGY BETWEEN EDTA AND AMPICILLIN

	MIC ampicillin (μg/ml.)				
EDTA (mM)	FW/ R126	*P. mirabilis*	*E. coli* DB100	*S. typhimurium* 100	*A. aerogenes*
0	4,000	16,000	500	2,000	64
4×10^{-2}	—	—	500	—	—
8×10^{-2}	—	—	500	—	—
$1{\cdot}0 \times 10^{-1}$	4,000	8,000	—	—	—

8×10^{-1}	—	400	—	—
1·6	—	200	—	—
3·2	—	100	—	—

MIC of EDTA (mM): DB100, 4×10^{-1}; *S. typhimurium* 100, 6·4; K12/R6, 4×10^{-1}; *P. mirabilis*, 4×10^{-1}.

Table 3

	MIC chloramphenicol (μg/ml.)		
EDTA (mM)	*E. coli* DB100	*E. coli* K12/R6	*E. coli* DB34
0	200	200	400
5×10^{-2}	100	200	400
1×10^{-1}	100	200	200
2×10^{-1}	50	200	200
4×10^{-1}	50	50	100

MIC of EDTA (mM): DB100, 8×10^{-1}; K12/R6, 8×10^{-1}; DB34, 8×10^{-1}. K12/R6 carries a resistance transfer factor.

Further experiments were performed with strains in which resistance was to less than 30 μg and not episomally determined. Both a Tris-based medium and a phosphate medium low in divalent cations were tested. The MIC for ampicillin and tetracycline was not lowered in *E. coli*, *Aerobacter aerogenes* or *Proteus mirabilis* strains by the use of EDTA.

The inability of EDTA to reverse tetracycline resistance of *Salmonella* was demonstrated in the following experiment. A culture of *S. typhimurium* 131 containing an episomal resistance factor for tetracycline was treated with 0·1 mM EDTA in 0·5 M sucrose for 10 min. The bacteria were then returned to 'Penassay' broth, and half of the culture received tetracycline (30 μg/ml.). Growth was followed spectrophotometrically at 660 nm for 2 h. The treated culture was able to grow in the presence of the drug in these conditions at a rate comparable with the control.

EDTA cannot be thought of as synergist with ampicillin, chloramphenicol or tetracycline in these Enterobacteriaceae. It is possible that selected isolates of Enterobacteriaceae contain permeability barriers, and that in these organisms EDTA would be efficacious in altering resistance patterns, but so far we have not found such laboratory or clinical isolates. Furthermore, the fact that the penicillinases of Enterobacteriaceae are surface enzymes[6] would mean that EDTA treatment of cells would make the destructive enzymes more accessible to penicillins. It is extremely doubtful that a clinical situation would arise in which an EDTA-penicillin, ampicillin or tetracycline combination would prove of value in treating infections caused by Enterobacteriaceae.

Complete Mutagenesis in a Bacterial Population induced by Thymine Starvation on Solid Media

BACTERIA unable to synthesize thymidylic acid (*thy*⁻) undergo thymineless death if cultivated in a liquid medium deprived of thymine[1,2]. We have found, however, that if *thy*⁻ bacteria are plated on solid nutrient devoid of thymine at a moderate density (not more than 10^5 cells in a Petri dish) thymineless death does not occur. Cells of *Bacillus subtilis* remain viable in these conditions for more than 70 h (Fig. 1); cells of *Escherichia coli* decrease slowly in number: for instance, the cell count of strain *B_3thy*⁻ manifests a drop of 50–60 per cent in the course of 60–70 h. We conclude that the effect is related in some way to the characteristics of growth on a solid surface as distinct from a liquid medium.

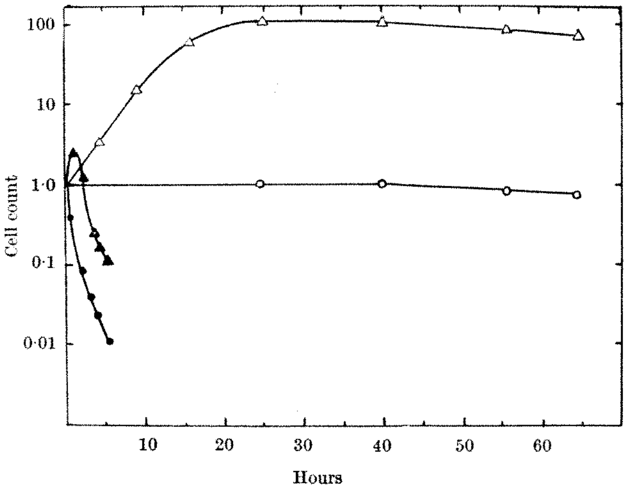

Fig. 1. Survival of *B. subtilis* cells (strain *168thy*⁻) in liquid and solid media at 32° C. ●, Incubation in Spizizen's growth medium I without thymine; ▲, incubation in Spizizen's growth medium I supplemented with 0·3 μg/ml. of thymine. Initial cell concentration, about 10^4 cells/ml.; ○, agar or silica gel solid medium supplemented with SGM without thymine; △, agar or silica gel solid medium supplemented with SGM plus 0·3 μg/ml. of thymine. About 10^5 *thy*⁻ cells were plated on every Petri dish and afterwards washed off with a standard volume (3·0 ml.) of SGM supplemented with an optimal concentration of thymine. Survival was determined by titration of the cell suspension on maximal agar plates.

The number of viable cells was measured by washing them from the plate and plating them subsequently on thymine-containing agar, or by transferring the agar block with the thymine starved cells to another plate supplemented with thymine. The constancy of the number of viable cells during thymine starvation proves that thymineless death is not occurring. If the solid medium is supplemented with a concentration of thymine (0·2–0·3 μg/ml.) which is far too low for the conventional cultivation of thymine deficient bacteria, the cells grow slowly and divide 5–10 times on the surface of agar. The bacterial population thus increases 50–100 times (depending on the density of seed) and thereafter stops growing. We have found that precisely at this time complete mutagenesis in the cell population develops: within 60–80 h it has affected more than 50 per cent of all cells present. During this time, moreover, the percentage of lethal events remains insignificant. Mutations are induced in all regions of the genome. The number of mutants increases in these conditions 10^3–10^4 times compared with the usual level of spontaneous mutations. Many of the cells become multiple mutants in different loci. It is well known that the thymine starvation which develops when thymine deficient bacteria are suspended in a liquid medium and are subject to thymineless death leads to a small mutational effect[3-6]. That the origin of the mutagenesis which we have observed is different is clear because it does not occur if thymine is entirely absent.

Two strains of *B. subtilis* were used. One (*168thy*⁻*ind*⁻) was obtained from F. Rothman (compare ref. 2). This strain originated from the well known Marburg strain and was deficient in thymine and indole. The second was obtained from *168thy*⁻*ind*⁻ by means of transformation to prototrophy for indole and marked as *168thy*⁻. Two well known strains of *E. coli* were used. One was *B_3thy*⁻, the other *15T*⁻. For normal growth these bacteria require 5 μg/ml. of thymine in the medium. Spizizen's growth medium I was used for cultivation[7]. An overnight culture was washed from the thymine containing medium with Spizizen's glucose-mineral medium (SGM) on a 'Millipore' filter, resuspended and plated on a series of Petri dishes at about 10^5 cells per plate. The agar contained SGM supplemented with a low concentration of thymine (0·3 μg/ml.). The Petri dishes were stored at 32° C for 3 days and some were taken at 10–15 h intervals for investigation. The cells were sampled by washing them off with 3 ml. of SGM containing an optimal (5·0 μg/ml.) amount of thymine. The cell suspension was titrated on maximal agar plates. Scoring for mutants was performed by transferring the colonies grown on maximal agar to plates with SGM supplemented with 20·0 μg/ml. of thymine. From the second day of incubation, when the growth of the culture stops, a massive accumulation of mutants was observed. These are wholly or partially auxotrophic, with different requirements for nutrient supplements. Either they are unable to grow on minimal

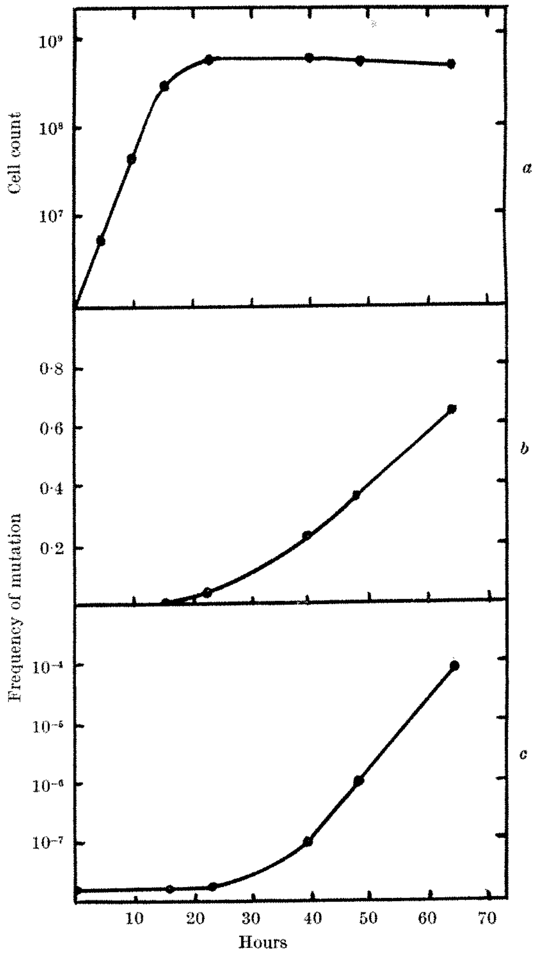

Fig. 2. Kinetics of overall mutagenesis and of the induction of specific (*Sm*ʳ) mutants in *B. subtilis* (strain *168thy*⁻) during incubation at 32° C on solid medium containing 0·3 μg/ml. of thymine. *a*, Kinetics of growth of the cell population on Spizizen plates with 0·3 g/ml. of thymine; *b*, overall yield of auxotrophic mutations; *c*, kinetics of induction of *Sm*ʳ mutants (resistant to 1·0 mg/ml. of streptomycin).

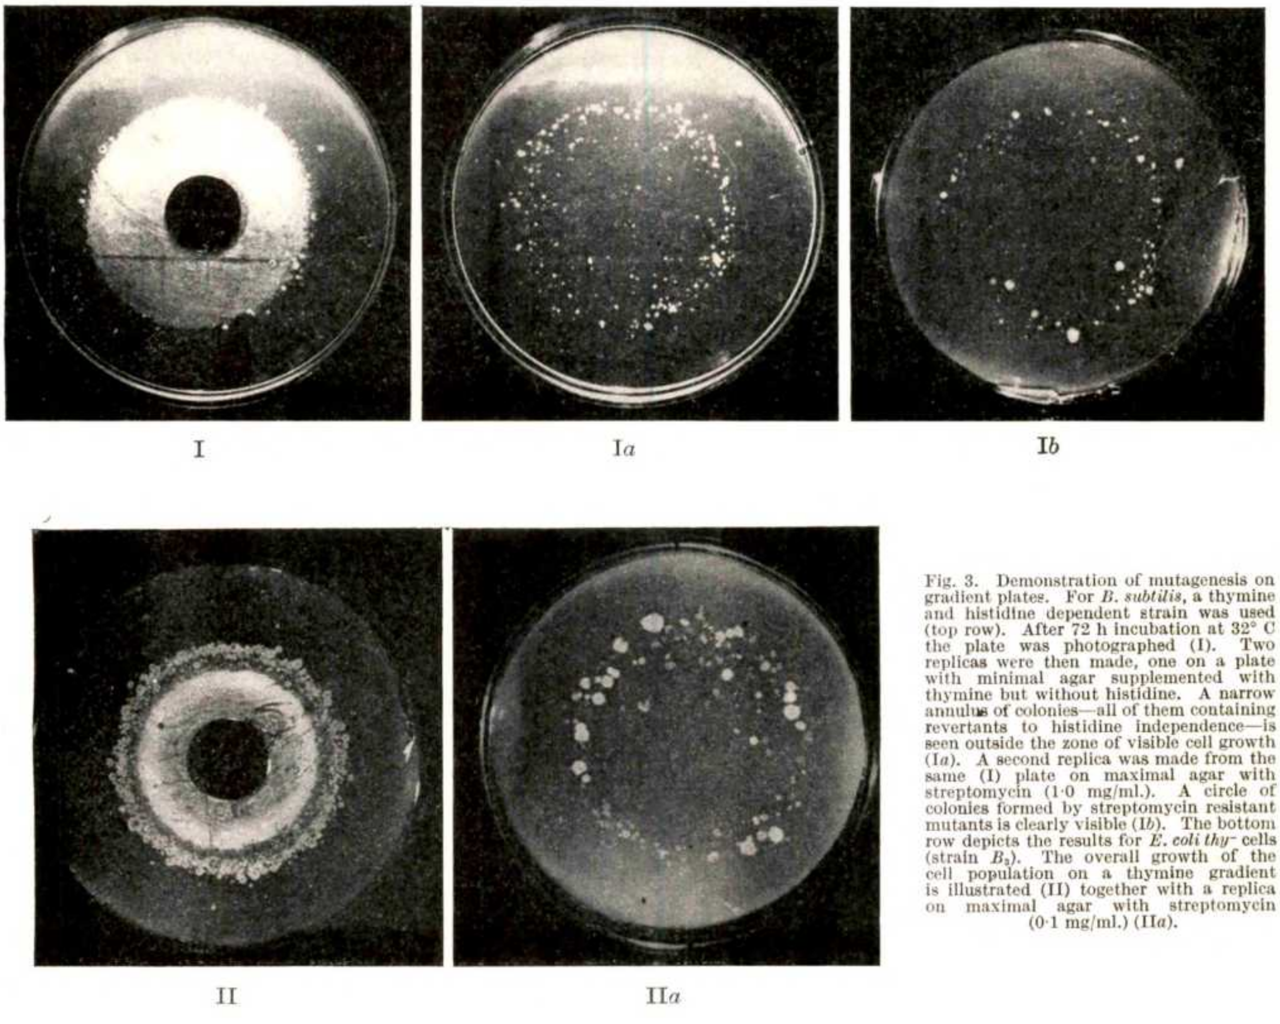
agar or their growth rate is much lower than that of normal cells. The number of mutants increased gradually with time and finally attained the level of 50–70 per cent of all cells present. The mutants induced in these conditions contained genetic lesions in different cistrons coding for the synthesis of amino-acids, nucleotides and vitamins, for drug resistance and so on.



I Ia Ib

II IIa

Fig. 3. Demonstration of mutagenesis on gradient plates. For *B. subtilis*, a thymine and histidine dependent strain was used (top row). After 72 h incubation at 32° C the plate was photographed (I). Two replicas were then made, one on a plate with minimal agar supplemented with thymine but without histidine. A narrow annulus of colonies—all of them containing revertants to histidine independence—is seen outside the zone of visible cell growth (I*a*). A second replica was made from the same (I) plate on maximal agar with streptomycin (1·0 mg/ml.). A circle of colonies formed by streptomycin resistant mutants is clearly visible (I*b*). The bottom row depicts the results for *E. coli thy*⁻ cells (strain B_3). The overall growth of the cell population on a thymine gradient is illustrated (II) together with a replica on maximal agar with streptomycin (0·1 mg/ml.) (II*a*).

We performed controls to be sure that we were dealing with real mutations. The cells from a mutant colony were cultivated alternately in liquid maximal medium and on maximal agar. This procedure was repeated three or four times. No change of mutant phenotype resulted. In 14 cases the mutational locus was identified by systematic trial of nutrient requirements. The particular mutations obtained in the case of *B. subtilis* $168thy^-$ were: dependence on histidine, arginine, biotin, nicotinamide, uracil, and a double mutant for serine and threonine and streptomycin resistance. For the strain $168thy^-ind^-$ they were: reversions from ind^- to ind^+. In the case of *E. coli*, the mutants identified were a riboflavine constitutive strain derived from 15*T*-strain, and lac^- and Sm^r derived from the B_3thy^- strain.

Fig. 2 depicts the kinetics of the increase in the overall auxotrophic mutations in a *B. subtilis* population; we plot the sum of full and partial auxotrophs. The latter are leaky mutants growing on minimal medium supplemented with 20·0 μg/ml. of thymine at a reduced rate. We emphasize that a substantial number of mutants, varying from experiment to experiment, was found in mixed clones because of segregation. To take them into account a slight modification of the experimental procedure was adopted. The colonies originally identified as non-mutated were taken from maximal agar, suspended in SGM solution, and replated on maximal agar (100–200 cells per Petri dish). Then, however, we replicated them on minimal agar to score for mutants. This improvement allowed us to detect all the auxotrophic mutants formed even if they were initially in mixed clones.

We studied, kinetically, not only the overall mutation rate but also certain special cases of identified mutations. Fig. 2 shows the kinetics of induction of streptomycin resistance in the conditions of our experiment. We see that the rate of induction of Sm^r mutants in *B. subtilis* amounts to 10^{-4}. In the case of reversions from indole deficiency to independence in the strain $168thy^-ind^-$ of *B. subtilis* the mutation rate is about 10^3 times higher than the background of spontaneous revertants which is found when an amount of thymine optimal for growth is supplied.

Of particular importance is the choice of a thymine concentration optimal for mutagenesis. The existence of such an optimum is demonstrated in the following experiment. A radial gradient of thymine concentration is generated in an agar plate initially devoid of thymine but with a round hole filled with 0·2 ml. of thymine solution (0·2 mg/ml.). Fig. 3 presents photographs of such plates on which 10^5 thymine deficient cells were spread uniformly. The mutants become concentrated in a narrow annulus in a distinct region of the plate, outside the zone of overall growth. Zero concentration of thymine, as already stated, is unfavourable for mutagenesis; some intermediate concentration is the most suitable.

We believe that the unusual phenomenon of complete mutagenesis is the result of replication mistakes induced by the slow replication of DNA or by an imbalance of DNA precursors. Observations on the origin of thymineless death and its dependence on growth conditions will be published elsewhere.

Population Growth and the Multi-type Galton–Watson Process

THE general Galton–Watson (GW) process with n types, T_i ($i = 1, 2 \ldots n$), is specified[1] by the type of the individual starting the process at time (generation) zero, and the vector-valued probability generating function (PGF)

$$f(\mathbf{s}) = [\mathrm{f}^1(\mathbf{s}), \mathrm{f}^2(\mathbf{s}) \ldots \mathrm{f}^n(\mathbf{s})]$$

where the scalar quantity $\mathrm{f}^i(\mathbf{s})$ is the multi-type PGF of the numbers of individuals of the various types produced by an individual of type T_i ($i = 1 \ldots n$).

I first consider a special case of the general process in which

$$\mathrm{f}^i(\mathbf{s}) = \sum_{j=1}^{n} p_{ij}\mathrm{f}(j;\ s_j),\ i = 1 \ldots n$$

where

$$p_{ij} \geq 0,\ \sum_j p_{ij} = 1,\ i, j = 1 \ldots n$$

$\mathrm{f}(j;\ s)$ being for each j a univariate PGF. The process so specified may be given the following general interpretation. Suppose that there is basically only one type of individual present in a population, but that the offspring distribution is not fixed once and for all, and may be any one of the n generated by the $\mathrm{f}(j;\ s)$, $j = 1 \ldots n$. Then, at each generation succeeding the initial ancestor, the population may be thought of as consisting of n types $T_1 \ldots T_n$, an individual being of type T_r if he arose as a result of reproduction according to the PGF $\mathrm{f}(r;\ s)$. He then chooses the distribution generated by $\mathrm{f}(j;\ s)$ for reproduction with probability p_{rj}, $j = 1 \ldots n$. The specialized GW process that I have presented then describes the evolution of such a population (with the usual "independence of reproduction" assumptions).

One biological implication is as follows: if the population under consideration consists of males only, the choice of offspring distribution may be interpreted as corresponding to the choice of type of wife out of n possible types, this choice being influenced via the Markovian probabilities $\{p_{ij}\}$ by the type of the male individual's mother. In a genetical context, the model may be used to describe the evolutionary progress of mutants whose fitness fluctuates in a stochastic manner, according to a finite Markov chain with transition matrix $P = \{p_{ij}\}$, along any line of direct descent (. . . grandfather, father, son . . .). If the Markov matrix P is stochastically degenerate in that it describes purely deterministic movement (for example, purely cyclic), all individuals at a particular time are of a single type only, and reproduce in the same manner, though the manner changes through time in a deterministic way; one may then interpret the process as describing the effect of a deterministically fluctuating environment, special cases of which have been studied by Koutský[2], Pollak[3] and Ewens[4]. (A stochastically fluctuating environment is not amenable to treatment by the technique, though an appropriate theory exists.)

Going on to another model, I now consider the n types of the general multi-type GW process as falling into two classes, the K-types and the R-types, so that the types can be written as $K_1, K_2 \ldots K_p$, $R_1, R_2 \ldots R_q$, where $p + q = n$. The special case of the process in which I am interested arises from the following assumptions: the process is initiated by a K-type, and is otherwise specified by the transition laws

Prob [1 individual of type R_j produces a vector $\mathbf{i}$ of R-types] = $\mathrm{f}_j(\mathbf{i})$

Prob [1 individual of type K_h produces a vector $\mathbf{e}_r$ of K-types and a vector $\mathbf{i}$ of R-types] = $p_{hr}\mathrm{b}_h(\mathbf{i})$

all other reproductive transitions having zero probability. Here $\mathbf{e}_r$ is a vector with p entries, all of which are zero save the rth, which is unity, and $\{\mathrm{f}_j(\mathbf{i})\}$ for each $j = 1 \ldots q$ denotes a multi-type probability distribution on the non-negative integer q-tuples $\mathbf{i}$, as does $\{\mathrm{b}_h(\mathbf{i})\}$ for each $h = 1 \ldots p$, the set of quantities p_{hr} defining a stochastic matrix, P, of dimension p.

This $(p+q)$-type process may be interpreted in terms of a population of q types, evolving according to GW reproduction rules, and whose offspring distributions are given by the $\{\mathrm{f}_j(\mathbf{i})\}$, the population at each time after the zeroth (when there are assumed to be no individuals) being subject to immigration according to one of the p immigration distributions $\{\mathrm{b}_h(\mathbf{i})\}$, fixed at time one, and the immigration then fluctuating from one distribution to another at successive times according to a Markov chain with transition matrix P. The progress of such a population is the progress of the R-types alone in the $(p+q)$-type GW process. (The introduction of the "fictitious" K-types in a simpler context to give the effect of immigration is due to Sevastyanov[5].)

Both the models described may thus be further investigated by using known results on the multi-type GW process. The second (immigration) model always gives rise to a reducible process, but may still be treated in the manner of Kesten and Stigum[6]. It also seems possible to consider to some extent the effect of an infinite matrix P in both cases.

I acknowledge support by a Nuffield Foundation travelling fellowship during my absence from the Australian National University.

Book Reviews

NATURE OF METAPHYSICS

Metaphysics and Common Sense

By A. J. Ayer. Pp. xi + 267. (Macmillan: London, November 1969.) 58*s*.

IT is disappointing to discover that this is not a new book by Ayer on metaphysics. It is, in fact, a substantial collection of his essays, from various sources, on a variety of topics. The nature of metaphysics is a recurring theme, however, and the essay which, like the book, is called "Metaphysics and Common Sense" is an extremely interesting discussion of it. The essay shows common sense, but the "Common Sense" of the title is G. E. Moore's. Moore's answer to those who sought to establish the unreality of time was that its reality was far more obvious to him—perhaps in such facts as that some of the events of his life lay in the past—than any premises and inferences which might be used to disprove it. Ayer is sympathetic to Moore's attitude, but rejects it because it implies that philosophy, being forced always to defer to common sense, is confined to the analysis and elucidation of opinions. Philosophical theories do not, Ayer argues, conflict with common sense in the direct way Moore assumed. They conflict only with the theories in which common sense views are embedded and against these theories they may prevail. Ayer makes generous amends to metaphysicians for his strictures in *Language, Truth and Logic*. Speaking of the paradoxical conclusions of Zeno about motion and McTaggart about time, he says: "But the problem for our metaphysicians was that they did not see how these consequences were to be avoided; they did not see what other account of time or motion could be given. And in this they were not so greatly to blame". The problem of the nature of philosophy arises again in the essay, "What Must There Be ?". Ayer maintains, characteristically, that such questions as "Do electrons exist ?" raise no one problem, but may give expression to a variety of problems about the nature of electrons. His approach here is an eminently successful one.

Ayer's great interest in the philosophy of science is evident in many of the essays, although most of them are general expositions rather than original contributions. In "Man as a Subject for Science" the reader longs for him to slow down and dwell for a while on one of the many problems he raises. The essay called "Chance" is marred, in my opinion, by a failure to distinguish two contentions about the calculus of probabilities: one that its propositions are true *a priori*, the other that they concern probabilities which hold *a priori*. It is possible that the propositions of the calculus of probabilities are *a priori* because they concern relations of implication between probability propositions which are not *a priori*.

Among several critical essays on other philosophers, including Russell, Moore and the existentialists, an especial interest attaches to his assessment of J. L. Austin's book, *Sense and Sensibilia*. For many years Austin gave, both at Oxford and in the United States, a course of lectures on perception in which he brought his very considerable powers of wit and irony to bear on phenomenalism and particularly on Ayer's presentation of it. Ayer had little opportunity to reply, because the lectures were not published until after Austin's death. Whether this essay vindicates sense-data is a question beyond the scope of this review. Philosophers should not too readily assume that the task is impossible.

JOHN WATLING

WASTE WATER PROBLEMS

Urban Planning Aspects of Water Pollution Control

By Sigurd Grava. Pp. xi + 223. (Columbia University Press: New York and London, November 1969.) **$7.50**; 67*s* 6*d*.

ONE can hardly pick up a newspaper nowadays without finding an article dealing with some aspect of pollution of the environment, for, as the blurb to this book says, the 1960s have seen "a general public awareness" of urban pollution and "the popular press has joined the battle". We can therefore expect that many more authors will be producing books such as this, which, again quoting the blurb, "is intended as a guide and a source of information for urban planners, community decision makers and active citizens".

The book is sponsored by the Institute of Urban Environment at Columbia University, at which the author is assistant professor of urban planning. It is essentially non-technical but contains some technical material. The principal sections of the book deal with the general nature of the problem, with the technology of waste water treatment, with legal and financial implications, with local planning aspects and, finally, with special problems of the developing countries.

The lengthy chapter on technological aspects is a readable and generally correct account of the present situation in regard to sewerage, sewage treatment and reclamation of water from sewage effluent. The only major error, repeated in the glossary, is the reference to the Zimmerman process (now promoted as wet-air oxidation) as a method of sewage treatment—it is, in fact, a method of sludge treatment. Some of the definitions in the glossary itself are not particularly helpful, for example: "Ion exchange: the separation of materials in solution by electrical charge". The chapter on sources and types of pollutants contains an adequate description of the nature and amounts of domestic sewage discharged by a community, but is much less adequate in discussing the problems of industrial wastes. It also contains the following incredible statement: " . . . any value of BOD above zero indicates pollution, i.e. that state where no free dissolved oxygen is found in the water".

The chapters on administrative, legal and financial aspects refer almost exclusively to the situation in the United States. The difficulties in achieving pollution control by cooperation between municipal authorities are pointed out, as is the desirability of extending control over a wider region—preferably a watershed.

It would be presumptuous to assert that the Old World has all the answers to the pollutional problems of the New; nevertheless, pollution of surface waters became a problem in Britain and in some parts of Europe at least as early as the appearance of similar problems in the more heavily industrialized areas of the United States. Presumably, the author, in proposing such measures as river basin management, regional control, and charging for reception of industrial effluents into municipal sewers, has had regard to the relevant experience of other countries in pollution control. The only reference to European experience, however, is a brief description of the operation of the Ruhrverband, the highly successful water supply and effluent disposal organization in Western Germany.

This book will no doubt serve a useful purpose in its country of origin, but its value to the non-American reader is less certain. Most of the technical matter contained within it is available in Britain in a number of specialized publications, while those parts of the book dealing with administration and finance would seem to have value chiefly to the student of American affairs. The last chapter on problems in developing countries has some sensible things to say and is apparently based on the author's own experience as a planning consultant.

One must agree with the author that the major questions nowadays are concerned not with the technical solutions to pollution problems—these are in most cases available—but with the amount which the community is prepared to pay to maintain a clean environment. There will be much discussion of such problems in Britain, but one hopes that the "decision makers and active citizens" involved will be able to supplement the material contained within this book by drawing on the ever-increasing volume of information now available from other sources.

G. E. EDEN

SERMON FOR THE UNCONVERTED

The Last of Lands

Edited by L. J. Webb, D. Whitelock and J. Le Gay Brereton. Pp. xvi + 203. (Jacaranda Press: Milton, Queensland, 1969.) $A6.95.

To the biologist, at least to the biologist who lifts his eyes above the laboratory bench, Australia is the most exciting of all continents. Admittedly, as the late Jock Marshall so graphically described in *The Great Extermination*, its wildlife has been raped as thoroughly as North America's in the nineteenth century and India's in the twentieth, but what remains is an assemblage at least as worth preserving as any other fauna in the world. Living fossils are thicker on the ground than almost anywhere else, and adaptive radiation is nowhere better illustrated than by the way the marsupials have exploded to fill so many of the niches occupied elsewhere by the carnivores, ungulates and other orders—could perhaps a marsupial primate have evolved if Captain Cook had stayed away for a few more thousand years ?

One might expect therefore that the Australian in the street would be prouder than he is of the natural endowment of his native land. But all too many Australians—and they are not alone in this—think of wildlife only at the end of a gun, so that the tiny handful of Australian naturalists have until very recently been very much a voice crying in the Great Sandy Desert. This book is part of the awakening of the Australian people to the realization that they and their ancestors have very nearly destroyed a pearl of great price, and, what is more, one that might even make them some money, if wildlife tourism is skilfully developed.

Stemming from a symposium held at the University of New England in 1964, the editors have produced a handsomely illustrated volume, with twenty-two contributions from twenty-six authors and the Australian Conservation Foundation, which incidentally benefits from the royalties. Such a composite work inevitably lacks the fire in its belly it would have had if Jock Marshall had survived to write even a couple of pages for it, but it is a sound and sober assessment of the problems of conservation in Australia: what has been done already and what needs to be done. Australia has a fine complement of national parks and nature reserves—New South Wales had a national park as early as 1870, eighty years before the United Kingdom—but so fast is the pace of development in this century that immensely more remains to be done. The manifold threats to the Great Barrier Reef, not least the natural one constituted by the decimation of the living coral by the crown of thorns, are a good example.

Prince Philip puts the dilemma clearly in his foreword: "Even today there are many Australians who find it hard to believe that the problem of conservation exists at all. Unfortunately these people are not likely to read this book". It was an Irish naturalist who pointed out recently that wildlife conservationists spend far too much time preaching to the converted in the comfort of the lecture hall and not nearly enough bellowing to the unconverted at street corners. If there is a criticism of this book, it is that it is one more sermon directed to the devout. Will somebody else now please take a deep breath, remember Jock Marshall and use the facts in this book to make a noise that all the unconverted will be bound to hear.

RICHARD FITTER

DESERT ENCYCLOPAEDIA

Deserts of the World

An Appraisal of Research into their Physical and Biological Environments. Edited by William G. McGinnies, Bram J. Goldman and Patricia Paylore. Pp. xxviii + 788. (University of Arizona Press: Tucson, 1968.) $15.

THIS encyclopaedic compendium, edited and written by faculty members of the University of Arizona, is a United States contribution to the International Hydrological Decade. Intended for those "seriously interested in planning, managing and executing research or development efforts in the arid parts of the world", it contains evaluative comments on the work that has been accomplished in these areas, summaries of what is known about them and recommendations for further research. The contents include: location maps of extremely arid, arid and semiarid regions by continents (after Meigs); appraisals of research on the weather and climate of desert environments by Clayton M. Reitan and Christine R. Green; geomorphology and surface hydrology by Lawrence K. Lustig; surface materials by Harold E. Dregne; vegetation by William G. McGinnies; fauna by Charles H. Lowe; desert coastal zones by Joseph F. Scheiber, jun.; and an appendix on ground-water hydrology by Eugene S. Simpson.

Each chapter is organized in the same way: a discussion of existing knowledge, followed by evaluations, recommendations and comprehensive bibliographies. The approach throughout is anthropocentric. For example, plants are assessed according to their qualities and uses by man, and whether they are undesirable and should be controlled. The fauna is classified as poisonous (potentially lethal)—"amphibians are considered to be potentially dangerous and they should be skinned before eating"—or suitable for use as human food, and so on. Pests, "unwanted animals", are divided into poisonous forms—centipedes, millipedes, tarantulas, urticating moths and vesicant beetles—and non-poisonous pests which include Reduviidae, sand-flies, mosquitoes, ticks, Solifugae, woodlice, ants, termites, locusts and other insects. In spite of this unbiological and somewhat unpromising emphasis, no doubt dictated by editorial policy, the various chapters contain a large amount of useful information. Nevertheless, each author decries the lack of basic knowledge in his own and related subjects; the geomorphologist of climatic data, the botanist of information on soils, the climatologist of satisfactory systems for determining local requirements of water. At the present rate of progress, however, it may take centuries before the information already available is properly applied.

The solutions advocated for disseminating further knowledge are not unfamiliar. They emphasize the importance of international programmes, electronic bibliographical control of translation services which are now scattered throughout the world, and so on. All this is highly commendable and could sometimes be very useful although it is possibly somewhat over-rated: there can be no substitute for hard and prolonged research work in the field. The deserts of the world are largely man-made. Particularly in developing countries, they are rapidly being extended through overgrazing, the felling of trees for firewood and charcoal, and by bad agricultural practices. Progress in the development or reclamation of deserts cannot be achieved without local governmental support, a genuine understanding of the inhabitants, their traditions and religions, and a real appreciation of the actual problems of their existence.

This volume will probably be of greatest use to research workers on account of its excellent summaries of existing knowledge and extensive bibliographies, rather than for its recommendations and perhaps unrealistic ideals.

J. L. Cloudsley-Thompson

GLOBAL CLIMATOLOGY

Climate of the Free Atmosphere

Edited by D. F. Rex. (World Survey of Climatology, Vol. 4.) Pp. x+450. (Elsevier: Amsterdam, London and New York, 1969.) 335*s*.

The free atmosphere comprises the whole of the atmosphere apart from the lowest layer, about 700 to 900 m deep, known as the friction layer, within which turbulence induced by the passage of the air over the Earth's surface is confined. In the words of the editor of this book, the reason for eliminating the friction layer from consideration is so that "we may deal with the atmosphere on a global basis without resorting to extensive discussions of point to point surface differences. Such pronounced regional and/or local features as may produce climatological anomalies in the free atmosphere will be discussed in the appropriate regional volumes of the series". In fact, some of the contributors to the seven sections of the book find this restriction inconvenient and deal with the atmosphere from the surface. Also, because routine climatological measurements have been directly made only up to a height of 50–60 km, the data presented in the multifarious tables and graphs refer only to the troposphere and stratosphere.

The book begins with an account and tabulation of recent standard and supplemental atmospheres. The succeeding four chapters deal with the characteristics of the troposphere and its upper boundary, the tropopause. In the first of these, median tropopause heights, average temperature profiles, meridional temperature cross-sections and global distributions of temperature and humidity are given for the different months of the year or for the seasons. The next, the longest chapter in the book, provides an excellent account, largely theoretical, of the dynamics of the tropospheric circulation including a detailed analysis of the structure and generation of the jet streams as well as shorter descriptions of tropical cyclones, monsoons and föhn and katabatic winds and concluding with an examination of the climatological consequences of the mean tropospheric flow. There follow a discussion of the major tropical and extratropical cloud systems, examined in the light of the synoptic pictures provided by meteorological satellites, and a further chapter presenting seasonal distributions of cloudiness, albedo and outgoing long wave radiation, also derived from satellites. Although it has not yet been possible to obtain absolute values of the radiation budget from TIROS data because of difficulties of calibration and the degradation of the radiation sensors, it is useful to have these preliminary findings.

Conditions in the stratosphere in so far as they are known are examined in the last two chapters. It was only with the development and use of meteorological rockets that reasonably accurate observations of temperature and wind in the stratosphere became available, and a descriptive account is given here of the data obtained by the American Meteorological Rocket Network during the early years of its operation from about 1960. The Stratospheric Circulation Index is defined as the mean zonal and meridional wind speed in a 10 km thick layer centred at an altitude of 50 km and from it is derived a set of stratospheric seasonal definitions. Seasonal mean wind (zonal and meridional) and temperature profiles are drawn for each of the rocket-sonde launching sites. Finally, there is a comprehensive account of the theory, measurement and significance of atmospheric ozone, beginning with the photochemical theory and then comparing theoretical ozone distributions with those observed. Below a height of about 25 km, photochemical reactions are so slow that the ozone concentration is largely determined by the redistribution of the gas by air currents. Thus in the lower stratosphere, the ozone–air mixing ratio is a quasi-conservative property of an air parcel and so ozone can be used as a tracer in studies of the circulation. It is pointed out that the three dimensional distribution of ozone and its variation with time are now sufficiently well known to make it possible to examine ozone flux in the atmosphere and the resulting ozone budget.

Even allowing for the cost of reproduction of more than 300 graphs, maps and line diagrams and nearly 60 tables, and for the fine book production, the price of this volume seems excessive.

James Paton

SIMPLE MAP MAKING

Simple Photogrammetry

Plan-Making from Small-Camera Photographs taken in the Air, on the Ground or Under Water. By J. C. C. Williams. Pp. x+211. (Academic Press: London and New York, December 1969.) 50*s*; $8·50.

Photogrammetry is the science and art of deriving the dimensions of objects by measuring the size and shape of their photographic images. The precision with which this can be done is satisfactory for many mapping, engineering and scientific projects. Much of the equipment that is used to achieve this precision is expensive although the overall cost of survey by photogrammetric means is often less than would otherwise be incurred. Where sophisticated equipment is not available it is possible to use simple graphical methods to construct plans of the areas or objects photographed. The accuracy of this work is inferior to that which can be achieved with better equipment but, none the less, it may be satisfactory for certain rudimentary surveys. This book deals with the simple graphical methods that can be used to derive the dimensions and relative positions of objects and areas using small-camera photographs taken in the air, on the ground or under water. One chapter introduces elementary astronomy and the uses of the Sun's shadows for measuring heights and directions. Many of the diagrams are intended as working drawings so that the processes discussed in the text can be followed by taking measurements on illustrations. Theoretically this is an asset but it makes for tiring reading. A good diagram should be self-explanatory but much of the text is given to describing the derivation of the illustrations.

The versatility of photogrammetry and its adaptability to a large range of problems are very considerable. The student should, however, bear in mind that the techniques advocated are often not the most appropriate. A false sense of accuracy is implied in much of the text and one must remember that graphical methods require good draughtsmanship and much patience. One must dispute the claim that the practical work discussed forms a good introduction to the study of map making by stereophotogrammetry—this book will not help the serious student of the subject. It is, however, a valuable reminder of what can be done with simple equipment, and those with sufficient patience to stick with this book will not be unrewarded.

P. F. Dale

MAGNIFICENT DESOLATION

The Times Atlas of the Moon

Edited by H. A. G. Lewis. Pp. xxxvii + 110. (Times Newspapers Limited: London, December 1969.) 95*s*.

For your money you get thirty pages of articles on the Moon, on mapping the Moon and the techniques of getting there, and of course the maps—110 pages of them, based on the charts produced by the US Air Force Aeronautical Chart and Information Centre. (Strangely, not the most complete set. Several tantalizingly blank areas of *luna incognita* appear on the far side maps.) The charts are, of course, a tribute to painstaking work in the United States beginning with mapping from photographs taken at the Pic du Midi, Yerkes, Lick and Mt Wilson observatories, and continuing with the Lunar Orbiter missions and the Soviet investigation of the far side, chiefly with Zond 3. Most people would rather the Orbiters had spent less time scanning the equatorial maria for allotment-sized crater-free areas and more time looking at more fascinating parts of the Moon, but that was the demand of the Apollo project. Without it there would have been none of the later Orbiters in polar orbits which made the photographic coverage of the Moon better than that of the Earth, providing the new breed of lunar geologists with enough material for a lifetime.

The 110 maps, then, which cover the best part of the front of the Moon, are at a scale of about 20 miles to the inch. The excepted parts are the polar regions beyond about 65° of latitude, and the limbs beyond 70° from the zero meridian (less at higher latitudes). The only coverage of these awkward areas is on the front and back endpapers, which are small scale maps of the northern and southern hemispheres. Then the far side, rather oddly, is elsewhere in the atlas, buried between a general article on the Moon and one on mapping. The area between 48° N and 48° S is given about 17 inches by 9·5 inches, with two separate projections for the polar regions. They are without the contribution from Orbiter 5, however, and hence the white patches. The accompanying text is a fair enough résumé of what is known about the Moon, although in places one feels that the stress might have been misplaced, and it is not without its errors. It seems to have been written at the time when the first news about the Apollo 11 specimens was leaking out of Houston, and enshrines the view that titanium is common in the maria.

It seems to me that the reproduction of the otherwise excellent illustrations in the text is not as good as it might have been. Green has been used lavishly. Many of the Apollo 8 pictures came out green of course, but in the atlas they look positively verdant, including one which I remember as blue when it first appeared. Somebody seems to have been inspired even to give the Orbiter photograph of the Alpine Valley a green caste—surely stunning enough in its original black and white. The Apollo 8 view of Goclenius gets the same treatment, and Copernicus from Orbiter 2 is battleship blue. One would like to have seen more use of the incredibly detailed Orbiter photographs, but not this way.

People will enjoy using the atlas, more I suspect for seeing how the published photographs from lunar flights fit in than for following the journeyings of the astronauts on the surface, which for the time being at least are going to be on too small a scale to register on these maps. It ought to be bought by libraries, but one wonders whether the non-astronomer, the extremely devoted excepted, would get enough out of it to make the outlay worthwile.

Edward Phillips

GROUNDING IN STATISTICS

Statistics and Experimental Design

By Geoffrey M. Clarke. (Contemporary Biology.) Pp. xi + 161. (Arnold: London, November 1969.) 42*s* boards; 21*s* paper.

This book is largely intended for undergraduate students of biology as basic guidance in the applications of elementary statistics to practical problems in their subject. Mathematical manipulation is therefore almost entirely absent, although there are clear explanations of the practical meaning of any statistical procedure discussed and worked examples are used to illustrate not merely the use of the procedure but also its appropriateness and limitations in different situations. The examples, and in one or two respects the subject matter, are conditioned by biological applications—reference to sample surveys and non-parametric tests is rather limited; however, as the author says, the book should also prove useful to non-biologists. Non-mathematicians will be helped by the author's consistent use of notation as listed at the beginning of the book.

Statistics as the common sense summarization of numerical data is developed from simple ideas of random variation, discrete and continuous variates and frequency-probability. The basic distributions (binomial, poisson and normal) are discussed with reference to practical examples, and the importance of the central limiting function of the normal distribution is emphasized. Significance tests and confidence theory involving the normal, t, χ^2 and F distributions are dealt with, but there is no graph of an F distribution and the expected value (not elsewhere defined) of F is wrongly stated to be 1 (page 67). There is also no mention of paired comparisons, and for Fisher's z-test of correlation the reader is referred elsewhere. There are good introductions to regression analysis (based on $y=a+bx$), and experimental design: there are careful discussions of the planning and analysis of completely randomized, randomized block and Latin square designs, together with simple factorial experiments. Unusually, interactions are introduced in factorial experiments rather than as a refinement of additive analysis of variance models. The author considers the problems of missing observations and non-normality and he describes the non-parametric sign and U-tests—but he gives no rank test of independence. Finally, the inclusion of comments and answers to exercises should help many students.

The book is usually clear and well written and may be strongly recommended to non-mathematical students requiring a common sense grounding in statistical methods.

VARIABLE RELATIONSHIPS

Models in Regression and Related Topics

By Peter Sprent. (Methuen's Monographs on Applied Probability and Statistics.) Pp. x + 173. (Methuen: London, October 1969.) 35*s*.

The subject of regression has changed a lot since Galton used the term to describe the phenomenon whereby the heights of adult males in successive generations regress toward the population average; tall fathers having, on the average, sons who are shorter than themselves. Nowadays, it is the method of describing asymmetrically the relation between one variable and one or more other variables, through the mean value of the first, conditional on specified values of the others. The most common form for this relationship is a linear one where, if y is the single variable and $x_1, x_2, \ldots x_n$ values of the others, it is supposed that the mean $E(y|x_1, x_2, \ldots x_n)$ is linear, say $\beta_0+\Sigma\beta_1x_1$. There is hardly a computer whose software does not include a program for performing linear regression, estimating the β's, carrying out significance tests and deciding which of the x's have an important influence on y. The procedure is undoubtedly popular because there are many research problems that call for an understanding of how one quantity is influenced by others, and the machine technique is easily applied to yield apparently meaningful results.

Unfortunately, the field of regression is not quite so simple as it often seems to the research worker. There are subtleties involving variates and variables, structural and functional relationships, and confusions between the joint and separate effects of factors. Dr Sprent has therefore written a monograph designed to give guidance in regression techniques to scientists. Topics include least-squares, law-like relationships, the effects of inhomogeneous and correlated errors, multiple regression, canonical analysis and non-linear models. There is a useful chapter on applications which occurs rather late in the book.

The author says that the prerequisite is about fifty lectures on statistics plus a knowledge of calculus and matrix notation. I feel that more than this is needed to understand a book which tries to get to grips with the difficulties but may have suffered from being written too hastily. I think research workers will find it hard going. This is a pity, because the material is there.

D. V. LINDLEY

HELIUM RESEARCH

Helium-3 and Helium-4

By William E. Keller. (The International Cryogenics Monograph Series.) Pp. xi + 431. (Plenum: New York, 1969.) $18.50.

W. H. KEESOM's classic book *Helium*, published in 1942, was a monumental and exhaustive work containing almost all that was then known about the helium-4 atom and its behaviour in the gaseous and condensed states (the helium-3 atom had not been identified until 1939, and then only as a minute fraction in naturally occurring helium-4). To a large extent, "Keesom" was a collection and summary of published papers, and it became and remained the reference bible of helium researchers until well into the 1950s—and is indeed still used. The mass of information accumulated since 1942 has been immense, and a proposal a few years ago to up-date Keesom, keeping its essential character, seems, not surprisingly, to have come to nothing. Such a book is now no longer possible, and some strict selection of material has to be made. Most of the later authors have chosen to select by limiting the subjects treated, usually to superfluid helium (for example, F. London, Atkins, Lane, Khalatnikov, Pines and Nozières, Donnelly), but the two most recent (Wilks and the present author) have attempted to cover both liquid and solid helium-3, helium-4 and helium-3–helium-4 mixtures (and, in the present case, gaseous helium) by selecting material within each topic. One advantage of this approach is that, although the physics of the various topics is really quite different, it encourages the tendency to enlarge one's point of view beyond the immediate problem. A disadvantage is that, because of the vast range of material and of physics which it spans, it may become a glorified review, which is not perhaps what this sort of book is for (Atkins, incidentally, seems to me to have combined most successfully the didactic and the factual approach—though he was writing ten years ago when there was a less severe problem).

As Dr Keller says in his preface, he has indeed deliberately constructed his book with each chapter like a short review article. This statement does not quite do justice to the book, which hangs together better than it implies. Two consequences of it are perhaps apparent though: namely, that the cross-referencing is not always as good as it could be, and that there is some imbalance reflecting the author's own special interests (which, he himself points out, is inevitable). For example, while the gas–atom properties of helium and superfluid flow are dealt with extensively (and very usefully), the nuclear magnetic properties of condensed helium and the properties of "finite" helium (thin films) and of isotopic mixtures are comparatively summarily treated. On the other hand, the treatment is up to date, although I should have liked to have seen more on the theories of phase transitions in the chapter on critical phenomena.

It is always easy to find deficiencies in a book, real or apparent, and much more difficult to assess its value until one has had the opportunity of using it for some time. I have greatly enjoyed this book. I am sure that it will be very much used, and that there is much to be learned from it. It will certainly form an essential part of the helium researcher's library, and will be a most useful introduction for new students.

D. F. BREWER

SEMICONDUCTOR ENGINEERING

Applied Solid State Science

Advances in Materials and Device Research, Vol. 1. Edited by Raymond Wolfe. Pp. x + 404. (Academic Press: New York and London, September 1969.) 140*s*.

A NOTABLE result of recent applied research on electronics materials has been the confirmation of silicon as the basic material of the semiconductor industry. It is now clear that the development of the science and technology of new semiconductors to a corresponding level of understanding and reliability requires very long-term effort and is only justified for specific applications for which silicon cannot be used. The advent of this present series, which aims to provide authoritative reviews of current work of industrial importance, is therefore timely.

All four articles in this first volume are well chosen. Each one covers an area of electronics materials science which is active and important, and each is written by authors of high professional standing. Without doubt, however, this first volume is distinguished by its first article on junction electroluminescence by P. J. Dean of Bell Telephone Laboratories. This leads the reader through a brief explanation of energy bands in semiconductors to an account of injection mechanisms in homojunctions and in heterojunctions. The bulk of the article is concerned with a detailed and extensive survey of energy transport processes and radiative recombination mechanisms in semiconductors with reference to both incoherent and coherent modes of emission. The relevant literature is thoroughly and critically explored and a great deal of information on energy levels and spectra is presented. There are more than 400 references for further reading.

The second article, by A. Goetzberger and S. M. Sze, also of Bell Telephone Laboratories, is concerned with the metal–insulator–semiconductor materials system which is a basic component of many devices and of monolithic integrated circuits. There is a detailed account of surface charges, and of accumulation, inversion and depletion layers in terms of standard semiconductor theory. The article continues at some length to describe, with reference to the silicon–silicon oxide system, the understanding and interpretation of the capacitance and conductance measurements which have been and still are useful in evaluating the physics of surfaces and interfaces.

The third article, by J. W. Mayer of the California Institute of Technology and O. J. Marsh of Hughes Research Laboratories, surveys the use of ion implantation for semiconductor device fabrication. The practical value and economic level of this technique are still uncertain and this article gives an authoritative and informative account of its capabilities and difficulties. The article begins with an account of range–energy relations in amorphous solids and of channelling in crystalline solids and then continues with descriptions of lattice disorder, annealing and diffusion. The measurement and interpretation of the electrical characteristics of implanted layers are then discussed and the article finishes with an outline of device structures which have been made wholly or partly by implantation technology.

The fourth article, by S. R. Pollack of the University of Pennsylvania and J. A. Seitchik of the Sperry Rand Corporation, deals with electron transport through thin films. This is a short review which summarizes the various physical mechanisms of current. Barrier-limited mechanisms, such as tunnelling and field emission, are first outlined and bulk mechanisms such as tunnelling between and emission from impurities and defects are then described. The article finishes with a very brief presentation of some typical experimental results on oxide films.

The volume ends with an extensive and detailed author index and a shorter but adequate subject index. The text, mathematics and diagrams are clear, typesetting and proof-reading errors are virtually absent, and the result is a book which is a pleasure to read.

This is a book primarily for the semiconductor engineer. Essentially, it is a treatment of selected areas of solid state physics which are being investigated and exploited by the semiconductor industry. Physical mechanisms which are relevant to the fabrication and operation of devices are described and explained sufficiently for the reader who has a good physics background to achieve a working understanding. Within its selected areas, this book will certainly provide a valuable source of fundamental information for many years to come. A surprising omission in a book of applied science is the almost complete lack of description of experimental techniques or practical processes. This is deliberate editorial policy, for the aim of the series is "to emphasize the basic physics and materials technology on which devices are based". The result is, however, in this first volume at least, to give a feeling of remoteness from the real world of the industry which the book is about.

G. T. Wright

MAMMALIAN CELLS IN CULTURE

Axenic Mammalian Cell Reactions

Edited by George L. Tritsch. Pp. xii+413. (Dekker: New York and London, August 1969.) $18.75; 178*s*.

The inclusion of the word "axenic" in the title of this book is potentially misleading; it is concerned neither with pure cultures of microorganisms nor with germ-free animals. It is composed, in fact, of eleven essays by American authors on various aspects of the establishment and use of long-term cultures of "pure" strains of mammalian cells. They are uneven in clarity and interest, but several of them may be instructive, depending on the particular interests of the reader.

Collectively, the essays reflect the increasing tendency of tissue culture workers to apply basic physiological principles to the design of culture systems, with closer control of factors such as pH and oxygen tension, so that the technique becomes less empirical and the environment provided for the cells approaches a little more closely to the *in vivo* situation. This approach is exemplified in the chapter by McLimans on the physiology of the cultured mammalian cell.

The other topics that are discussed include the cytogenetics of haematopoietic cells, transformation of human amnion cells by simian virus 40, the effects of exogenous nucleic acids on cultured cells, study of enzyme regulation and inhibition by antimetabolites, the use of isolated thyroid cells in studies of thyrotropin and the role of peptides in growth control.

Typographical errors are sufficiently numerous to detract from an otherwise well produced volume; some of the half-tone illustrations are too small, and Fig 2 on page 160 has a mistake in the legend.

The book is intended to give both tissue culture specialists and those having a passing interest in the technique some indication of the difficulties and potential value of "axenic" cultures of mammalian cells; it does so quite successfully.

J. A. Sharp

Obituaries

Dr Anna Cosslett

Anna Joanna Cosslett (née Wischin) died in Cambridge on December 6, 1969, at the age of 57, after a long illness. Born in Vienna and educated at Baden, she took her doctorate in physical chemistry at the University of Vienna in 1937. Her work with Professor Philipp Gross was interrupted by a period in prison, as a result of her activity in the Titoist wing of the underground Yugoslav Communist Party. When Hitler annexed Austria in 1938 she fled to London, where she worked for a time as a domestic servant before being rescued by the Society for the Protection of Science and Learning. She found a research position at Bristol University, working with Professor W. E. Garner on microscopical studies of the crystallization of sugar and later the explosive decomposition of azides, in the interpretation of which she was associated with Professor N. F. Mott. After her marriage in 1940 she spent the war years in Oxford as a demonstrator to the elementary classes in the electrical laboratory of the university, and also as instructress in air raid precautions to the women undergraduates.

Migrating to Cambridge with her husband after the War, she became a part-time research assistant in the Cavendish Laboratory, building up a unit for optical microscopy and microphotometry in the electron microscopy section. She was particularly insistent on the need for the coordinated use of optical and electron microscopy in biological research. As there was no suitable instrument on the market, she built a versatile ultraviolet microscope by marrying refractive optics to the Beck-Burch reflecting stand, with which several comparative studies were made in collaboration with microbiologists. Out of an early interest in evaporated carbon films, used for replicas and specimen supports, came a critical investigation of their optical density as a measure of thickness which led to a study of their structure by electron diffraction.

When methods of ultra-thin sectioning were developed she set about improving the technique as well as making accurate measurements of section thickness by two-beam interferometry. She devised a simple way of making glass knives with reliable cutting properties for the ultramicrotome, long before a commercial gadget became available. Always a stickler for accuracy, she was at pains at meetings and in print to deflate the wilder estimates of section thinness made by some electron microscopists. In the same vein she was interested in what happened to a section during microscopy, and she made one of the first quantitative investigations of the loss of embedding material in the electron beam. Her last research was to devise a method of reflexion interference microscopy for comparative measurement of the size of scales on hair of differing origins, in collaboration with Dr R. T. Sims of the anatomy department at Cambridge.

Her work became so well known that her advice was much sought not only by other departments in Cambridge, but by laboratories in Britain and abroad. She did not publish a great deal, but acknowledgments of her help appear in numerous papers by others. Her knowledge of German was also made freely available; in particular she collaborated in the translation of *Equidensitometry*, by Lau and Krug. She took a full part in the social activities of the Cavendish, whether of the assistant or the academic staff, and she had a warm-hearted sympathy for the personal (often the family) problems of successive generations of research students. Perhaps she will be most remembered for the annual party, to which all ranks were invited, in the garden in Long Road which was her chief leisure interest.

Correspondence

Science and Government

SIR,—A group of the Nobel Prize winners published in *Nature* (October 4, 1969) an appeal to the scientific community concerning measures which ought to be taken by scientists against those countries the governments of which interfere with international scientific communications by preventing their scientists from travelling freely and from enjoying other civil rights which are essential to scientific communication.

Certainly, manifestations of solidarity with the scientists afflicted by persecution are touching, and those who are emotionally induced may even see in this a certain kind of consolation. However, a good scientist is guided by reason rather than by emotions, and efficient help means more for him than touching sympathy. There are doubts about the effectiveness of the measures suggested by the Nobel Prize winners who signed the appeal. A government which would encroach by brutal restrictions on civil rights, and whose scientists would be prevented from participating in conferences in their fields of interest held abroad, or who would be persecuted in some other manner, would only be too glad if scientists from other countries were to boycott conferences held at home. The ones to suffer from these measures would be the persecuted scientists themselves. In short the retaliatory measures suggested would only have one positive though questionable effect—they would appease the consciences of the scientists who are incapable of inventing a more ingenious way of helping their persecuted colleagues.

An example of the absurd consequences of such well intended actions can be seen in the communication published in "Miscellaneous Intelligence" (*Nature*, January 10, 1970). It appeals to the colleagues who have been invited by the Institute of Macromolecular Chemistry to attend symposia to be held in Prague and Marienbad to think twice about doing so, on the grounds that I am politically persecuted in my country and that I would not be allowed to reciprocate their visit because of the ban imposed on my travelling abroad.

What has really happened represents a rather mild persecution compared with what happens in other authoritarian systems. Because of differences of opinion, I have only been dismissed from the post of the Director of the Institute and from some other functions, which is a measure stipulated by offended bosses all over the world. As far as my travelling is concerned, I daresay that so far I have much less been afflicted by the restrictions than other colleagues in this country. And even if both my friends and myself were to become victims of whatever evil terror there may arise, non-participation in the conferences organized in this country would not help us but only those who wish to put restrictions on our work and communications with the other countries.

Yours faithfully,
O. WICHTERLE

Institute of Macromolecular Chemistry,
Prague.

Attitudes to Conservation

SIR,—I am sure that I am not alone among your readers in being dismayed by your optimism in envisaging the problems of conservation, and especially in the way in which you have taken sides, your derisive attitude to opponents, your disregard of interests unable to exercise political pressure and your acceptance of short-term expediency.

In your one-sidedness, you are unfair to opponents, as shown in the use of emotive words such as "hawks" and "doves", "doomsdaymen" and "jeremiahs"; and in misrepresenting your opponents as counselling "despair". You suggest (*Nature*, December 27, 1969) that the conservation lobby is threatening us with science fiction horrors ("unisexed morons", etc). Surely it is for theologians and not for scientists to accuse their opponents of heresies ? And surely it is an impropriety to stigmatize the statements of responsible persons with whom you disagree as "misguided" and "reprehensible" ?

In this series of leading articles, one is inclined to see a consistent campaign, honourably intended, to protect the advance of technology. But your view appears to be directed along a narrow perspective, without awareness of such important areas as ecology and ethology. Surely no biologist could have written (*Nature*, November 15, 1969) "human beings . . . may be more be more like ants and bees than laboratory rats". Your concern for man, mainly that he should continue to be fed, is for man, and not at all for the world which is his home. Let us assume that your optimism is justified, and that food production can keep pace with population growth for an indefinite period. Is not the future that would be upon us in another hundred years even more horrible than that of those unisexed morons ? Your faith that no acceleration of the rate of change will be beyond the power of self-correction or the power of our governors to adjust to will not be well taken by the cyberneticist or the social scientist. In making your forecasts do you think you should make room for contingency planning ? Suppose that the green-house effect of increasing carbon dioxide in the atmosphere does show up, and that the Antarctic ice-cap does begin to melt. Have you a plan ready for what we should do then ?

These are problems in which our own emotional responses are necessarily involved, and perhaps we should disclose our "interests", our convictions. I believe that mankind has a responsibility to more than himself; if the Earth is our space-ship, then we are only the officers and we must have a care for the crew. Of all the dangers, perhaps the worst are those of genocide. Once a species is extinct, its loss can never be made good. What is the present rate of genocide, in terms of species per century ? The destruction of non-human societies and local eco-systems must be proceeding at an accelerating pace. It is probably impossible, I would say, for any ordinary man to make an equivalent positive contribution over the course of his lifetime for all the damage he does just by living. Right now, every new child born is an entry on the debit page, acceptable only if required for replacement. I conceive it our first duty to try to contain this destructive process; and to turn ourselves from exploiters to guardians, curators, trustees. It is not too soon, now, to be thinking of what the Earth will be a million years from now.

Yours faithfully,
ELIOT SLATER

Institute of Psychiatry,
De Crespigny Park,
Denmark Hill, London SE5.

The Third London Airport

SIR,—One had become accustomed to the way in which the popular Press has long been campaigning for a decision to locate the Third London Airport at Foulness without waiting for the evidence presented to the Commission enquiring into the matter, leave alone its decision; but it is a surprise to see you join them (*Nature*, **225**, 486; 1970). This is one of the most interesting, difficult and portentous decisions that our generation is ever likely to have to make in Britain, and your decision that "there is little to choose between one site and another", so that "in short, the airport will be best placed where it will be least nuisance. Foulness, it would seem, is the best place" seems so superficial that a protest is surely called for, if only in the hope that more attention will be paid to some of the implications of the evidence now becoming available in time to permit a better-informed discussion at Stage V of the enquiry in two months' time.

First, permit me to point out that the "extra" cost of an airport at Foulness compared with the cheapest site, Cublington (discounted to 1975) is £120 million, which is surely no small matter when the greatest difference in cost of the inland sites is only £9·3 million. While this may be only 5 per cent of the total cost, personally I doubt whether it can be glossed over so easily, because it is my impression that the Commission has in many cases taken conservative estimates of the likely cost of factors difficult to estimate, such as difficulties with transport, preparation of the site, meteorology, and air safety; and with the exception of meteorology, on present showing most of these unknowns are likely to be most important at Foulness, so that the most serious risk of underestimated costs occurs there. There is already ample experience of construction and operational problems inland, but it is quite possible that our hopeful entrepreneurs will encounter a whole new dimension of unforeseen expense as they start to construct transport facilities out through the East End of London to build runways among the shifting sands and sea fogs of the North Sea. And it will not be they, but the taxpayer, who receives the bill.

Second, while you abuse the devoted and (I would have thought) generally rather efficient civil servants, who have made our existing international airports the busiest and most successful ones outside North America, with none of the major transport problems that beset the larger ones there, for ignoring wider aspects of the decision where to site the Third London Airport in favour of the choice which they know to be safe, may I point out some other wider implications which you in your turn do not mention ? The question of the nuisance value of the airport to which you attach prime importance is of only local, not even regional, interest, but the establishment of a major, well appointed, conveniently sited airport in the near future to take overflow traffic from our existing airports is a matter of national importance if we are to compete for the transatlantic tourist trade with foreign centres such as Paris, and facilitate the smooth growth of air freight services in the interests of the need to increase exports. If there is any question of undue delay or difficulty of access to the new airport as a result of a decision to minimize its local nuisance value in the way you suggest, the cost to the country could be very serious in terms not just of a little local noise but as an influence on our total balance of trade.

Third, while national considerations surely ought to take precedence over local ones, there are also some local considerations that have received curiously little comment. It would appear from the commission's calculations that they anticipate that if the Third London Airport is built inland it will be ready fairly soon and will result in the closure of a whole series of other nuisances such as Luton Airport and various military airfields, and will attract business away from more distant sites such as Birmingham and Manchester airports, so that while a major new nuisance will be created in a tract of countryside apparently specially chosen because its remoteness will minimize the effect, other nuisances are liable to be reduced over a wide area round about. Judging by recent protests in the Press, the closure of Luton airport alone will cause more alleviation of local discontent than will ever be provoked by the utmost development of any of the other inland airport sites currently under consideration for development. On the other hand, the Commission appears to anticipate that if the new airport is sited at Foulness, both Luton and Gatwick airports may have to be developed to take overflow traffic while it is being constructed, while much traffic from the Midlands, which might have gone to an inland Third London Airport, will be diverted to Birmingham and Manchester instead. If so, Foulness will miss much of the business that might have been expected inland, which will be diverted to not just one but four or more other proliferating sources of local nuisance instead, leaving an expensive white elephant stranded in idleness on the Thames mudflats.

There are several other matters which one could raise, such as what will happen to Southend and north Kent if it turns out that Noise and Number Indices are among the variables that have been underestimated; but I have added too much to the verbiage being lavished on this issue already. Basically, I would like to suggest that whereas it is possibly arguable that the original decision to select Stansted was perhaps based on too narrow grounds of operational convenience, even now the level at which you argue the decision should be taken, local nuisance value on a regional basis, is still too narrow. The moment that it is enlarged further to a national scale, in terms of the facilitation of trade, and the alternatives of the dispersal of traffic to many sites, each of which becomes a growing local nuisance itself, or concentration at a single central site, deliberately placed where it will cause least nuisance, with the minimum difficulties of construction, and close to existing transport facilities, then an inland site must win.

Yours faithfully,

W. R. P. Bourne

62 Vicarage Road,
Watford,
Hertfordshire.

Goldfinger no Longer

Sir,—I wish to associate myself with the views of R. S. Glover (*Nature*, **225**, 570; February 7, 1970) and in particular his comments on the relationship between field data, the analysis of natural fluctuations and the study of marine pollution. To the number of points which, as he says, are self-evident, I would like to add another that cannot be over-emphasized but does not yet appear to have been appreciated: the quantitative data relating to complex ecosystems will be obtained only by the simultaneous deployment of experienced personnel on a scale and for a duration that would be new to environmental research in this country. The one man/one species approach, forced on so many biologists by circumstances beyond their control and which has nonetheless contributed so much to our knowledge of marine biology, must now be supplemented by the multi-disciplinary, large-team approach if the dynamics of natural populations are to be recorded, analysed and understood. As one who has tried with limited means to move into this more complex sphere, I am obliged to concede that the majority of marine biologists, working as we do in coastal universities as small units with or without a few research students, can achieve neither the continuity nor the breadth essential for this type of study. Collaboration between people with complementary or similar interests who also happen to be close neighbours affords a partial remedy, but the nature of the subject makes it pre-eminently one for research institutes or other major units.

Your doubts about routine data collection ranking as research must surely stem not from failure to see the relevance to population dynamics, but perhaps from a belief that natural fluctuations are so well documented and understood already that we need routine observations solely to set against established base-lines. Nothing could be further from the truth. For a variety of reasons, not least the scale of effort required and the pursuit in recent decades of more fashionable fields or quick results, we know very little about the extent and causes of natural fluctuations. Nor are we within sight of being able to predict the probable biological repercussions of the elimination or weakening (through pollutants) of one or two "key" species in marine communities. A massive new programme of fundamental research is required to establish the base-lines of natural variation, and its essential basal requirement is routine, long-term field observation and measurement. The point where such activity becomes "routine" in the perjorative sense and contributes little to research is far distant.

If, however, base-line studies are seen as merely the collection of numerical data at particular sites in anticipation of a possible pollution incident, and if such data are not used to further our understanding of natural variation, you are correct to feel that this activity does not qualify as research. If it is considered necessary, and this I doubt in most cases, the problems of who does it and finances it have yet to be faced; but it seems most unlikely that universities will accept it as a just demand on their limited research time and facilities.

Yours faithfully,

J. R. LEWIS

Wellcome Marine Laboratory,
Robin Hood's Bay,
Yorkshire.

Sir William Grove

SIR,—In your issue of January 24, 1970, there appeared an extract from *Nature* of 100 years ago consisting of a letter from Sir W. R. Grove concerning the correlation of physical forces. The following footnote to the letter was appended: *From a letter to the Editor*, Nature, **1**, 335, *January* 27, 1870. *Grove was the first to demonstrate the electrolytic decomposition of water.*

The *Dictionary of National Biography* gives the dates of birth and death of Sir W. R. Grove as July 11, 1811, and August 1, 1896, respectively. If these particulars are correct, Sir W. R. Grove could hardly have been the first to demonstrate the electrolyte decomposition of water, as the first mention of this having been accomplished was in *Nicholson's Journal*, **4**, 183 (1800), which was an account of experiments done by W. Nicholson and Sir A. Carlisle.

Yours faithfully,

SYDNEY GILL

University of Manchester
Institute of Science and Technology.

The Social Sciences

SIR,—In "Miscellaneous Intelligence" for January 31 (*Nature*, **224**, 405; 1970) you state: "if any of the social sciences is a science, social anthropology is, . . .". A more preposterous statement is difficult to imagine. Surely that must have been written by one of the visionary prophets of the sect. It is not rigour that is exhibited by the long period of introspection between field work and publication, but an inability to apply anything like scientific method to the materials. I think you owe an apology to anthropological linguists, physical anthropologists, and archaeologists, who exhibit some measure of the rigour of science and its methods.

Yours faithfully,

JOHN BUETTNER-JANUSCH

Duke University Medical Center,
Durham,
North Carolina.

British Diary

Monday, February 23

Genius in Science (5 p.m.) Professor Michael Polanyi, London School of Economics and Political Science, at Houghton Street, Aldwych, London WC2.

Modern Mixing Systems (6.45 p.m.) Mr P. Whitaker, Institution of the Rubber Industry, at the Waldorf Hotel, Cooper Street, Manchester 2.

Terminal Units and Transmission in Electronic Telephone Exchanges (5.30 p.m.) Mr T. H. Flowers, Institution of Electrical Engineers, at Savoy Place, London WC2.

The Mechanical Equipment for the Construction of the Victoria Line (6 p.m. discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

Thermoplastics in the Cable Industry (7.30 p.m.) Mr R. H. Greenhalgh, Plastics Institute, at the Stork Hotel, Queen Square, Liverpool.

Tuesday, February 24

Design of Pressure Vessel Components (all-day discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

Electrolyte Movements within the Colon (5.30 p.m.) Professor O. M. Wrong, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1. (Fourteenth of fifteen lectures on "The Scientific Basis of Medicine".)

Excavations at Swanscombe 1968–69 (5.45 p.m.) Dr J. Waechter, University of London, at the Institute of Archaeology, 31–34 Gordon Square, London WC1.

Some New Concepts in Polymer Stabilization (6 p.m.) Professor G. Scott, Society of Chemical Industry, Plastics and Polymer Group, at 14 Belgrave Square, London SW1.

The Content of Measurements Courses for Electrical Engineers (5.30 p.m. discussion) Institution of Electrical Engineers, at Savoy Place, London WC2.

Yorkshire's Pink Gold—Its Discovery, Exploitation and Evaluation, Mr L. S. Phillips; **The Analysis of Crude Potash Materials,** Dr J. M. Skinner (8 p.m.) Society for Analytical Chemistry; and the Royal Institute of Chemistry, at Constantine College of Technology, Borough Road, Middlesbrough.

Wednesday, February 25

Hi-Fi (6.30 p.m.) Mr J. Moir, Institution of Electrical Engineers, at King Edward VI Grammar School, Chelmsford.

Investigation into the Permeametry and Crystal Structure of Fats and Fat Blends, Mr G. C. Evans; **The Use of Low Resolution NMR for the Rapid Determination of Solids Content of Fat Blends,** Mr P. Mansfield, Society of Chemical Industry, Oils and Fats Group, at 14 Belgrave Square, London SW1.

Kinetics and Regulation of Erythropoiesis (2 p.m.) Dr L. G. Lajtha, University of London, at the Royal Postgraduate Medical School, Du Cane Road, London W12.

Low Light Television Tubes (6 p.m.) Dr P. L. Batey, Institution of Electronic and Radio Engineers, at 9 Bedford Square, London WC1.

Man, Mind and Machine (1.10 p.m.) Professor Philip M'Pherson, City University, at the Graduate Business Centre, Gresham College, Basinghall Street, London EC2.

Maps as a Medium of Scientific Information (1 p.m.) Royal Institution, History of Science Discussion Group, at 21 Albemarle Street, London W1.

Newer Techniques of Thermal Analysis with special reference to Calorimetry (2.30 p.m.) Society for Analytical Chemistry; and the Chemical Society, in the Department of Chemistry, University of Keele, Staffs.

Stereophonic Transmission (7.30 p.m.) Dr G. J. Phillips, Institution of Electrical Engineers, at the Star and Garter Hotel, Dorking, Surrey.

Sterilizable Plastics Packaging for Foodstuffs (10.30 a.m. symposium) Society of Chemical Industry, in the Meeting Room of the Zoological Society of London, Regent's Park, London NW1.

The Application of Test Results to the Calculation of Short-circuit Levels in Large Industrial Systems with Concentrated Induction Motor Loads (5.30 p.m.) Mr C. B. Cooper, Dr D. M. McLean and Mr K. G. Williams, Institution of Electrical Engineers, at Savoy Place, London WC2.

The Direct Determination of Oxygen in Organic Compounds (6.30 p.m.) Mr P. Gouverneur, Society for Analytical Chemistry, at the Leicester Lounge, Glasshouse Street, London W1.

The Interaction of Power Supply Systems and Digital Equipment in Aircraft (6 p.m. discussion) IEE/RAeS, London Joint Group, at the Royal Aeronautical Society, 4 Hamilton Place, London W1.

The Neuropharmacology of Sleep (5.30 p.m.) Professor M. Jouvet (Lyon), University of London, at Charing Cross Hospital Medical School, Chandos Place, London WC2.

Trends in Diffusion (two-day conference) Institute of Physics and the Physical Society; The Institute of Metals; and the National Physical Laboratory, at the NPL, Teddington, Middlesex.

Thursday, February 26

Ammonium Nitrate Production (6.30 p.m.) Mr R. Carter, Institution of Chemical Engineers, at I.C.I., Ltd, Billingham.

Architectural Aerodynamics (9.30 a.m., two-day meeting) Royal Society, at 6 Carlton House Terrace, London SW1.

Medical Problems of Cold Immersion (5.30 p.m.) Dr W. R. Keatinge, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1.

Man's Place in Nature (1.15 p.m.) Dr J. R. Napier (Smithsonian Institution), University of London, at Queen Elizabeth College, Campden Hill Road, London W8.

Numerical Machine Tool Control (6.30 p.m.) Mr D. F. Walker, Institution of Electrical Engineers, at the University Engineering Laboratories, Trumpington Street, Cambridge.

Precoated Plates and Films for Thin-layer Chromatography (6.15 p.m.) Mr E. J. Shellard and Mr G. Whitechurch, Society for Analytical Chemistry, at the Leicester Lounge, Glasshouse Street, London W1.

The Binding Mechanism of Agglomeration and the Hardness of Agglomerates (5.30 p.m.) Professor Hans Rumpf (Karlsruhe), University of London, at the School of Pharmacy, 29/39 Brunswick Square, London WC1. (Further lecture on February 27.)

The Development of Agricultural Research in the United Kingdom (8.15 p.m.) Sir Frederick Bawden, at Wye College, near Ashford, Kent.

The Lubrication of Moving Elements in Present and Future Machines (6 p.m. discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

Zinc Production Expansion at Avonmouth (6.30 p.m.) Mr R. M. Sellwood, Institution of Chemical Engineers, at the School of Chemistry, University of Bristol.

Friday, February 27

Abortion Problems (9 p.m.) Dr C. B. Goodhart, Royal Institution, at 21 Albemarle Street, London W1.

Lithographic Printing Inks (7.15 p.m.) Mr A. Stone, Oil and Colour Chemists' Association, at the Royal Hotel, Bristol.

Numerical Machine Tool Control (8 p.m.) Mr D. F. Walker, Institution of Electronic and Radio Engineers; and the Institution of Electrical Engineers, at Cambridge University Engineering Laboratories, Trumpington Street, Cambridge.

Saturday, February 28

Recent Excavations at Swanscombe (3.30 p.m.) Dr John Waechter, Inner London Education Authority, at the Horniman Museum, London Road, Forest Hill, London SE23.

Monday, March 2

Developments in the Use of Plastics in Railway Rolling Stock (6 p.m.) Mr B. J. Hawthorne, Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

Physics Exhibition (four days) Institute of Physics and the Physical Society, at Alexandra Palace, London.

Stereophonic Transmission (7 p.m.) Mr G. J. Phillips, Institution of Electrical Engineers, at the Royal Star Hotel, Maidstone, Kent.

Structural Enzymology (1): Conformations of Enzyme Molecules (5 p.m.) Professor D. C. Phillips, University of London, at the Middlesex Hospital Medical School, Mortimer Street, London W1.

The Competition for Cash between Innovation and Extension (6.30 p.m.) Dr D. S. Davies, Society of Chemical Industry, at 14 Belgrave Square, London SW1.

The First Steps Into Space (8 p.m.) Professor R. A. Lyttleton, FRS, University of Hull, in the Middleton Hall. (The St John's College, Cambridge, lecture.)

The Value of Polymer Blends (7.30 p.m.) Mr P. W. Milner, Institution of the Rubber Industry, at the Midland Hotel, Burton-on-Trent.

What are the membership privileges of the EM 300 Club?

MEMBER SIGNATURE OF THE PHILIPS EM 300 CLUB
EM 300 CLUB

The members of the EM 300 Club are the over 500 users, in 24 countries, of the EM 300 Electron Microscope.

They are a privileged class - we cannot deny it - by the mere ownership of the finest high-resolution electron microscope on the market today. And they enjoy other benefits as well. For example. At the recent Rome Conference on Electron Microscopy, four new EM 300 accessories were introduced: a new TV display system with image intensifier, a new X-ray spectrometer attachment, a new pre-pumped airlock, and a radically improved specimen chamber cold trap capable of reducing specimen contamination rate to 1 Å per minute or less.

The existing owners of the EM 300 have the first opportunity to benefit from these innovations because they can all be retrofit to existing equipment. But that's only the beginning. Philips' staff of research scientists and engineers are developing new improvements all the time, and these developments are available for incorporation onto instruments already in use. Ownership of an EM 300 is an investment against obsolescence! There are even more membership privileges. To learn the whole story, write for our EM 300 brochure.

Eindhoven, the Netherlands.

ANALYTICAL EQUIPMENT

PHILIPS

UNIVERSITY OF NOTTINGHAM

DEPARTMENT OF CHEMISTRY

OIL POLLUTION AT SEA

Applications are invited from qualified colloid scientists for a **POST-DOCTORAL RESEARCH FELLOWSHIP** to commence at a date to be arranged in the near future to work with Professor D. D. Eley, F.R.S., on water-in-oil (" chocolate mousse ") and oil-in-water emulsions, their formation, structure and stability in relation to oil pollution. The salary will be in the range £1,240 by £115 to £1,585 according to qualifications and experience, reviewable yearly for a total of three years. (786)

UNIVERSITY OF IBADAN

NIGERIA

Applications are invited for **LECTURESHIPS in (i) GENETICS and (ii) COMPARATIVE AND CELLULAR PHYSIOLOGY IN DEPARTMENT OF ZOOLOGY.** Salary scale £N1,200 to £N2,175 per annum (£N1 = £1 3s. 4d. sterling). Salary supplemented in range £450 to £625 per annum (sterling) and education allowances and children's holiday visit passages payable in appropriate cases under British Expatriates Supplementation Scheme. F.S.S.U. Family passages ; biennial overseas leave.

Detailed applications (six copies), naming three referees, by March 13, 1970, to Inter-University Council, 90/91 Tottenham Court Road, London, WIP ODT, from whom particulars are available. (663)

UNIVERSITY COLLEGE OF RHODESIA

Applications are invited for two posts of (a) SENIOR LECTURER or (b) LECTURER IN DEPARTMENT OF GEOGRAPHY. Salary scales: (a) $R5,616 to $R7,536 per annum ; (b) $R3,624 to $R5,832 per annum ($R1 = 11s. 8d. sterling). Family passages and allowances for transport of effects on appointment. Installation loan of up to half of one year's salary if required. Assistance with accommodation for three years from persons recruited from outside Rhodesia. Sabbatical and triennial visits with travel allowances. Superannuation and medical aid schemes.

Detailed applications (six copies), naming three referees, by March 23, 1970, to Inter-University Council, 90/91 Tottenham Court Road, London, WIP ODT, from whom particulars are available. (665)

UNIVERSITY OF EAST AFRICA

MAKERERE UNIVERSITY COLLEGE UGANDA

Applications are invited for the post of **PROFESSOR IN PLANT SCIENCES IN DEPARTMENT OF CROP SCIENCE AND PRODUCTION.** Faculty of Agriculture, available in July, 1970. Salary £U3,150 per annum (£U1 = £1 3s. 4d. sterling). Salary supplemented by £1,068 per annum (sterling) and education allowances and children's holiday visit passages payable in appropriate case by British Government. F.S.S.U. Family passages ; biennial overseas leave.

Detailed applications (six copies), naming three referees by March 25, 1970, to Inter-University Council, 90/91 Tottenham Court, Road, London, WIP ODT, from whom particulars are available. (667)

VIROLOGY SENIOR TECHNICIAN OR Technician required to assist in the day to day work of the non-specific immunity section. Experience in Virology and tissue culture techniques essential. Salary in range £868 to £1,436 according to age, qualifications and experience. 37½ hour week, superannuation scheme and four weeks annual leave. Applications in writing to Departmental Superintendent, Department of Biochemistry, Imperial College, London, S.W.7. (765)

EAST MALLING RESEARCH STATION. Graduate or equivalent in horticulture, botany or forest botany, male, keenly interested both in scientific aspects of practical fruit culture and in people, required for Scientific Liaison Section. Appointment in Assistant Experimental Officer or Experimental Officer grade. Details and application forms from the Secretary, East Malling Research Station, Maidstone, Kent. (767)

TWO RESEARCH ASSISTANTS

are required to join an Electron Microscope Unit engaged in a study of chromosome structure.

ASSISTANT (I) is required to develop methods for the study of chromosomes and other biological materials in the Scanning Electron Microscope.

ASSISTANT (II) will be responsible for the establishment of tissue culture methods and processing techniques involved in the extraction of chromosomes.

Graduates or Technicians with an interest/experience of cell research and who seek an opportunity to work in new, well-equipped laboratories, should apply, giving full details, to Dr. B. V. Kingsley Smith at the above address. (792)

LAKEHEAD UNIVERSITY

THUNDER BAY, ONTARIO, CANADA

ASSISTANT PROFESSOR OF CHEMISTRY

Applications are invited for the post of Assistant Professor in the department of chemistry at Lakehead University. The successful applicant will be required to lecture in the area of physical-organic chemistry and should have applied research interests in, for example, some aspects of rubber or plastics.

The appointment will be initially for one year and the salary will be in the range $10,700 to $13,000 and be dependent on suitable experience. Applications, as soon as possible, should be sent to Professor S. Walker from whom further details of the department and its research interests are available. (791)

UNIVERSITY OF SIERRA LEONE

FOURAH BAY COLLEGE

Applications are invited for LECTURESHIP IN PALAEONTOLOGY in Department of Geology. Preference given to candidates with an interest in Micropalaeontology. Salary scale: Le2,400 to Le4,740 per annum (Le1 = 10s. sterling). Salary supplemented in range £425 to £650 per annum (sterling) and education allowances and children's holiday visit passages payable in appropriate case by British Government. F.S.S.U. Various allowances ; family passages ; regular overseas leave.

Detailed applications (six copies), naming three referees, by March 23, 1970, to Inter-University Council, 90/91 Tottenham Court Road, London, WIP ODT, from whom particulars are available. (666)

EDITOR WANTED FOR FUEL ABSTRACTS. Fuel Abstracts and Current Titles is a specialised international Journal. The Editor must be able to interlink detailed editorial shortening, classification and indexing of abstracts with supervision of small editorial staff, working to a monthly printing schedule; and also to produce and implement long range ideas and planning on every aspect of the Journal's production and circulation. Experience of abstracts classification, preferably in the field of fuel and energy, would be an advantage. Someone without abstracts experience but who likes collecting and sorting data and keeping several jobs running simultaneously should enjoy this job. Salary in range £1,500 to £1,800. Informal atmosphere in small professional organisation. Please apply to The Secretary, The Institute of Fuel, 18 Devonshire Street, London, WIN 2AU, marking envelope " Personal." (777)

GUY'S HOSPITAL—AN EXTENSION TO the laboratories of the Poisons Reference Service at New Cross Hospital, London, S.E.14, will be opened this summer. Vacancies will occur for graduates in Chemistry and Biochemistry. The work is concerned with the analysis of body fluids and other specimens for drugs and poisons, both to provide a service for clinicians and to advance research in pharmokinetics and the treatment of poisoning. Opportunities are afforded for original work in order to obtain a higher degree of the University of London. —Further details of these posts including salary and conditions of service may be obtained from the Director of the laboratory to whom applications should be sent. (776)

UNIVERSITY OF BRISTOL. APPLICATIONS are invited for the post of Technician in the Department of Physiology. The person appointed will be required to assist in tissue culture studies of nerve cells and, preferably, will hold a H.N.C. or be an A.I.M.L.T. Experience of tissue culture techniques would also be useful. Commencing salary within the range: £743 to £1,127, according to age, qualifications and experience.—Applications, giving full details, including qualifications, should be addressed to: Dr. T. Biscoe, Department of Physiology, The Medical School, Bristol BS8 1TD. (775)

ROYAL FREE HOSPITAL SCHOOL OF MEDICINE

(UNIVERSITY OF LONDON)

Applications are invited for the post of **LECTURER** in the Department of Medical Physics from October 1, 1970. Initial salary up to £1,585 on scale £1,240 by £115 to £2,045, then subject to review by £115 to £2,850, plus London allowance and superannuation benefits. Further particulars from the Secretary, 8 Hunter Street, London, W.C.1, to whom applications (5 copies) should be sent not later than March 6, 1970. (787)

SENIOR TECHNICIAN I OR II

Required in Department of Clinical Pharmacology to join a group studying the metabolism of new drugs in man, and be responsible for management and operation of new gas chromatograph and/or mass spectrometer. Considerable experience of analytical techniques essential. Experience with gas chromatography and/or mass spectrometry an advantage. Salary range: Senior I £1,265 to £1,635 ; Senior II, £1,725 to £2,120 per annum.

Applications to the Secretary, Royal Postgraduate Medical School, Hammersmith Hospital, London, W.12, quoting ref.: 20/270. (711)

UNIVERSITY OF HULL

Applications are invited for a post as **TECHNICIAN** in the Department of Botany. Successful applicant will be required initially to assist a Senior Technician in the day to day running of the teaching laboratories and the training of Junior Technicians. Qualifications: City and Guilds Laboratory Technicians Advanced Certificate, or equivalent preferred. Salary on scale £773 to £1,127 depending on age and qualifications.

Applications to Technical Staff Officer, The University, Hull, quoting reference TB/1. (686)

UNIVERSITY OF MANCHESTER

LECTURER IN CHEMICAL BACTERIOLOGY

Applications invited for this post in the Department of Bacteriology and Virology. Duties include undergraduate teaching and supervision of research students. Salary range per annum: £1,585-£2,850. F.S.S.U. Duties commence as soon as possible after March 31.

Particulars and application forms (returnable by March 6) from the Registrar, The University, Manchester M13 9PL. Quote ref.: 20/70/Na. (687)

HEAD OR SENIOR TECHNICIAN

Required for new laboratories shortly to be opened. Applicants must have a wide experience in Pharmacological Techniques. The Position offers good opportunties with excellent conditions, salary and Pension Scheme.

Apply in writing to the Research Director, Biorex Laboratories Limited, Biorex House, Canonbury Villas, London, N.1. (672)

MASSEY UNIVERSITY

PALMERSTON NORTH, NEW ZEALAND

LECTURER IN AGRONOMY

Applications are invited from qualified persons for the above-mentioned position. The appointee will be largely concerned with undergraduate teaching in Agronomy with emphasis on Crop Science. Some postgraduate teaching may be required.

The particular requirement is for a graduate in agricultural science with some experience in applied research and extension in the field. Such a person would also be required to link with other staff members in extending and developing the basic principles taught in earlier stages of the course, to agronomic practice.

Opportunities and facilities for personal research in the general field of agronomy are available with particular encouragement being given to studies in crop agronomy.

Salary: $NZ3,100 to $NZ4,800 (by $200).

(As University salaries are at present under review, this figure could be changed in the near future.)

Further details of the position and of the University, together with the general conditions of appointment, may be obtained from the Secretary-General, Association of Commonwealth Universities (Appts), 36 Gordon Square, London, W.C.1, or from the Registrar of the University.

Applications close on May 1, 1970. (724)

For further classified advertisements see page viia

UNIVERSITY OF EDINBURGH

Department of Forestry and Natural Resources

Applications are invited for the post of DEMONSTRATOR (Ecology) in the above Department. The successful applicant will be expected to assist in the teaching of second-year ecology. He or she will also be expected to pursue research studies in the field of ecology.

Salary Scale: £1,060 to £1,445 per annum.

The successful candidate will be expected to take up duty not later than October 1, 1970.

Applications, giving full details of age, qualifications and experience, should be sent to the Secretary to the University, Old College, South Bridge, Edinburgh, EH8 9YL, from whom further particulars may be obtained. The closing date for applications is April 1, 1970. Please quote reference 1008. (669)

THE GAME CONSERVANCY

FORDINGBRIDGE, HAMPSHIRE

Applications are invited for the post of ASSISTANT SCIENTIFIC OFFICER to help carry out the diagnosis of disease in gamebirds and to assist in various field projects. Some previous experience in laboratory techniques in the diagnosis of disease in poultry would be desirable.

Further particulars from the Director, The Game Conservancy, Fordingbridge, Hampshire. (730)

UNIVERSITY OF STRATHCLYDE

SCHOOL OF MATHEMATICS AND PHYSICS

DEPARTMENT OF APPLIED PHYSICS

SENIOR LECTURESHIP OR LECTURESHIP

Applications are invited from physicists preferably with research interests in the biological applications of physics. A knowledge of either solid state physics, or of some branch of biology (e.g., physiology), or of cybernetics, is particularly desirable.

The successful candidate will be expected to take part in undergraduate and postgraduate teaching and to help to establish research with emphasis on long-term relevance to social and industrial problems, particularly in their biological aspects.

Salary Scales: Senior Lecturer £2,995–£3,670; Lecturer £1,240-£2,850 with F.S.S.U. Placing according to qualifications and experience.

Application forms and further particulars (quoting 1/70) can be obtained from the Registrar, University of Strathclyde, George Street, Glasgow, C.1. with whom applications should be lodged. (732)

DIRECTOR

Fishing Industry Research Institute South Africa

The post of Director of the Fishing Industry Research Institute, University of Cape Town, Rondebosch, will fall vacant on 1st June, 1970, on the retirement of Prof. G. M. Dreosti. Applications are invited for this post, which carries a salary not less than R10,000 (approx. £5,800).

Full details of the Institute, duties and privileges of the post may be secured on application to:

The Office of the Scientific Counsellor (Ref. N.),
Chichester House,
278 High Holborn,
London, W.C.1.

Closing date for completed applications 7th March, 1970.

(719)

AHMADU BELLO UNIVERSITY

ZARIA, NIGERIA

Applications are invited for the following appointments:

DEPARTMENT OF ELECTRICAL ENGINEERING

Chair of Electrical Engineering. Appointee will be expected to take a particular interest in the development of the teaching programme and he should be prepared to carry a large share of the administration of the undergraduate courses and the running of the department as well as leading research in his own field. There are, in addition, two other Chairs, both filled, in Power Engineering and Telecommunications, but specialisation in either of these fields would not necessarily disqualify a suitable candidate.

DEPARTMENT OF GEOGRAPHY

(a) **Professor and Head of Department.**

(b) **2 Lecturers** in either (i) Geomorphology and biogeography, (ii) economic and/or agricultural geography, or (iii) settlement geography. Preference given to candidates who in addition to these qualifications have experience and interest in resource analysis and regional planning.

DEPARTMENT OF GEOLOGY

Lectureship in Geology. Good honours degree with research interests in mineralogy and/or structural/metamorphic geology desirable.

DEPARTMENT OF MATHEMATICS/COMPUTER SCIENCES

(a) **Senior Lecturer and Lecturer.** Good honours degree in mathematics and considerable research experience desirable.

(b) **Computer Programmer and Systems Analyst** (both Lecturer grade). Candidates must be graduates with computer experience.

Salary scales: Professor and Head of Department, £N3,200 per annum; Professor, £N3,000 per annum; Senior Lecturer, £N2,275 to £N2,575 per annum; Lecturer, £N1,200 to £N2,175 per annum (£N1=£1 3s. 4d. sterling). Salary supplemented in range £450 to £925 per annum (sterling) and education allowances and children's holiday visit passages payable in appropriate cases by British Government. Family passages; various allowances; superannuation or gratuity; regular overseas leave. Detailed applications (6 copies), naming 3 referees, by April 6, 1970, to Inter-University Council, 90/91 Tottenham Court Road, London, WIP ODT, from whom particulars are available. (743)

LABORATORY SUPERVISOR

Applications for the post of Supervisor of a small veterinary field laboratory in the Cheltenham area are invited from those with not less than 5 years' experience in microbiology or pathology and who are Associates of the Institute of Medical Laboratory Technicians or hold equivalent qualifications.

The applicant should be male (25–30 years of age), physically fit and capable of acquiring and performing new techniques.

The post demands versatility, adaptability and the ability to accept sole responsibility for provision of laboratory services in support of field trials and investigations.

Starting salary will depend on age and experience but will not be less than £1,200; fringe benefits include contributory pension and free life assurance schemes.

Please write giving details of age, qualifications, experience and present salary to:

The Company Personnel
Manager, Cyanamid of
Great Britain Ltd.,
Bush House, Aldwych,
London W.C.2

CYANAMID

LIVERPOOL EDUCATION COMMITTEE

LIVERPOOL REGIONAL COLLEGE OF TECHNOLOGY
(Polytechnic designate)
BYROM STREET, LIVERPOOL, L3 3AF

Applications are invited for the following post:

SENIOR LECTURER/ LECTURER GRADE II IN PHARMACOLOGY

SCHOOL OF PHARMACY

The successful candidate will be expected to assist in the expansion of research work and in the development of undergraduate and postgraduate courses.

SALARY: Senior Lecturer, £2,417 to £2,752; Lecturer Grade II, £1,827 to £2,417.

The commencing salary will be assessed according to experience with additions for graduate qualifications and training.

Application forms and further particulars can be obtained from the Director of Education, 14 Sir Thomas Street, Liverpool, L1 6BJ, on receipt of an addressed foolscap envelope.

Return forms to the Acting Principal of the College not later than March 4, 1970.

STANLEY HOLMES,
Town Clerk.

(759)

UNIVERSITY OF ADELAIDE

Applications are invited for the following appointments, the closing date for applications being stated in parentheses after each post.

LECTURER IN BIOCHEMISTRY. Present interests of the Department lie in the area of protein biosynthesis, phage and virus biochemistry, regulation of enzyme activity and metabolism, structural studies on proteins. (15.3.70.)

LECTURER IN MATHEMATICAL PHYSICS. Preference will be given to a candidate with several years' postgraduate experience who has specialised in the field of general relativity or elementary particle physics and is capable of supervising M.Sc. and Ph.D. students. (28.2.70.)

SALARY SCALES: Lecturer $A5,400 by $A280 (1) by $A270 (6) to $A7,300, with superannuation on the F.S.S.U. basis.

FURTHER PARTICULARS about each post and the conditions of appointment and other information sought will be supplied on request to the Registrar of the University, or to the Secretary-General, Association of Commonwealth Universities (Appts.), 36 Gordon Square, London, W.C.1.

Applications should be sent in duplicate and giving the information listed in the statement that will be supplied to the Registrar, The University of Adelaide, North Terrace, Adelaide, South Australia 5001. (752)

RESEARCH COUNCIL OF ALBERTA

A position is available within the Geology Division of the Research Council of Alberta, a research institute located on the campus of the University of Alberta, for investigations concerning the distribution, stratigraphy, and origin of the Quaternary glacial deposits of Alberta. Applicants should have an M.Sc. or Ph.D. degree in geology or physical geography with a strong background in Pleistocene geology, geomorphology, air photo interpretation, and sedimentology. Duties will involve mapping of surficial deposits at various scales and studies of specific problems related to urban development, land utilization, industrial minerals, and hydrogeology. Salary commensurate with qualifications and experience.

For further details write the Administrative Assistant to the Director, Research Council of Alberta, Edmonton, Alberta.

(704)

UNIVERSITY OF ADELAIDE

PROFESSOR OF PHYSICS

Applications are invited for the above-mentioned appointment.

There are two established Chairs within the Department of Physics and the present appointment relates to one that has recently been vacated. The major research interests of the Department are in the fields of atmospheric and space physics, cosmic rays, laboratory astrophysics, solid state physics and seismology. It is hoped that the research interests of the new Professor will be within one of these fields and that he will develop research activities in experimental physics which will strengthen and expand the present research work of the Department.

Further information about the work of the Department of Physics may be obtained from Professor J. H. Carver.

SALARY: at present $A12,000 a year with superannuation on the F.S.S.U. basis.

FURTHER INFORMATION: Potential candidates are invited to obtain from the Secretary-General, Association of Commonwealth Universities (Appts), 36 Gordon Square, London, W.C.1, or from the Registrar of the University, a more detailed Statement about the Chair and formal terms of appointment. Any further information desired may be had on request to the Registrar.

APPLICATIONS (in duplicate) giving the particulars listed in paragraph 6 of the Statement should reach the Registrar of the University at North Terrace, Adelaide, S.A. 5001, not later than April 15, 1970. (722)

UNIVERSITY OF IBADAN

NIGERIA

Applications are invited for the following appointments in the FACULTY OF MEDICINE:

(i) SENIOR LECTURESHIP IN DEPARTMENT OF BIOCHEMISTRY from candidates with research experience in Human Nutrition.

(ii) LECTURESHIP IN DEPARTMENT OF BIOCHEMISTRY from candidates with research experience in Biochemical Toxicology.

(iii) LECTURESHIP IN DEPARTMENT OF PHYSIOLOGY.

Salary scales: (i) £N2,275 to £N2,775 per annum (ii and iii) £N1,200 to £N2,175 per annum (£N1 = £1 3s. 4d. sterling). Salary supplemented in range £450 to £825 per annum (sterling) and education allowances and children's holiday visit passages payable in appropriate case by British Government. F.S.S.U. Family passages; various allowances; regular overseas leave.

Detailed applications (six copies), naming three referees by March 26, 1970, to Inter-University Council, 90/91 Tottenham Court Road, London WIP ODT, from whom particulars are available. (744)

UNIVERSITY OF CAMBRIDGE

Applications are invited for the office of

UNIVERSITY DEMONSTRATOR IN THE DEPARTMENT OF PHARMACOLOGY

The initial appointment will be for three years from October 1, 1970 or earlier. The pensionable stipend is on a scale £1,355 to £1,815 a year with initial placing above the minimum where appropriate. There is a grant towards removal expenses.

Candidates should send twelve copies of their applications, together with the names of not more than three referees, to Mr. G. R. Anderson, The Old Schools, Cambridge, CB2 1TT, to arrive not later than March 16, 1970. (680)

Unicam UV Spectrophotometers make light work

What does this mean to you ? In research, results you can trust and repeat. In routine applications, error-free operation by the least experienced member of your staff.

When you come to Pye Unicam, even the selection of your UV spectrophotometer is simple. There is a choice of instruments broad enough to meet your every requirement and to match your budget, with a staff of experienced application specialists to back them up.

Just look at what is available . . . **SP500 Series 2** and **SP600 Series 2** quantitative single beam spectrophotometers, **SP700** for research, **SP1800** for low-cost double-beam operation, **SP3000** automatic digital instrument, **SP8000** for the ultimate in flexibility, and the **SP1300 Series 2** low-cost colorimeter.

Write or 'phone for free information today. That's simple too, isn't it.

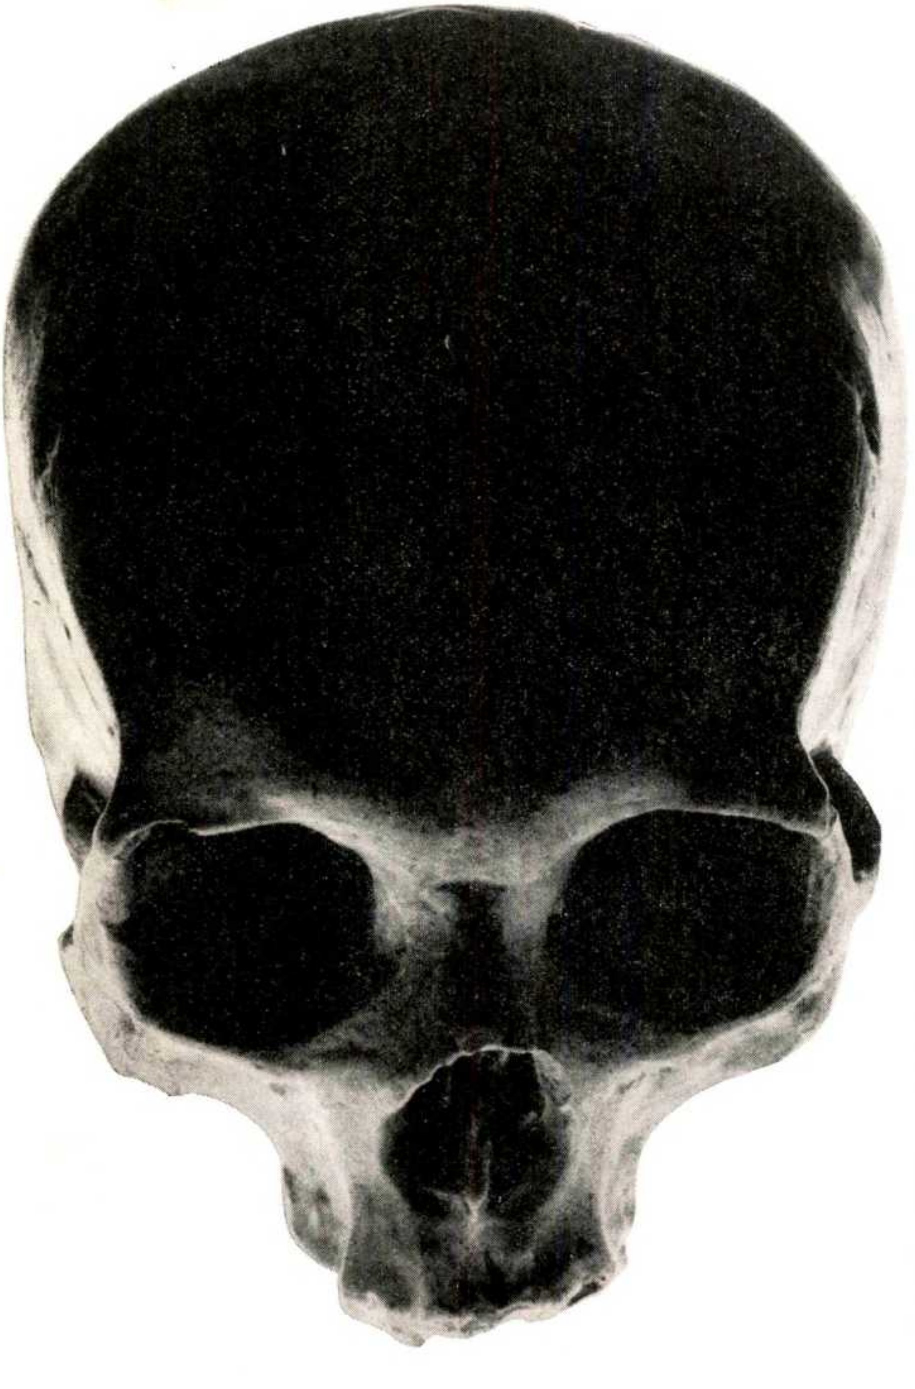
YOU'VE JUST UNEARTHED BONE.

WITHIN WEEKS WE CAN TELL YOU ITS AGE.



Our radiocarbon laboratory and counting facilities can give you the fastest service available anywhere. A complete age determination report of your bone specimen will be in your hands within weeks.

And, the stress is on accuracy. Not only do we routinely date your bone specimens directly by the collagen method, at the same cost as normal radiocarbon dating, but our C^{12}/C^{13} analysis can compensate for natural isotopic fractionation.

Prices are based on the number of samples we date for you during any given 12 month period. Prices range from $170 for a single sample to $130 per sample for 50 or more samples. For C^{14} plus C^{12}/C^{13} analysis, the charge is $195. Again, less for multiple analyses.

Non-existent Machinery does not Function

THE examination of the budget of the National Science Foundation for 1971 which has been going on in Washington for the past ten days (see page 785) has only served to emphasize the long-standing deficiencies of the machinery for administering the money spent on university research in the United States. The latest trouble is that agencies such as the Department of Defense and the National Aeronautics and Space Administration are being forced not merely by the general shortage of money but also by a formal request from Congress—the Mansfield amendment to the defence budget for the present financial year—to apply with increasing stringency to proposals for research expenditure the tests of relevancy. The result is that a great many worthy projects are likely to be dropped by agencies which only a few years ago were trying hard to breathe life into them—in this spirit, for example, NASA will be spending literally nothing on long term research projects which have in the past cost $9 million a year, and will be trimming its sails in other fields as well. Unfortunately, however, there is no guarantee that these abandoned projects will find sponsors elsewhere. The National Science Foundation has $10 million in its budget for succouring the casualties, but this could easily fall short of the real need which will nevertheless not become apparent for several weeks. The biggest uncertainty lies in the spending of the Department of Defense. How much of the $370 million which has been requested for research as distinct from development will eventually fail to meet Congress's stern if somewhat arbitrary criteria of relevance? With a little bad luck, the National Science Foundation will have a crowd of orphans on its doorstep.

The first thing to be said is that the lack of coordination between the plans of the several government departments is excusable but nevertheless intolerable. The projects now at risk include schemes for training graduate students in noise engineering and schemes for operating particle accelerators—it seems, for example, that the accelerator shared by the University of Pennsylvania and Princeton University will be closed down. Although the sums of money involved are comparatively small, the careers of able people are bound up in them and the changes now in prospect, by their suddenness and the sense of arbitrariness which they convey, are bound to unsettle not merely those directly concerned but all those who depend on the knowledge that modern research must be sponsored by modern government. So why should not the shift of interest in the mission oriented agencies, inevitable as it has been, have been better coordinated? Now that the annual budget has been dumped more or less in the lap of Congress, the Administration can wring its hands and draw attention to the way in which scientific expenditure falls within the jurisdiction of a score of congressional committees. But should not something have been done to anticipate these problems and to arrange for a more orderly transfer of responsibility from one agency to another? After all, the National Science Foundation has power to take over research projects sponsored by other departments if both agencies are agreeable. Would it not have been better to have arranged for transfers of this kind instead of waiting for muddle to become overt? And is this not in any case what the Office of Science and Technology is for? Or is the coordination needed for the smooth administration of university research so far outside that office's power that some other instrument is necessary?

In one sense, of course, the gap between expectation and reality which has now emerged could have been predicted several years ago. In the fifties, when every agency of the federal government seemed a potential fairy godmother, the scientific community in the United States relished the opportunity which this diversity provided for playing off one benefactor against another. The result, unfortunately, was that most university research came to be sponsored by agencies whose real interests lay elsewhere. As things are, agencies other than the National Science Foundation provide more than 85 per cent of all the federal money that finds its way into academic science. Nobody can therefore be surprised that during a period when the agencies with other jobs to do have been under severe pressure to economize, the total expenditure on scientific research in the universities has been declining, both absolutely and in real terms. The increase of two per cent in the estimate of what will be spent in universities in the coming financial year will not outweigh the effect of inflation on the real cost of doing scientific work. In short, even if Congress agrees to what the Administration has asked of it, the coming year will be another bad one for university research. The shadow cast by the old plurality of research sponsors is long. The question now is how damaging it will be.

This is where the report of the National Science Board, published last week (see page 789), should be taken as a starting point. The decline of expenditure on university research which began in 1967 seems destined to continue. The implication is that the United States has decided, perhaps without acknowledging as much, that the time has come when university research should consume a smaller share of what the federal government has to spend. Dr Philip Handler was right last week to point to the consequences there must soon be for the output of graduate students from the universities and colleges which have in the past two decades striven successfully to meet what then seemed to be an urgent need. The report of the National Science Board itself makes vivid the way in which a prolonged halt to the growth of university research may damage not merely the pattern of university research and teaching but, in the long run, the capacity of industry in the United States to renew itself. At a time when only interdisciplinary proposals for dealing with the environment seem to have an easy passage, the appearance of the National Science Board's report on the physical sciences may serve as a challenge to the government and those who pay its taxes to make an explicit decision about the scale of university research in the sciences in the years ahead. It will be strange if the achievements of postwar research in the United States can be discarded as lightly and as passively as the budgets of the past few years imply.

But what is to be done ? The National Science Board, which manages the National Science Foundation as well as making public pronouncements, is in the invidious position of having to recommend that the best course is to channel more money through the National Science Foundation. This, however, has been beyond dispute for several years. Only when a substantial fraction of university research is supported in this way will it be possible for the merits of competing proposals to be objectively assessed and for the recipients of what money there is to spend to be assured of the kind of continuity on which good planning must depend. Those who doubt this proposition should be convinced by the quite scandalous way in which radioastronomy is being neglected in the United States—the best that the federal government has been able to secure for the radio-astronomers among its pensioners is $800,000 for resurfacing the instrument at Arecibo and the promise on behalf of the Jet Propulsion Laboratory that five per cent of the time on instruments in the Deep Space Tracking Network should be made available to academics. The way in which, by all accounts, a great deal of work in organic chemistry is being threatened by the tighter budget at the National Institutes of Health should be another proof of the need for the kind of continuity that can only be provided by an agency which has not merely the will to fight for what it believes in but the power to do so successfully. This is why it should now be a first objective, among scientists in the United States and by the National Science Foundation itself, to see more growth in the years ahead. The signs are that when all the chickens have come home to roost, the foundation will be as hard pressed in 1971 as it has been in the past. In the circumstances, it may well have been too soon to embark on some of the admittedly popular but possibly speculative projects which the foundation is about to embrace.

OLD WORLD

France to Double Research Budget

from our Paris Correspondent

For the past few days, members of the government have had on their desks the reports of the various commissions appointed to prepare the Sixth Plan. When these documents have been revised or approved by the Council of Ministers, they will be forwarded to parliament, where they will be discussed during the spring session. The commissions will then have to work out in detail ways of carrying out the projects that have been chosen. These will come into effect in 1971 and extend to the end of 1975.

It is probable that the report on the various possible research and development projects (the text of which runs to some twenty pages or so) will not be modified much in the course of the proceedings that have just begun. Thus the selections made by the Commission of Research give us quite a good idea already of what French scientific policy will be, *deo volente*, during the coming five years. This is provided, of course, that the execution of the Sixth Plan is not impaired along the way by economic difficulties like those which prevented the objectives of the Fifth Plan from being reached.

Expenditure on research and development now represents 2·2 per cent of gross home production (this criterion is now preferred to gross national product, which has been used in calculations until now). It should reach 3 per cent in 1975 if the annual rate of growth of the economy is only 5·4 per cent as had been originally forecast (in fact, the rate of growth chosen by the government will without doubt be greater than 6 per cent). In practical terms this means that expenditure on research and development will increase by an average of 13 per cent every year to reach 32,500 million francs in 1975, which is about double the present figure. The proportion of this total supported by the state will stay more or less at 70 per cent. On the other hand, it should be noted that the expected development will particularly favour civil expenditure; military research and development will certainly grow in volume but will remain stationary in relative terms.

Execution of the plan, however, does not only depend on financial resources but is strictly limited by the available manpower. The number of scientists cannot be increased at the drop of a hat and measures agreed on last week in the field of education will only bear fruit during the Seventh Plan (1975–80). Thus the existing manpower must be deployed in other ways than in the past. The commission believes that in the course of the next few years France will need a majority of young scientists (that is, 65 per cent instead of 35 per cent) to begin their careers in research, with a part of these then going into production work and teaching.

Another important change lies in the way in which money is used and this points up characteristically the distance between the politics of General de Gaulle and those of M. Pompidou. In fundamental research the accent will be on the biological and social sciences, where the annual rate of growth will be about 23 per cent. The study of the interaction between man and his environment and the struggle against pollution will be given preferential treatment. On the other hand, nuclear physics and high energy physics, both of which have for a long time been given priority, will be pegged at a growth rate of only 5 per cent. The fields of chemistry and physics will develop at the rate of 15 per cent a year.

Notable changes are in store for industrial research and development. The grand and spectacular projects favoured by the previous government (aeronautical programmes, nuclear complexes and the computer project Plan Calcul) will be severely restrained and France will be more circumspect before becoming involved in any more operations of the same kind. The purchase of foreign licences will be encouraged when this can obviate costly duplication of effort made in other countries. The execution of research and development programmes will, as far as possible, be the responsibility of industry rather than state organizations. The part devoted to development in the overall expenditure will increase. Among these sectors to which the commission attaches priority is that of housing, urban development and transport, which has admittedly been scandalously neglected until now. Other priority areas will be chemistry, metallurgy, mechanics and, of course, electronics. The writers of the report, obviously wary of lavish expenditure, declare forcefully that in the tactical choices stemming from this new policy, "the attribution of state aid should systematically take into account the probability of technical success and the possibility of profit from the proposed operations". It is, of course, surprising that these common sense rules should need to be solemnly declared in an official document after a decade of concerted scientific policy. But better late than never.

PLANT BREEDING

Fears of the Private Sector

The Agricultural Research Council (ARC) has decided that it cannot accede to the wishes of dissatisfied plant breeders who want the council's institutes to cease producing new varieties of plants. The present dissatisfaction has grown up since the passing of the Plant Varieties and Seeds Act in 1964, which made it possible for breeders to obtain royalties on the sale of new plant varieties. This was intended to encourage private companies to take more part in the breeding of new varieties. This task had for many years been largely the concern of state organizations, which were not obliged to make a profit on their new material. But many private breeders still feel that they are at an unfair disadvantage in trying to compete with institutes which have their overheads paid by the government. As a result, there has emerged a strong lobby which calls for the activities of the ARC to be restricted to fundamental research in plant breeding.

In response to this pressure the council has reviewed its policy with respect to the support of plant breeding at state aided research institutes. The decision to make no change was taken in the light of reports from the directors of the plant breeding institutes in Cambridge, Aberystwyth and Pentlandfield, Scotland, and from Mr G. C. Stevenson, the council's adviser on plant breeding. After visits to private breeders, Mr Stevenson has come to the conclusion that they are not ready to take over full national responsibility for producing new plant varieties. Apart from the fear that the private sector could not cope with all the breeding that must be done, there is concern for the morale of ARC workers who would have to hand over their work to private breeders once a new variety was in sight. This, the council thinks, would be a bad thing. Furthermore, the council sees its institutes as useful training grounds for plant breeders; a claim which must be supported by the companies that have recruited scientists from ARC staff.

The decision not to reduce ARC effort devoted to the breeding of new varieties does not mean that the worries of the private sector are being brushed aside completely. It is, after all, responsible for developing many of the new varieties of vegetables grown in Britain, although the state aided institutes dominate when it comes to cereals and grasses. There is already cooperation between state and private breeders, and the ARC is now looking into the question of extending this.

TELEVISION

Graph with a Slipped Slope

An unfortunate slip of the pen has been made on the drawing boards of Television House, London, the headquarters of Thames Television. Last month, in an issue of the "Today" programme, Professor Ernest Sternglass of Pittsburgh University exhibited a graph depicting the infant mortality in England and Wales since 1935. Many of those who watched the programme

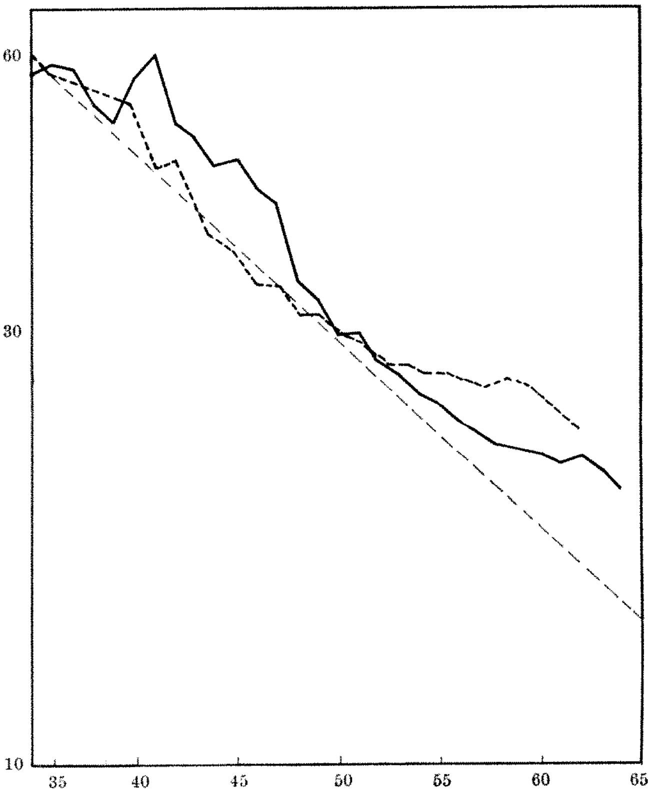

Fig. 1. Infant mortality in England and Wales (deaths per 1,000 of population). Solid line: graph based on statistics supplied by the Registrar General. Broken line: graph prepared by Thames Television for display on "Today" programme.

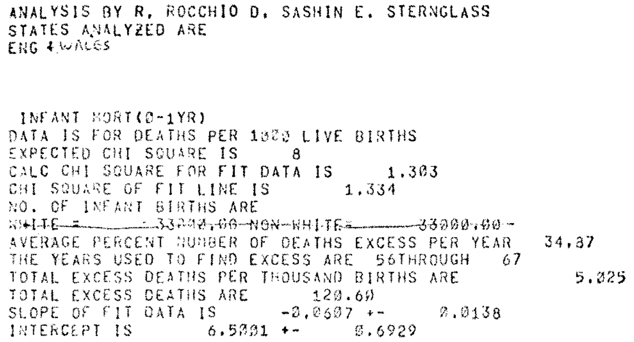

```
ANALYSIS BY R, ROCCHIO D, SASHIN E. STERNGLASS
STATES ANALYZED ARE

Fig. 2. From the print-out of a computer program designed to calculate "excess deaths" in various countries.

must have been alarmed by the graph, because Professor Sternglass used it to show that something like 100,000 British children may have died since 1950 because of nuclear fall-out.

Alarm of a different kind was felt by another of the participants in the programme, Professor Joseph Rotblat of St Bartholomew's Hospital, London, who had also prepared a graph of infant mortality in England and Wales, based on the statistics issued by the Registrar General. As can be seen from Fig. 1, the two graphs bear little relation to each other. A few days after the programme Professor Rotblat wrote to Thames Television to point out the discrepancy and suggested that a correction should be broadcast. Copies of the letter were sent to other participants in the "Today" programme, including Lord Kennet, who raised the matter with the Independent Television Authority. As the result of an inquiry by the ITA, Thames Television announced last week that the exhibited graph had been wrongly drawn but that the burden of Professor Sternglass's argument was not affected.

How can it have happened that the graph prepared by Thames Television was so totally at variance with the true data? From the reply sent by Professor Sternglass to Professor Rotblat and the other participants, it seems that the draughtsman at Thames Television was furnished not with exact figures but with a graph that had to be copied. But the figures used by Professor Sternglass to compute the tally of 100,000 "excess deaths"—the difference between the actual figures and a linear extrapolation of the apparent rate of decline in infant mortality between 1946 and 1955—are almost identical to those of the Registrar General. Professor Sternglass comments, "Any inaccuracies in the charts prepared by the draughtsman in the Thames Television studio without the benefit of actual numbers, although regrettable, do not appear to be so serious as to have given a misleading impression".

However, in the chart shown on the "Today" programme the infant mortality graph for England and Wales was displayed together with the corresponding graph for the United States. For both of these the slopes of the straight lines were drawn parallel, thus giving the striking impression of exactly the same behaviour in the two countries. With the true data for England and Wales, Professor Sternglass himself can only draw a straight line between 1946 and 1955 instead of 1935 to 1950 as on the chart displayed in the programme.

Another puzzling feature of the "Today" programme that has since come to light is the figure of 100,000 excess deaths calculated by Professor Sternglass for England and Wales. A copy of the computer print-out on which the figure was based has been supplied to *Nature* by Thames Television (Fig. 2), from which it appears that the "total excess deaths" are "120·60" or presumably 120,600. The computer presumably arrived at this figure by multiplying the "total excess deaths per thousand births" (5·025) by "years used to find excess" (12) and 1/1,000 × the average total of annual births in England and Wales. On this assumption the average total of annual births works out at a neat 2,000,000. If this were true Malthus would have leapt triumphantly from his grave long ago. Total live births in England and Wales between 1956 and 1967 (the period of Professor Sternglass's "excess deaths") have averaged about 800,000. On this basis the "excess deaths", according to Professor Sternglass's hypothesis, would be nearer to 48,000 than 120,000. That is still a lot of deaths, but it seems that something a bit more reliable than Professor Sternglass's computer or the draughtsmen of Thames Television is needed to prepare the certificates.

ACADEMIC COOPERATION

Another Name for Kew

by our Botany Correspondent

The special relationship between Kew and Reading has been made formal by the recognition of the Royal Botanic Gardens as an associated institute of the university. This sets the official seal on cooperation in teaching and research which has been steadily increasing during the past ten years. The director of Kew, Sir George Taylor, has been made a visiting professor of the university, and several of his colleagues have become members of the academic staff.

At present, cooperative ventures include an MSc course in pure and applied plant taxonomy, run jointly by staff at Reading and Kew. Botanists from Kew take part in graduate seminars at Reading, and also supervise PhD students from the university. Collaborative research includes the *Flora Europea* project which has been centred at Reading since one of the editors, Professor V. H. Heywood, became professor of botany there. The director of Kew is an advisory editor for this project.

These and similar joint activities are expected to increase in the future, although exactly what will happen depends to some extent on the attitude of the new director of Kew, due to be appointed soon on Sir George Taylor's impending retirement.

ENVIRONMENT

Appointment of Royal Commission

The Royal Commission on environmental pollution holds its first meeting this week. The commission is chaired by Sir Eric Ashby, Master of Clare College, Cambridge, and former professor of botany at Manchester University, and will be responsible in the first instance to Mr Anthony Crosland, Secretary of State for Local Government and Regional Planning. The commission is intended to be permanent, and has been given terms of reference that charge it "to advise on matters, both national and international, concerning the pollution of the environment; on the adequacy of research in this field; and future possibility of danger to the environment".

The interpretation of these terms depends largely on the members of the commission, who will also be free to decide when and how to report, what priority to give to international rather than British problems, and what sort of research is to be assessed. Advisory machinery on environmental matters already exists in the form of bodies such as the Natural Environment Research Council, but because the commission has no executive powers it is expected to provide a more general view by taking into account the arguments of both polluters and conservationists.

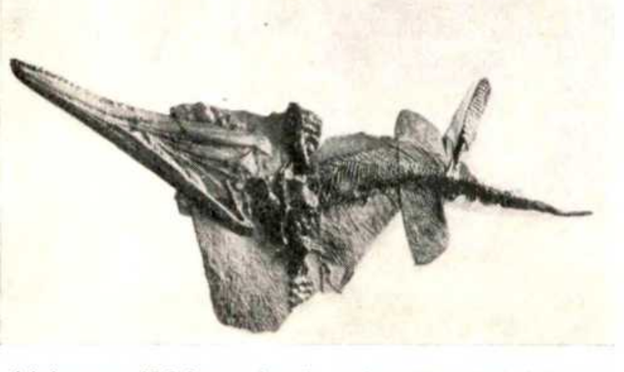
Other members of the commission are Dr W. Beckerman (professor of political economy at University College, London), Mr Aubrey Buxton (British Trustee of the World Wildlife Fund), Dr F. Fraser Darling (vice-president of the Conservation Foundation), Professor V. C. Wynne-Edwards (chairman of NERC), Dr W. L. S. Fleming (Bishop of Norwich), Mr N. A. Iliff (Shell Chemicals (UK), Ltd), Sir John Winnifrith (National Trust), and Sir Solly Zuckerman (the chief scientific adviser to the government).

AUCTIONS

Ichthyosaur under the Hammer

An ichthyosaur that paddled on Lower Jurassic Seas 150 million years ago and came to grief somewhere near the present site of Lyme Regis has now been washed up in the sales rooms of Sotheby's, the London auctioneers, and will fall to the highest bidder on March 5. For many years the ichthyosaur occupied a niche 17·5 feet long and 4 feet high on the walls of a corridor in the Grant Institute of Geology at Edinburgh. Because the corridor at that point had to be turned into an office, and there was no other place to house the ichthyosaur, Professor G. Y. Craig decided after consultation with the Royal Scotland Museum to put the creature up for sale. Market prices for small ichthyosaurs exceed £2,500 and Professor Craig will be "reasonably happy" if the Edinburgh ichthyosaur makes as much as £30,000.

The museum of the Grant Institute has no records of how the fossil came into its possession, but the presumed site is the Lower Lias of Lyme Regis, Dorset, where the first identified specimen of an ichthyosaur was discovered in 1810. The specimen, though sans its right hind paddle, is a fine example of *Ichthyosaurus platyodon* (Conybeare).



Ichthyosaur, 17·5 feet in length, to be sold at Sotheby's on March 5.

The ichthyosaur is joined in the sale by minerals, shells and other fossils including trilobites, ammonites and several fossil fish such as a Jurassic age *Leptolepsis sprattiformis*, 2·5 inches in length.

SRC FELLOWSHIPS

More for Fewer

From next October the Science Research Council is cutting the number of its postdoctoral fellowships from forty to twenty-five a year but is making them more valuable. The new fellowships will be worth between £1,450 and £1,800 a year, compared with the present value of £1,045 to £1,300. As a further bonus fellows who are working in Britain will be allowed for the first time to apply for SRC research grants on top of the basic award. The fellowships, which usually last for two years, are given to outstanding young researchers so that they can spend all their time on their investigations.

The changes imply that the SRC may be spending several thousand pounds less on the fellowships each year: with a mean figure for the value of a fellowship the expenditure would fall from about £47,000 to nearer £41,000. The SRC points out, however, that its total backing for the fellows is likely to increase because of their eligibility for grants. It seems that this increase will come simply from money that is earmarked for grants anyway, for the fellows who apply for grants will be judged on merit in the same way as anybody else.

In its report for 1968–69 the SRC said that it wanted to make its support of research more selective with respect to the quality of the people it finances and the practical relevance of their subjects. The new fellowships are accordingly designed to give better opportunities to an even more select few: the SRC is basing its choice entirely on ability and independent achievement. But it is not picking out any field for special benefit, and has not changed its industrial fellowships or its one-year awards to British scientists who want to come back from North America. Full details of the new scheme will be published shortly in an SRC booklet on *Studentships and Fellowships 1970*.

OIL

Search in Liberia

from our Geomagnetism Correspondent

Liberia, well known for allowing its flag to be flown on tankers carrying other people's oil, has begun to seek oil of its own. No oil has actually been found on Liberian territory, but scientists from the US Geological Survey and the Liberian Geological Survey who have been surveying the region report that "the potential for petroleum deposits beneath the continental shelf of Liberia is promising".

This discovery comes as a result of a joint US–Liberian programme of mineral resources investigations covering dry land as well as the continental shelf. The principal impediment in the search for oil on land has been the thick layer of residual soils, produced by tropical weathering, which masks most of the bedrock. Moreover, swamps, sandy savannas and bush have made ground-based studies of the underlying geology difficult if not impossible. But the resources and experience of the United States have now been used to provide airborne gravity and geomagnetic surveys. Mapping of the coastal areas has thus revealed the presence of at least two onshore structural basins filled with Cretaceous sediments. Preliminary surveys of the adjacent continental shelf and slope suggest the existence of similar basins there also. Such discoveries are guaranteed to make oilmen's (and governments') hearts jump for joy, for similar geological environments throughout the world are the sources of most of the oil produced today.

MOON

Moon Rocks Begin the Rounds

NASA has begun the distribution of 28·6 pounds of scrapings from the Ocean of Storms, and hard on its heels go the astronauts who did the digging on their obligatory exhausting itinerary of twenty countries in forty days. Other countries, the White House says archly, could well be added later. But the dissemination of the Apollo 12 lunar material to 139 scientists in the United States and 54 elsewhere will be less dignified than on the previous occasion, when Dr S. O. Agrell, of the University of Cambridge, made a much heralded arrival at the London offices of the Science Research Council with the British share in a canvas bag. This time most of the material will travel by registered mail, or by diplomatic courier, although some scientists will still be going to Houston to collect their samples personally.

NASA expects to get back 23·7 pounds of the Apollo 12 material—the rest will go in destructive experiments—and the analyses are to be presented at the January 1971 Lunar Science Conference at Houston.

The number of principal investigators involved shows an increase of 51 on the Apollo 11 list, when there was 18 pounds of material to share. One of the additions is Dr M. Vobecky, of the Nuclear Research Institute of the Czechoslovakian Academy of Sciences, who will be receiving a gram of fines and a gram of rock specimens for element abundance work by neutron activation. NASA is also to distribute more Apollo 11 samples to scientists in the United States and Japan for second generation experiments, and the bits of the Surveyor spacecraft have already been released to JPL and to the Hughes Aircraft Co.

The credo behind the examination of the Surveyor bits and pieces is to see how machinery might survive exposure to the lunar environment, but it seems clear from investigations at the Manned Spacecraft Center that damage to the Surveyor during the Apollo 12 touchdown far outweighed anything that happened previously. According to a report from NASA, the surfaces of the TV camera and of a length of tubing removed from the Surveyor show numerous recent shallow craters which seem to have come from the direction of the landing site of the lunar module 600 feet away. The fresh craters show up white against the brown colour of the painted camera, and it is clear that the particles originated from the dust cloud raised when the lunar module landed. So far nine craters which might be due to genuine meteoroid impacts have been identified on the pieces which were exposed on the Moon for 950 days.

SOVIET UNION

Another Academic Village

from our Soviet Correspondent

A SITE in Siberia has been chosen, a few miles from Novosibirsk, for yet another in the series of "Academic Villages". The latest site is to comprise the new Siberian Centre of Agricultural Science and its associated institutes and living accommodation.

The site has been carefully chosen in connexion with the proposed experimental work of the Centre, being on the bank of the Ob' and in an area of gentle relief. A further advantage of the site (following the Russian proverb "Don't look for a house, look for a neighbour") is the presence, a few miles across the river, of the Academic Village of the Siberian Branch of the Soviet Academy of Sciences. A close cooperation is envisaged between the two Villages, especially on problems of agricultural biology and chemistry.

The new Centre, which is being organized by the "V. I. Lenin" All-Union Academy of Agricultural Sciences, will comprise five research foundations. The Institute of Agricultural Economics and the Institute of Mechanization and Electrification of Agriculture are being organized on the basis of local branches of the All-Union Institutes. The existing Siberian Scientific Research Institute of Stock-breeding will be developed here into a full-scale research and development institute. New foundations will be the Institutes of Chemical Applications and Animal Foodstuffs.

The residential quarters of the Village will be provided with the usual cultural and recreational facilities including a landscape park. The designs for the Village have been produced by the same team of architects that worked on the Village of the Academy of Sciences, across the river.

FURTHER EDUCATION

Eighteen and Beyond

by our Education Correspondent

THE Association of Teachers in Technical Institutions, a body representing 27,000 teachers in further education, has fired the latest shot in the debate leading up to a new education act, which is almost certain to be the subject of a white paper later this year. In a policy document (*Education for the Future*, ATTI, 2*s*), the association calls for the school leaving age to be raised to eighteen, for industrial training to be removed from the control of the Department of Employment and Productivity and placed under a new Department of Education, Science and Training, and for a national council to plan and coordinate the whole of further and higher education.

The ATTI believes that when the school leaving age is raised to sixteen, pupils should be allowed to take "linked courses" at colleges of further education, while remaining firmly based in the schools. Such courses, the association argues, would help to give young people some idea of various jobs, and of the importance of further education when they enter employment. But the ATTI also believes that full-time education to the age of eighteen should become mandatory "as soon as is practicable". Education for this age-group should not be confined to one particular pattern, however: "the association considers that there is advantage in maintaining both sixth forms in schools and full-time education in colleges of further education alongside experiments in tertiary institutions".

Placing the responsibility for industrial training with the Department of Employment and Productivity, and not with the DES, has, in the opinion of the ATTI, created unnecessary confusion. Some courses of further education, the association claims, are designed to correspond to schemes of training rather than to the needs of the young person, with the result that education and training are becoming separated, and the student does not acquire the theoretical understanding of his training which would allow him to adapt to changes in technique. The ATTI argues that these problems could be alleviated if responsibility for training were vested in a new Department of Education, Science and Training.

As far as the binary system is concerned, the ATTI is very sceptical of proposals to bring all institutions of higher education under a unified administrative structure. Although it accepts the fact that "the present structure has an arbitrary division between the autonomous and the non-autonomous sectors of higher education which is hard to justify", the proposed alternative "would produce a far more arbitrary division between the parts of the further education system offering higher education and the remainder, and would be unworkable as well as unjustifiable". The ATTI argues that the best way to rationalize and standardize course structures would be to reduce the number of local authorities controlling higher and further education, and to set up a National Council for Further and Higher Education, composed of representatives of government, local government, staff, students, industry and commerce. This body should keep the needs of further and higher education under constant review, while similarly constituted regional councils would be responsible for approving plans of local authorities. Once approval is given, however, the ATTI suggests that local authorities should continue to administer their own institutions.

WORLD WILDLIFE FUND

Anonymous Bounty

THE British National Appeal of the World Wildlife Fund has suddenly become richer by £250,000 through an anonymous donation given to assist the appeal's target of £1 million in European Conservation Year. In making the donation, the donor paid tribute to the part Peter Scott has played in wildlife conservation throughout the world and asked for the donation to be used to establish a Peter Scott Wildlife Endowment Fund, but gave no stipulation as to how the money should be spent. The World Wildlife Fund does not only seek to protect wild animals from film stars with a yen for exotic furs, but also has many other worthy causes and successes to its credit both in Britain and internationally. Between January and May last year, for example, the British National Appeal provided £25,453 for international projects, which included the sum of £13,747 towards the cost of enlarging the Coto Donaña Nature Reserve through the purchase of the Guadiamar Marshes in southern Spain, £1,536 for a road building project for national parks in Botswana, and £7,125 to help with the establishment of the Hai-Bar Wildlife Reserve in Israel. Nearer home, the appeal is supporting research on the effects of oil pollution on sea birds and on ecological communities, and several nature reserves are benefiting. The fund has not yet found any other generous benefactors to match Mr X, but it has eleven more months to go before the deadline.

RESEARCH STATIONS

How to Help Industry

GOVERNMENT research stations should undertake more industrially sponsored projects, should concentrate on mission-oriented research, and should allow their staff more opportunities to transfer to industry. These proposals, which in effect call for extension of the government's stake in civil research and development, have been put forward by Mr John Lyons, deputy general secretary of the Institution of Professional Civil Servants, a body representing more than 80,000 scientists, engineers and associated specialists in government establishments (*The Role of Public R and D in Exploiting Technology*, available from the IPCS).

Mr Lyons argues that government research and development provides an important source of new ideas, and of long and medium term research which industry cannot provide for itself. In particular, the government sector can bring a wide range of disciplines and techniques to bear on particular projects, whether it be "back-up" research or research carried out directly under contract to industry. Mr Lyons criticizes the attitude of the Confederation of British Industry, which believes that government research establishments not engaged on defence or community work should be shut down as soon as possible. Such a policy, Mr Lyons argues, would cause a straightforward loss of the effective employment of qualified technological manpower.

To provide a better service to industry, Mr Lyons suggests that the policy management of government research stations should be shared with representatives of industry. This and other measures would remove the basis of the CBI's criticism that government research establishments have no feel for market economics. Mr Lyons says that it would be much more useful if the Confederation of British Industry, "instead of devoting its considerable energies solely to knocking the civil work done by the highly qualified scientists and technologists in the government stations, should bend its efforts together with the institution to securing their freedom to assist industry in the most helpful way".

Government policy, Mr Lyons says, is the chief obstacle to providing a useful service to industry. Arbitrary limits to staff imposed on the research establishments seriously inhibit their ability to do all the work that industry requires, and directors of the establishments should be given more freedom to determine how much work they can take on a repayment basis. Decisions about the nature, amount and time-scale of the payments for industrial research should also be left to the directors of research establishments.

Parliament in Britain

Concorde

The British and French governments have given the go-ahead for six production models of Concorde, and a further four will be authorized next summer. Materials have already been made available for the first seven to ten. Mr Wedgwood Benn, who made this announcement, also estimated in a written reply that about £500 million out of the total joint development estimate of £730 million will be spent by the end of 1970. In answer to an earlier question, Mr Neil Carmichael, Joint Parliamentary Secretary, Ministry of Technology, said that sixteen airlines have signed option agreements for seventy-four models of Concorde. These agreements do not specify delivery dates, and these will be a matter of negotiation between the manufacturers and the airlines when definite contracts are signed. (Oral and written answers, February 23, and written answers, February 19.)

Sea Bird Deaths

Mr Gerald Fowler, Minister of State, Department of Education and Science, said that the Natural Environment Research Council expects to publish a report in May on the deaths of sea birds in the North Irish Sea. The council has been carrying out bacteriological and virological tests on the dead birds, and has also been studying information about weather conditions, the availability of food, and traces of pollutants in seawater. (Written answers, February 19.)

Teacher Training

Students at present undergoing courses of initial or further training in colleges of education number 111,077, and existing plans provide for an increase in the number of places to 119,000 during the next three to four years. Mr Fowler, who gave these figures, also said that some colleges failed to fill all their places at the beginning of the current academic year. (Written answers, February 20.)

Gas Centrifuge Plant

Dr Ernest Davies, Joint Parliamentary Secretary, Ministry of Technology, said that, although no decision can yet be taken about the siting of a plant to manufacture gas centrifuges, it would be desirable for assembly of centrifuges to take place near the uranium enrichment plant at Capenhurst. No estimates of staff numbers or other details can be made for some time, he said. (Written answers, February 16.)

Beagle Aircraft Company

The government's handling of the Beagle Aircraft Company came under strong attack in the House of Lords. The Earl of Kinnoull, who asked whether the government is aware of the deep concern over the company's present position, charged the Minister of Technology with showing total disregard for ministerial responsibility during the whole affair, and the Earl of Bessborough called for an investigation into the situation. Lord Delacourt-Smith, Minister of State, Ministry of Technology, said that the government had become involved in Beagle Aircraft substantially as a rescue operation, and that, although there is deep regret and disappointment at the failure of the company, the government could not continue to finance it. Lord Delacourt-Smith also said that no concrete proposals for linking Beagle with an existing British aviation company were put to him. (Debate, Lords, February 19.)

Miscellaneous Intelligence

Two hundred scientists in the University of Cambridge who submitted to an intelligence test have revealed their corporate acumen to range from 110 points to 141, with a mean of only 126·5 (*Journal of Biosocial Science*, **2**, 1; 1970). Indeed, the 15 per cent of the savants who scored below 118 would have been expected (and some did) to fail the 11+ examination. The residents of other Academes should not be quick to scoff or assume that their groves are greener; the Cambridge graduates in the sample gained significantly better scores than the alumni of other alma maters. Nor is it clear whether the survey was designed to demonstrate the inadequate wit of scientists or of intelligence tests.

In a speech made to the Royal Society of Arts last week on the achievements of medicine, Sir Brian Windeyer, the vice-chancellor of London University, said that "in our increasingly permissive society [the pill] has taken away an important constraint and has contributed to a greater laxity in sexual morals and to greater promiscuity. The pill has played a part in the disturbing increase in venereal disease . . . particularly in the teenage groups". This week Sir Brian, who was formerly professor of radiotherapy at the Middlesex Hospital in London, declined to cite the evidence for his belief that the pill has helped to spread venereal disease, saying that he did not claim to be an expert on family planning.

An alarming trend is afoot in high energy physics, if the latest issue of *Physics Letters* is anything to go by. The account of an experiment performed at 50 MeV was signed by five authors, each of two papers on experiments at 5·7 GeV was compiled by seven authors, fifteen signatures were appended to an article describing experiments at 25 GeV, and two 60 GeV experiments conducted at the Serpukhov accelerator were described by thirty-nine and forty authors respectively. Extrapolation of this trend reveals that when the 200 GeV accelerator at Batavia, Illinois, comes on stream the editors of physics journals may expect communications signed by 130 to 140 authors at a time.

A portent unparalleled in the annals of biology has become the talk of Palermo. The Sicilian city is home to two million rats which have recently begun to dispatch the local cats by "tearing out their throats and nibbling at them". The rats of Palermo, which outnumber the humans by three to one, are thought to consume some 200,000 tons of foodstuffs a year, not counting the cats.

From the rats of Palermo to the dogs of Tokyo. The 100,000 stray canines that now roam the Japanese capital are being rounded up lest a rabies epidemic should start among them. Tokyo dogs have never had it so good since 1687 when the Shogun Tsunayoshi decreed that on pain of exile the citizens should not only protect dogs but address them honorifically as Mr or Mrs Dog (O Inu Sama) as the case might be. The city government resolved an intolerable situation by removing some 50,000 dogs to a specially built shelter in the suburbs where they were fed on rice and dried fish at the expense of the taxpayers.

NEW WORLD

Trendy Research Programmes Win Friends

Dr William D. McElroy, the new director of the National Science Foundation, has had an easy ride in the past ten days during his first application to Congress for funds. This is not just beginner's luck. Many people are anxious to see the National Science Foundation put firmly on its feet, but this year there is also the advantage of a trendy programme. Environment is the watchword, and there have been several occasions during the foundation's evidence to the Daddario subcommittee when Dr McElroy's own work with dinoflagellates in the ecosystem of Chesapeake Bay has been used to show that the foundation now has its heart in the right place.

To make assurance doubly sure, however, the proceedings before the subcommittee on science, research and development of the House of Representatives Committee on Science and Technology were begun by Dr Philip Handler, chairman of the board of trustees at the foundation, and, as president of the National Academy of Sciences, one of the foundation's most powerful champions.

This is only the second year in which the National Science Foundation has been dignified by authorization hearings. On the face of things, the prospects are brighter than for a long time. The United States budget for the coming financial year (which begins on July 1) includes $513 million for the National Science Foundation, an increase of $63 million, although much of this will be spent on projects abandoned by other agencies. Yet there have been several previous years in which the foundation has found riches running through its fingers at the last minute.

Mr Emilio Q. Daddario, the chairman of the subcommittee, has his own ambitions for the foundation, and its witnesses have done everything they could to jump through those hoops. First, the argument goes, "we have foremost in our mind the deteriorating environment". So people are inclined to put the blame on science and technology—the real trouble is a failure to anticipate their consequences. Mr Daddario, for one, will look to the National Science Foundation for making this kind of assessment, known by the name technology assessment, but will expect it in the process not to hinder the swift application of new techniques. But how can that be done without strong university research and teaching? This is why, Mr Daddario said, he for one is worried that in the new budget, agencies such as the Atomic Energy Commission, the National Aeronautics and Space Administration and the Departments of Defense and of Health, Education and Welfare have less to spend on research and development. This is a "shortsighted and dangerous policy", and even though many of those now short of funds will turn to the National Science Foundation, the foundation "has not thus far been given the resources".

When like-minded men listen to each other's speeches frequently, they are liable to say similar things, which is why, no doubt, Dr Handler's evidence to the subcommittee may have seemed an echo of the chairman's speech. Dr Handler has, however, a different gloss on the problem of the environment. "While it may be true that the environment is deteriorating, there is no quantitative evidence. And although Lake Erie may be in such a state that it will take 100 years to put it right, for the most part the environment is better now than several centuries ago . . . you can now drink the water in any American city without the risk of typhoid." "We're still ahead," even if increasing vigilance is needed to keep ahead.

Dr Handler was more concerned with young people. These are "troublous times", with scientists in a quandary and young people disturbed and insisting that science is not relevant. So is it not time that young people were reminded of tales like that of cytosine arabinoside—the potential means of treatment

Table 1. PAST AND FUTURE EXPENDITURE ON SCIENTIFIC RESEARCH (MILLIONS OF DOLLARS)

Support of scientific research:	1969 (actual)	1970 (est.)	1971 (est.)
Scientific research project support:			
Atmospheric sciences	8,205,695	8,100,000	9,800,000
Earth sciences	7,917,288	8,000,000	8,800,000
Oceanography	19,381,729	18,400,000	19,000,000
Biological sciences	38,307,362	40,400,000	42,000,000
Physics	30,346,738	27,700,000	31,400,000
Chemistry	17,848,276	18,000,000	19,300,000
Astronomy	6,816,879	6,000,000	6,600,000
Mathematics	12,696,597	12,900,000	13,500,000
Social sciences	15,238,808	15,900,000	17,300,000
Engineering	19,265,222	19,600,000	22,300,000
Subtotal	176,024,594	175,000,000	190,000,000
Specialized research facilities and equipment	7,215,817	6,000,000	6,200,000
National and special research programmes:			
International Biological Program (IBP)	1,215,800	4,000,000	7,000,000
Interdisciplinary research relevant to problems of our society	–0–	6,000,000	13,000,000
Global atmospheric research programme	536,490	1,500,000	2,000,000
Earthquake engineering	–0–	–0–	2,000,000
Weather modification	2,433,974	2,500,000	3,000,000
Subtotal for research	4,186,264	14,000,000	27,000,000
Total	187,426,675	195,000,000	223,200,000

for some forms of leukaemia which has emerged almost by accident from academic work on sponges and the organic chemistry of biogenesis ? It is not an acceptable solution to "retreat towards nature"—the truth lies in the other direction.

Dr Handler had a trade union point to make about the supposed surplus of PhDs in the past few years, based as he described it on "a few anecdotes about a few theoretical physicists". In the past three months the National Academy of Sciences has been able to trace the fate of 80 per cent of the PhDs graduating in 1968 and 1969. Of the earlier group, only 0·4 per cent are at work where their training is irrelevant and 0·7 per cent are unemployed. For those graduating in 1969, the corresponding figures are 0·7 per cent and 1·1 per cent. Allowing for the incidence of pregnancy, travel and the like, there is no "national tragedy", even if some PhDs may not now be doing what they "expected to at the beginning".

What Dr Handler does protest about is the way in which the mission oriented agencies are being frozen out of basic research. He said that the provision tagged on to the budget for the Department of Defense for the current fiscal year, which requires that it should spend money only on research that can be shown to be directly relevant to defence, may by implication apply to other agencies. To be sure, he said last week, the situation in the fifties when the military dominated research and development in universities was unhealthy, but he regrets the Mansfield amendment "only in the sense that it is absolute". For one thing, both universities and the military would profit if there were strong links between basic science and the Department of Defense. On the danger that the Mansfield amendment may affect policies of other agencies adversely, Dr Handler pointed out that the National Institutes of Health, which used to be an important source of funds for organic chemistry, will now hardly ever support a grant application with the name of a plant in the title, with the result that investigators in photosynthesis were under pressure.

Dr McElroy was anxious to emphasize that the National Science Foundation's new look is represented by activities which add to the existing programme and are not substitutes for it. Where the new programmes are concerned, the text is that "the American people are increasingly united in the sense of emergency under the three closely interrelated banners of environmental quality, social relevance and, most recently, technology assessment". For all purposes, Dr McElroy said, new research and interdisciplinary research are necessary. The foundation has decided to earmark a "modest though significant" part of its budget for activities such as hailstorm prevention, earthquake engineering and the mathematical modelling of environmental systems. One novel feature of this new work is that the foundation may have to take the initiative in seeking out new proposals. Dr McElroy emphasized that he would not expect the foundation to be able to see the pattern of its new activities clearly "within a single year", but that in approving proposals for socially relevant activities, the foundation would be guided by the potential benefits to other federal agencies and by the extent to which specific research projects would help universities to play a part in "finding solutions to local problems". So far as the foundation's familiar activities are concerned, it plans to devote more of its institutional support for science "in a direction that will strongly recognize the research needs in the social sciences". In the past few years the foundation has been spending roughly ten per cent of its budget on the general improvement of good university departments—centres of excellence as they were once known—and is asking for $55·5 million for the coming fiscal year. In practice, the foundation's interest in the support of science education is tailing off ($96·9 million in 1971 compared with $121·7 million in the coming fiscal year) and within this tighter budget plans to emphasize the development of science curricula among specialists, the support of research projects which are initiated and carried out by students and the development of curricula for people who are described as "highly trained technologists"—people "who can provide effective and much needed support, in industry as well as in the universities, to senior research and development personnel". The reduction in the foundation's education budget is, according to Dr McElroy, "due in large measure to the reduction of graduate traineeship support and for secondary school teacher institutes", and it is clear that the foundation is apprehensive of the consequences even though there will be no reduction of the scale of the foundation's support for graduate students in the academic year which begins next September.

Table 2. NSF SUPPORT FOR NATIONAL RESEARCH CENTRES

	1969 (actual)	1970 (est.)	1971 (est.)
Arecibo Observatory	$900,000	$1,400,000	$5,800,000
Cerro Tololo Inter-American Observatory	4,550,000	1,900,000	2,200,000
Kitt Peak National Observatory	5,699,510	6,465,000	7,220,000
National Radio Astronomy Observatory	7,278,214	5,855,000	6,460,000
National Centre for Atmospheric Research	11,036,737	11,705,000	15,530,000
Subtotal, obligations	$28,564,461	$27,325,000	$37,210,000

Table 3. RESEARCH SUPPORT IN BIOLOGY

	1969 (actual)	1970 (est.)	1971 (est.)
Cellular biology	$8,684,237	$8,700,000	$9,200,000
Ecology and systematic biology	6,887,157	7,900,000	8,000,000
Molecular biology	9,665,621	9,800,000	10,100,000
Physiological processes	9,295,115	9,800,000	10,100,000
Psychobiology	3,775,232	4,200,000	4,600,000
	$38,307,362	$40,400,000	$42,000,000

The emergence of the "technologist" seemed to take the subcommittee a little by surprise. Dr McElroy said that it would not be the foundation's intention to substitute technologists for PhDs and that, so far as the output from the graduate schools was concerned, "we're all right up to the 1980s", even though it might be necessary to produce more ecologists and oceanographers, for example. Dr Handler, however, has a slightly different gloss on the new development—"it is agreed that for some positions, the PhD is overtrained", and that less exacting educational courses might be more appropriate for many kinds of jobs. This exchange seemed only to deepen Mr Daddario's suspicions of the Bureau of the Budget, which, he said, has decided that the output of PhDs is excessive.

The response of the National Science Foundation to the research programmes being discarded by other agencies has been a recurrent theme in the past week. For one thing, it is clear that nobody yet knows how many university research projects will be looking for new sponsors in the coming fiscal year—that will only be clear after the mission oriented agencies have emerged from this year's congressional mill, by the end of March at the earliest. Even so, the foundation seems to have compiled what Dr Edward P. Todd, deputy associate director for research at the foundation, called a "pressure list" of projects in other agencies likely to be affected. He reckoned that the annual cost of these projects lies between $30 million and $35 million. In practice, the National Science Foundation's budget includes nearly $10 million for the support of projects like these which may have to be transferred from other agencies, which means that, come what may, the foundation will have very little extra elbow room for increasing its support for new research projects. The greatest confusion, however, seems to attend the problem of how best to handle the impending fall-out from the mission oriented agencies.

The National Science Foundation, in the person of Dr McElroy, promised last week that steps would be taken to make sure that younger investigators continued to receive a fair share of the funds available. He did not rise successfully to Mr Daddario's suggestion that there should be a formal mechanism for effecting transfer from one agency to another, although everybody seemed to agree that the Office of Science and Technology is inadequately equipped to do this job. Dr McElroy seems to be satisfied that "the President does not want funds to be cut from the academic community any more than they are at present". The current preoccupation with relevance and the environment seems likely to benefit a great many people.

Dr Todd explained, for example, that the National Science Foundation has decided to put $2 million into earthquake research, partly in the belief that a sufficiently farsighted programme which took account of engineering construction might help to diminish the cost of future earthquake disasters—the Alaskan earthquake in 1964 is reckoned to have cost $60 million in Anchorage alone. One part of the new programme consists of an earthquake simulator—a 20 foot square platform which can be moved in such a way as to simulate seismic movement—which is being built at the Richmond laboratories of the University of California, Berkeley. The hope is that it will somehow be possible to improve on the design of buildings now in use in the United States; 200,000 of them are thought to be potentially hazardous.

The concern for relevance has also justified the foundation's decision to take over from the Office of Naval Research financial support for the 500 foot superconducting electron linear accelerator at Stanford University. Dr Todd argued last week that apart from its fundamental interest, the pi-mesons which the accelerator could produce could "revolutionize" medical radiation therapy, while superconducting niobium cavities have potentially important applications in high intensity radar and the confinement of high temperature plasmas, and that the technology in general could stimulate new techniques for power generation and transmission.

The most startled Cinderella to benefit from the preoccupation with the environment must, however, be the US National Committee for the International Biological Program. The new budget includes $7 million for this purpose, more than twice what the foundation was able to spend on these activities in the current year. Even so, it seems likely that Dr W. Frank Blair, the chairman of the US National Committee, will still have to go around with his begging bowl. In the current year, he has been able to raise only $5 million towards the programme which could have cost $15·2 million. For the coming fiscal year, he and his colleagues are hoping to get their hands on $15·9 million, more than twice what the National Science Foundation will be able to spare, and in the present climate of short commons for most agencies, he is unlikely to be greatly fortified by the general expression of goodwill towards the International Biological Program (IBP) now passed by both the Senate and the House of Representatives.

Dr Blair said last week that although the IBP is not "in the environmental management business", he is hoping that it will provide "baseline data" for this purpose. He is hopeful that the request for a two year extension of the IBP will be agreed to later in the year by ICSU. The discovery of oil in Alaska has apparently given impetus to IBP's work in the Arctic tundra, but everybody, including the subcommittee, seems downcast that there has been very little support so far for the study of the Amazon forest—diplomacy and indifference in Latin America seem to be the causes. In general, Dr Blair last week was optimistic about what IBP might be able to accomplish—he agreed with one suggestion that "the decimal point might be moved over a notch".

The spearhead, if that is the word, of the National Science Foundation's march towards relevance is, however, the programme known by the name of "Interdisciplinary Research Relevant to Problems of Our Society". Dr Joel Snow, the acting head of the Office of Interdisciplinary Research, explained last week that "our society seems to be in very serious trouble", and that it was necessary to find ways of repairing the quality of the environment and making better use of human and economic resources without retreating to the eighteenth century. The National Science Foundation, he said, is the only one among the federal agencies with a charter broad enough to support fundamental research "on the whole environmental system". So far, he said, his programme has attracted enquiries from more than 300 university groups and the projects now being considered carefully include a plan by engineers and social scientists at a New England university to "distil from their previous experience the essential ingredients for successful attacks on environmental problems", a scheme to study the contamination of the environment by heavy metals and another to apply techniques of nuclear science to criminology.

Another cloud on the foundation's horizon is to be seen in the exchange between the sub-committee and Dr McElroy about the abandonment of the traineeship programme for graduate students. Although the foundation's sails may not be trimmed in the academic year beginning in September, Mr Daddario takes the view that decisions like this cast their shadow before them, spoiling plans and damaging morale. Is there not also a danger that stopping traineeships will further concentrate scientific research in a handful of universities? Dr McElroy took the line, on Tuesday this week, that many research investigators would respond by re-writing research applications so as to put more research assistants on the NSF payroll, while state universities would be able to obtain extra money for teaching posts. Even so, he thought, graduate enrolment at private universities might well be reduced by a half when the foundation's cutback came into effect.

According to Dr McElroy, the decision to reduce federal support for graduate students has been taken by the administration as a whole but the President's science adviser, Dr L. DuBridge, has agreed to "go along with it for a year" on the understanding that they may apply for the cut to be restored next year. At the same time, Dr McElroy said, both the foundation and the National Science Board considered that there is now a "good steady state" in PhD production and, in particular, no need to increase the rate of output. Whether this view will be accepted by the sub-committee remains to be seen—some members of the sub-committee are plainly bent on considering whether to add to the foundation's budget some part of the $9·5 million which will have been saved by cancelling graduate traineeships.

NAS

Environment and People

THE National Academy of Sciences, through its involvement with the International Biological Program, and the Public Affairs Council, which likes to think of itself as the conscience of American industry, put their heads together last week on the problems of the environment. The outcome of the proceedings seems to have been a recognition that there are serious but interesting problems to be tackled. The theme for the conference was provided by Mr Robert Finch, Secretary for Health, Education and Welfare, and the man widely credited with having made California conscious of the dangers of the automobile. He emphasized that for a better environment people should be "prepared to pay pollution taxes—put up with less powerful automobiles, for example", that international standards would at some stage be necessary and that the best guarantee for the environment would be to make sure that married couples had only two children.

GENERAL BIOLOGY

Salk Institute goes Public

THE implications of recent discoveries in biology are to be followed closely by an international organization called the Council for Biology in Human Affairs, set up last week by the Salk Institute. The intention is to carry out a series of specific studies of the public impact of the new biology. The programme, for which $400,000 a year is already available for each of the next five years, will be the responsibility of six separate commissions under the general coordination of Dr Jacob Bronowski, a resident fellow at the Salk Institute at La Jolla, California.

The new council differs from previous organizations formed to educate the general public in the implications of modern biology first by being provided with money and second by the distinction of the people who have so far agreed to serve on the council and to be chairmen of the commissions which will be responsible for the first group of studies. Dr Jacob Bronowski explained last week that the chairman of the commission on "biology and international affairs" will be Professor Paul Doty of Harvard University and that its first study will probably be an examination of the possible implications of intra-uterine genetic diagnosis.

The intention is that commission chairmen shall remain in office for a limited period and that each of the six commissions should include a lawyer and an educator among its members. A second commission on "biology, ethics and the law", under Professor Abram Chayes of Harvard University, will to begin with be concerned with the ways in which new pharmaceutical products are brought into service.

The remaining commissions are one on "biology, learning and behaviour" (Professor Eugene Galanter of Columbia University); "biology in contemporary culture" (Dr Bronowski); "ecology, environment and population" (Professor Cyrus Levinthal of Columbia University); and "biology, medicine and health care" (chairman not yet chosen).

The members of the council include Dr Daniel Bell (Harvard), Dr Robert W. Holley (Salk Institute), Mr Kiichiro Kitaura (Nomura Securities Company, Tokyo), Dr Antonie T. Knoppers (Merck and Company), Dr Daniel Lehrman (Rutgers), Dr Salvador E. Luria (MIT), Sir Peter Medawar (National Institute for Medical Research, London), Dr Robert K. Merton (Columbia), Professor Jacques Monod (Institut Pasteur, Paris), Dr Herbert Passin (Columbia), Professor David Pines (Illinois), Mr Oscard Ruebhausen (Russell Sage Foundation), Dr Jonas Salk (Salk), Mr Joseph E. Slater (Salk), Dr James D. Watson (Harvard) and Dr O. Meredith Wilson (Stanford).

By all accounts, the formation of the council is the outcome of the preoccupation of Mr Joseph Slater, the president of the Salk Institute, since he took over that job two years ago, with the implications of the contemporary research in biology. He says that he would like the council to be able to respond to the "problems that emerge from the biological revolution" more perceptively than was possible twenty years ago with the growth of nuclear power. Dr Bronowski says that the council will try to "form public opinion by informing it".

RESEARCH FINANCE

New Plea for More Money

A SOMBRE warning of the dangers of skimping on university research has been delivered by the National Science Board at what may be a telling moment—the point when the criterion of relevance seems to be all important. The warning appears in the second annual report of the National Science Board, which is now required by law to make regular assessments of the condition of various parts of science. In his introduction, Dr Philip Handler, the chairman of the National Science Board, says that the apparent remoteness of astronomy, physics and chemistry from the problems of environment, urban decay and foreign affairs should not tempt the United States to "surrender its leading position" in scientific research. He says that there is a danger that in the anxiety to use scientific resources to deal with social problems, the pace and scope of scientific research may be so reduced that it fails to provide "a platform for tomorrow's applied science". The board's report has been passed on to Congress by the President in what seems to be an ostentatiously nonchalant way, which is taken by Dr Handler to suggest that the physical sciences are not at present "at the center of the Administration's interest".

The report asks for a number of specific improvements of the present arrangements for support of university research. It asks that the federal government should increase its support for graduate education to the point at which universities can make forward commitments. It wants enough money for research in the physical sciences so that the threat of mediocrity can be avoided. It asks that "a substantial fraction of the necessary increase" should be channelled through the National Science Foundation, but that all agencies should keep an interest in the relevant physical research. The National Science Board is particularly anxious about the provision of new instruments for physical research, and draws attention to the plight of radio astronomers where, it says, $200 million should be spent in the next ten years.

In other fields, there is need for more national centres where expensive research facilities could be shared, but the cost of these could sometimes be offset by closing down central facilities no longer needed. The board is keen that the United States should collaborate with other countries wherever possible, that the National Science Foundation should be given funds to take over worthwhile research programmes which other agencies can no longer support and that "the present trend to decrease funding for the scientific aspects of the space program should be reversed". One anxiety here is that the fullest benefit will not be obtained from the space programme for lack of suitable supporting research in optical and radio astronomy, but the science board also asks for an urgent strengthening of the scientific plans for future visits to the Moon.

TELECOMMUNICATIONS

Intelsat's Woes

from a Special Correspondent

UNCOMFORTABLE is perhaps the best word to describe the conference on communications satellites now in progress in Washington. All of the 73 members of Intelsat are a bit embarrassed at their failure to agree on a permanent structure for their international satellite consortium. They do not want to go home without an agreement; an Australian delegate expressed a wish not to spend many more Australian summers wintering in Washington. But the fact is that a successful resolution to the conference, which began a year ago and has been chugging along, through working parties in the interim, is not in sight. There are two opposing camps —one led by the United States, and including Chile, Australia, Italy and numerous but uninfluential allies; and another, including Britain, most of Europe and Mexico. Each side is urging the other to compromise; each has less desire than ever to do so.

What divides them is the issue of the managership of Intelsat by Comsat, the American satellite corporation. The United States and cohorts want Comsat to continue as manager; failing that, they would like a long study of the problem of managing such an international corporation to be made by outside experts, during which time Comsat would continue as manager. Britain, Germany, Switzerland and others want Comsat kicked out—as formal manager. Instead they want an international team headed by a secretary general. (Mr James Gill, recently retired director of external telecommunications for the British Post Office, has been rumoured to be dreaming of this job.) Then it could buy from Comsat advice on what kinds of satellites and ground stations to buy, but it could make up its own mind. Under the present arrangements, which have prevailed since 1964, Comsat, as manager, has simply told members of the international steering committee, representing the biggest users of the satellite system, what was good for them. The foreigners had no way of questioning Comsat's advice even when they suspected that what was good for Comsat was not necessarily good for Intelsat. This came up particularly with the choice of design of the big Intelsat 4 satellite due to be launched next year. The Intelsat members from abroad suspected that Comsat was recommending a design that would be suitable for the American domestic satellite system that Comsat has been begging the Federal Communications Commission to build for several years.

The question of the American domestic system hangs heavy over the proceedings at the State Department. President Nixon's policy, just presented to the FCC, elbows Comsat to one side and opens the American skies to all comers; if the American Telephone and Telegraph Company and the big television networks want to put up their own satellites, Comsat would have no customers even if it got its domestic satellites into orbit—a nasty position, and one which the members of Intelsat appreciate for its awfulness. "I sometimes feel," said one delegate, "that seventy-three nations are here trying to deal with a domestic American problem." Needless to say, while haggling over the future of an American private company, the Intelsat people have little time to consider how their organization might be shaped so as to leave room for special services, like air navigation and meteorology, which their satellites might sell some day to all comers, whatever nationality.

It is possible, however, that some form of words may be found to shelve the managership issue and to allow delegates to agree on the very beginnings of an agreement before going home in a few weeks' time. There has been general admiration, even awe, for the report of the preparatory committee under Mr John Killick of the British Foreign Office. It has summarized all the opposing views so succinctly that extracts from it could be lifted bodily and put into a permanent agreement, once the conference decides which of the views to accept. The Foreign Office, like the State Department and other diplomats present, quite apart from telecommunications representatives, believe the Intelsat agreement to be important as a model for other international commercial agreements that may have to be reached in the future—on nuclear energy or exploitation of the seabed floor, for example. And that is why there is genuine anguish all round that the Intelsat treaty is proving so hard to draft. If this one fails, it will be a bad omen for future attempts.

So much for internationalism. The American view, as it is felt in Congress and in Comsat, if not in the State Department, is bitter. The United States, they believe, did not need to invite a lot of outsiders to participate in its satellite consortium. Having developed the technology through its space programme, the United States could have found a way simply to sell it. "'We gave it to them and now they're trying to take it away from us," is the complaint. "Why should we give it to them ? What did they ever contribute to it ?" These are questions which the British–European and other Comsat opponents believe put the problem in a nutshell. Now is the time to make sure that there is not over-dependence on American technology for decades to come. Some of them are even willing to come back to another conference to do so.

SPACE RESEARCH

Scientific Work for Space Stations

The scientific objectives of the piloted rockets on which the National Aeronautics and Space Administration is now working have been defined during the examination of the administration's scientific programme in the past week. After five more journeys to the Moon, the first so-called Saturn Workshop will be launched in the second half of 1972. The hardware for this device has already been tested on the ground and will be equipped with instruments and electronics in the next eighteen months or so. The first of the orbiting workshops, itself a part of the Apollo applications programme, will be used for the best part of a year by successive groups of men. Beyond that, however, the National Aeronautics and Space Administration is planning a more ambitious space station which will be supplied as necessary by means of the space shuttle rocket on which work is now beginning (see *Nature*, **225**, 685; 1970)—the best part of $110 million in the new budget will go on the design of the engine.

In his statement to the Committee on Science and Astronautics, House of Representatives, a week ago, Dr Dale D. Myers explained that it is now intended to launch the first Saturn Workshop as a completely equipped device using a Saturn V rocket, which will simply put the device into an orbit about the Earth 235 nautical miles up and at an inclination of 50° to the equator. The crew of three will be launched by means of a Saturn IB rocket one day later, and they will spend a month on largely astronomical work. It is also intended that a second crew will be launched after three months and will stay for two months and will in turn be replaced by a third crew.

The centrepiece of the first workshop will be a solar telescope consisting of five separate experiments for solar studies. The system can be pointed with an accuracy of 2·5 seconds of arc at any point on the surface of the Sun which is not too near the limb. The intention is that the signals received by the telescope will be monitored by the crew, although there is also an arrangement for sending a television signal to the ground. Data from the telescope experiments will be recorded photographically and eventually returned to the Earth.

The telescope instruments include two X-ray telescopes, one designed by the American Science and Engineering Company and the other by the Goddard Space Flight Center. The former is intended to have high geometrical and spectral resolution, while the second will provide a record of the X-ray emission over the entire disk and the near corona between 0·3 and 10 nm. The Naval Research Laboratory is providing a spectroheliograph operating between 15 and 65 nm and a spectrograph with high geometrical resolution operating between 90 and 390 nm. A complementary experiment (between 30 and 130 nm) has been designed by Harvard College Observatory—by making photoelectric scans of small parts of the disk, this spectrometer should provide precise information of the intensity of solar emission. The corona out to six solar radii will be recorded in white light by a coronagraph supplied by the High Altitude Observatory in Boulder, Colorado. One intriguing feature of the equipment is that the Sun's disk will be monitored by means of a display of the Sun obtained by recording extreme ultraviolet light and H alpha light in appropriate telescopes. Prototypes of this equipment have been carried on a variety of rockets in the past few months, so that final versions of the systems can be incorporated into the telescope used by midsummer.

The Saturn Workshop will also carry a great variety of scientific and technological experiments. For example, there will be a nuclear emulsion pack for recording cosmic rays, a Schmidt camera with calcium fluoride optics for obtaining stellar spectra in the ultraviolet, advice for photography of the Sun in the ultraviolet and a camera with a fused silica window for photographing the air glow in the ultraviolet. Similarly, the Saturn Workshop will be able to make photographs of the zodiacal light, while the enthusiasts for Earth resources satellites will be given a series of photographs of a number of ground locations taken through six synchronized shutters at different wavelengths. Micrometeorites will also be collected, while a number of cell cultures of human tissues will be carried and observed in flight in an attempt to determine the effects of weightlessness. Finally, there will be some experiments to determine the effect of space flight on circadian rhythm of *Drosophila*, mice and potato respiration.

NEWS AND VIEWS

Protein-lover's Baedeker

THREE articles in this issue of *Nature* (pages 802, 806 and 811) offer a brisk canter through the elastase molecule. The work, from the Cambridge Molecular Biology Laboratory, places this enzyme into the three-star category in the protein chemist's canon, as one of the still small number whose sequence and conformation have been fully determined, and the active site delineated in detail. It also marks the emergence of protein crystallography out of the primitive and into the classical phase of development. The sense of blood, sweat and broken research students which pervaded so many of the earlier effusions in the field is replaced by one of sureness of aim and mastery of technique. To most middle-aged research workers it will come no doubt as an infinitely demoralizing revelation that the determination of the sequence and of the three dimensional structure to 3·5 Å should form the substance of the PhD thesis of one of the authors.

To go so smoothly, the structure determination, and especially the chemistry which has to precede it, still of course requires a certain measure of luck. If, as is alleged, fortune favours the prepared mind, then the minds of the Cambridge group were immaculately prepared. It is clear that elastase was designed with the crystallographer in mind, even more perhaps than the pig (whose particular advantage in possessing the enzyme is uncertain): crystals 1–2 mm long, containing one molecule per asymmetric unit, grew overnight. They were well ordered, and gave reflexions to 2 Å, which is close to the theoretical limit. They were unusually stable in the X-ray beam, allowing a complete set of data to 3·5 Å to be collected from one crystal, and finally the inhibited (tosyl) and mercurial-modified molecules were wholly isomorphous, with a superbly clear electron density difference map.

Elastase is one of the serine proteases, and therefore related to the other pancreatic enzymes, chymotrypsin *A* and *B* and trypsin. The sequence, which is given in the first paper (Shotton and Hartley, page 802), shows extensive homologies with those of the related species, with some 40 per cent of corresponding positions filled by identical amino-acids. It is now an established rule that substitutions are much more likely in positions on the outside of the molecule, in contact with the solvent, than in the interior, where the close packing of the side chains restricts drastically the changes that can be accommodated by the conformation. Since the structure is known, it is possible to distinguish between external and internal residues in the chain, and it turns out indeed that in 71 per cent of the internal positions strict homology is preserved, and what substitutions do occur are highly conservative. Only 4 per cent of these positions show no homologies within the group of four enzymes. Practically all the charged residues are on the outside. The sequences bear out the supposition that all the pancreatic proteases evolved from a common precursor.

The structure determination, and comparison of the result with chymotrypsin, settle the issue of whether a pair of proteins with broadly homologous sequences should possess similar conformations. With the aid of sequence it was possible (Watson *et al.*, page 806) to follow the course of the chain, identifying successive residues, and to make out the disulphide bridges and the tosyl group in the inhibitor attached to the active centre. The chain conformation of elastase turns out to be almost identical with that of α-chymotrypsin (page 811), and Shotton and Watson predict that trypsin will also fit into the same mould.

Finally, a comparison of the active site geometries explains the relatively low specificity of the enzyme. In chymotrypsin, the peptide carbonyl group of the substrate abuts on the active site Ser-195 residues, and the aromatic side chain, which characterizes the specificity of the enzyme, hangs into a deep cleft, with another serine at the bottom. The cleft is present in elastase, but almost entirely occluded by a valine across the entrance. It is for this reason that elastase attacks at uncharged aliphatic residues, and an alanine peptide, its favoured food, will fit nicely on the active site, the methyl group in contact with the valine at the top of the cleft. Some reasonable speculations about the catalytic mechanism can be made. The crystals of elastase have enzyme activity, and it is interesting to note that in contrast with chymotrypsin the active centres front on to large lattice interstices, some 18 Å across. Shotton and Watson envisage the possibility of introducing various species of molecule into this space, and then using difference maps to determine the structure of the guest.

DOCUMENTATION

More Nuclear Information

from a Correspondent

IT was inevitable that the International Atomic Energy Agency's first symposium on the handling of nuclear information held in Vienna on February 16 to 20 should have included a full discussion of the International Nuclear Information System concept (INIS), although only a few speakers dealt directly with the topic. INIS is hardly a new idea (*Nature*, **213**, 4; 1967), but clearly progress is being made, as reported by Dr J. E. Woolston and others (International Atomic Energy Agency, Vienna), and indeed the system is expected to produce its first output to users next May. In outline, INIS will receive its input from cooperating countries, and from this will produce, by computerized techniques, a publication called *INIS Atomindex* supplemented by various other services. There should be no shortage of input—the system is supported by more than twenty countries which between them will provide coverage of more than 80 per cent of the sources of publications.

No doubt problems will arise in the setting up and day to day operation of what will be the world's largest computer-based documentation service relying on input prepared on an internationally decentralized basis. Much of the information to be included in *INIS Atomindex* is currently contained in *Nuclear Science Abstracts*. But it would perhaps be wrong to look at INIS from a narrow point of view—there is, after all, a wider community of scientists equally concerned about information problems and interested to know whether an international approach might effectively supplement the excellent endeavours made by the core abstracting journals. Indeed, Dr S. Adams (National Academy of Sciences) dealt with UNISIST, the feasibility study for a programme of increased voluntary cooperative networking of existing and future information services—in effect, a world scientific information system. If international cooperation can succeed in one scientific area this could be a happy augury for other areas potentially able to benefit from an international approach.

The symposium also gave nuclear librarians and documentalists a welcome opportunity to discuss the problems of handling the voluminous nuclear literature. Mr A. Mauperon (European Communities, Luxembourg) gave some idea of the size of the nuclear literature when he said that each year *Nuclear Science Abstracts* covers 40,000 journal articles, 10,000 reports from laboratories, institutes and so on, and 4,300 books, theses and patents.

SUPERCONDUCTIVITY

Promise in Thin Films

by our Solid State Physics Correspondent

HOPES that "high" temperature supercurrents may be induced in thin films have received a boost from a calculation of the effects of lattice orientation on the superconducting transition temperature. R. E. Allen and F. W. de Wette (*Phys. Rev.*, **187**, 883; 1969) have worked out the phonon frequencies for an ultrathin crystal specimen and have shown that the diminution from the values for the bulk material must cause an increase in the superconducting transition temperature. They also found that for aluminium the orientation of the film has a pronounced effect on T_c, which varies by a factor of three between films oriented with the (111) and (110) axes perpendicular to the boundary.

The incentive for this calculation sprang from the measurements of Strongin *et al.* in 1968, who observed a considerable increase in T_c when thin layers of two different metals were fabricated into a sandwich structure. The change in T_c was attributed to a drop in the phonon frequencies compared with the bulk material, although no direct measurement of the frequencies was made. Allen and de Wette decided to calculate the frequency distributions for oriented face-centred cubic films from a simple Lennard-Jones power law potential.

For thin films, of course, the static displacement of atoms cannot be assumed to vanish. Minimizing the static energy, therefore, they found that the vibration spectrum includes a low frequency surface mode which greatly reduces the mean frequency of the crystal. The transition temperature, which depends on the electron–phonon coupling constant and the mean square frequency, was then found to increase by up to twenty-two times for correctly oriented aluminium, although Allen and de Wette point out that it would be hard to attain this for the imperfect free films that normally exist. In contrast, lead was found to be quite isotropic, with a transition temperature about 25 per cent greater than that of the bulk material.

In practice, it is, of course, extremely hard to manufacture films only a few atoms thick, let alone to obtain them as single crystals and to orient them. But vacuum deposition and sputtering techniques can be used to produce films thinner than 100 Å quite reliably, and the promise of surprises in the superconducting properties must add impetus to refining these techniques.

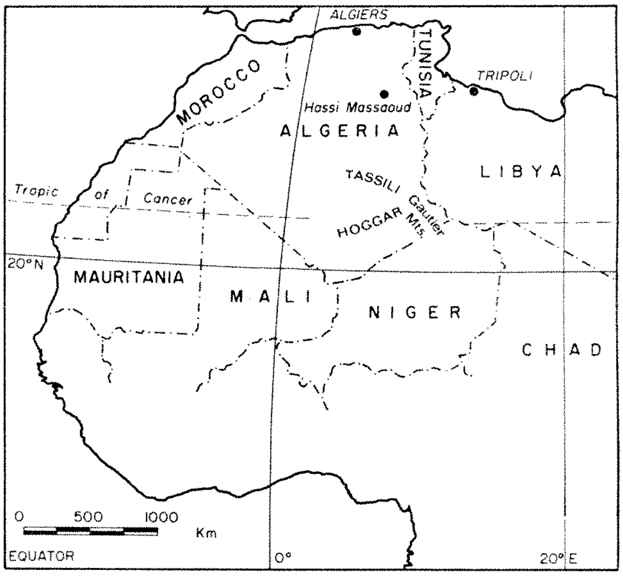
SEDIMENTOLOGY

Saharan Glaciation

from a Correspondent

THE hottest part of the Earth was once the coldest. Proof of this has come from Algerian and French geologists during the past decade, and between January 11 and 25 the Institut Algérien de Pétrole mounted an expedition to demonstrate the evidence on the spot. Sedimentological specialists of twelve nations participated, led by Dr A. Bennacef of Algeria and Drs P. Rognon and B. Biju-Duval of France. The critical area was in the Central Sahara astride the Tropic of Cancer, near the Niger and Libyan frontiers, where Lower Palaeozoic sediments lap on to the Hoggar pre-Cambrian massif. Two days of discussion in Algiers rounded off the operation, resulting in unanimous agreement that the case had been made.

From the Gautier Mountains to the Tassili Interne, Upper Ordovician glacials (450 million years old) were plainly displayed in a region of tectonic simplicity. The party saw glaciated valleys, sediments grooved by glaciers and icefloes, tillites, iceberg-borne erratics, eskers, and so on. The glacial valleys, opening northwards to the Ordovician sea, may have formed true



North-west Africa, showing the area visited by the members of the expedition.

fjords, but this was uncertain. Their depths reached 300 m, suggesting to some the biggest ever drop in sea level (and therefore the biggest polar ice-caps) of the Earth's history. Enough evidence was at hand to start serious thinking about the isostatic behaviour of the African Ordovician crust.

At times the area north of the Hoggar became a subaerial meltwater plain strewn with glacial debris. It was at least 1,000 km wide because some of the evidence has been observed in the Hassi Messaoud oilfield. Soil polygons, possibly permafrost-motivated sand-volcanoes, endglacial channels terminating in gravelly fans, kettleholes, pingos and so on are exposed in three dimensions. Because of the greater depth of erosion, glaciological knowledge of features based on Quaternary information may be enhanced and entirely new phenomena revealed.

Since the deposits pass laterally and vertically into marine strata, the glaciation must have been at sea level. It was therefore not due to high altitude, but to high latitude. Fossil faunas had previously suggested that the Ordovician seas cooled southwards across Europe into North Africa (Spjeldnaes, 1961, 1967). Palaeomagnetic evidence indeed placed the Ordovician south pole in the general region of NW Africa, from which it has since "wandered" to its present site. (The Ordovician north pole was in the Pacific.) Now we know with certainty that the Hoggar was part of Ordovician "Antarctica". But today the glacial sediments swelter in summer temperatures that must sometimes exceed the record 137° F at Hassi Messaoud.

Proof that the icecap extended westwards into Mauretania and eastwards into Chad is at hand. Some of the Algerian evidence has already been published locally (*Rév. Inst. fr. Pétrol.*, **21**, 363; 1966; *Pub. Serv. Algérie*, Bull. **38**, 39, 53; 1968). Earth scientists eagerly await a full account in a major international journal.

GEOLOGY

Core and Mantle

from our Geomagnetism Correspondent

THE theme of geophysical discussion at the Royal Astronomical Society on February 20 was the nature and behaviour of the Earth's core–mantle interface, and it became very clear that this boundary deserves more attention than it has received so far. Many important processes occur in both the core (for example, the production of the geomagnetic field) and the mantle (global tectonic processes, convection currents and so on)—and any interactions which may occur across the boundary between them are likely to have a significant effect on each part.

The meeting was opened by Dr R. Hide (Meteorological Office), who reviewed some of the problems which a more detailed study of the core–mantle interface might solve. Chief among these is undoubtedly the secular variations in the length of the day, or the Earth's period of rotation on its axis. The basic cause of these variations is thought to be horizontal stresses at the core–mantle boundary which prevent the core and mantle moving completely independently of one another. But how are these stresses produced? Because viscous stresses couple the core and mantle only weakly, it has been suggested that the electric currents responsible for the geomagnetic field leak into the lower mantle thereby causing so-called electromagnetic coupling. But the torques produced on the mantle by fluctuations in the electric currents would only give changes of about 1 ms per decade in the length of the day, whereas changes of several milliseconds in only a few years have been observed. In short, the stresses set up by electromagnetic coupling are ten times too small to explain the known variations in the length of the day.

Another stronger form of coupling is thus required—and Hide suggests that it arises from topographic irregularities, or "bumps", on the core's surface. Calculations show that bumps a few kilometres high would be sufficient to produce stresses a hundred times greater than those from electromagnetic coupling, and thus ten times greater than required to explain length of day variations. Thus there is ample margin for error.

If core surface undulations exist, they are likely to have some effect on the geomagnetic field originating in the core, almost certainly making it more complex than a field produced in a perfectly spherical core. As Hide pointed out, some of the complexities are already familiar, but have been "swept under the rug" pending adequate explanation. What, for example, is the true cause of the non-dipole field low in the Pacific? And why does the reversal frequency of the Earth's field vary so markedly over geological time? Unfortunately the answers to these questions are not yet forthcoming; but they almost certainly depend on perturbations at the core–mantle boundary.

Meanwhile, evidence for the complexity of the dipole field itself is accumulating. According to Dr J. C. Briden (University of Leeds), palaeomagnetists have so far tended to take the pessimistic view that deviations from a geocentric axial dipole in the past are undetectable because their effects are smaller than the uncertainties inherent in palaeomagnetic data. Even so, some progress is being made in pinning down the precise characteristics of the ancient dipole field. Briden reviewed the dipole models suggested so far—spherical harmonics (Gauss), non-central radial dipoles (Alldredge), northward displaced axial dipole (Wilson) and off-centre dipole (Creer)—and added one of his own. An analysis of the geomagnetic field before Wegenerian drift suggests that the dipole was displaced southward.

Hide and Malin (*Nature*, **225**, 605; 1970) have already demonstrated a correlation between the Earth's gravity and non-dipole magnetic fields with a displacement of about 160° between the two. They interpreted this as evidence for the existence of core surface bumps. But could such bumps be observed more directly—seismologically, for example? There is little doubt that undulations a few kilometres in amplitude are undetectable by seismological methods in current use. But Mr D. R. Jones (Atomic Weapons Research Establishment, Aldermaston, and University of Liverpool) has developed a method based on a comparison of P and PcP waves from nuclear explosions, which he claims is theoretically capable of detecting core surface bumps down to an amplitude of about 4 km. So far progress has been limited to the development of the technique; but Jones is now applying it to the thousand or so nuclear explosions known to have occurred.

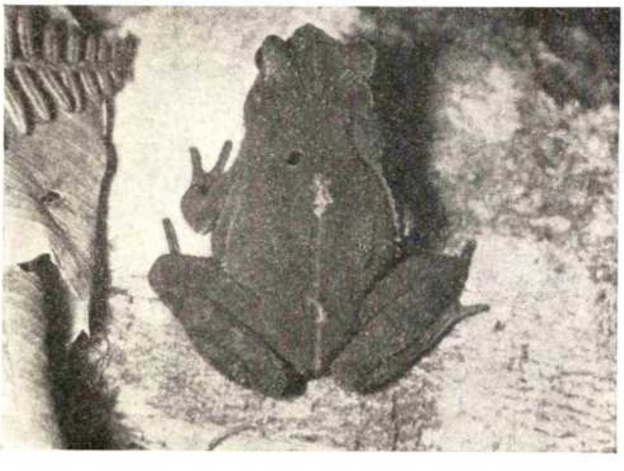
Finally, Dr P. G. Harris (University of Leeds) courageously confronted the audience of geophysicists with a discussion of the geochemistry of the core and mantle. The greatest difficulty, of course, is to determine how chemical properties are likely to be modified by the high pressures in the Earth. The composition of the core is thought to be simpler than that of the mantle; but there are still many unknowns, particularly the nature of the light element(s) which must be combined with the core iron to reduce the density of the core to its known value.

But details of composition apart, Harris's chief point was that there is likely to be chemical disequilibrium between the core and mantle. If the core is highly reduced and the mantle more oxidized, the system could act as a galvanic cell. In this case the potential across the core-mantle interface would be small, though what e.m.f. might be produced at such high pressures is not known. A second possibility is that the electric currents in the core might cause electrolysis and reduction in the mantle, and the growth of the core. Chemical interactions across the core-mantle boundary may or may not occur; but geophysicists cannot afford to dismiss the possibility lightly.

AMPHIBIA

Possible New Toad

SINCE October 1968 a South American toad has been baffling herpetologists in the British Museum (Natural History) and at the Rijksmuseum at Leiden. In August 1968 Brian Ridout, at that time a London zoo keeper, and Adrian Warren, a student of zoology, were collecting small animals along a tributary of the Echerak River, which flows into the Potaro River, a day's walk west of the Kaieteur Falls in Guyana. Mr Warren writes: At an altitude of 1,500 feet a toad jumped from the floor of the dense tropical rain forest; had it not moved it would never have been seen, so effective was its cryptic coloration among the leaves. It was an adult female 64 mm long, with upper surfaces a rich red brown with a lighter stripe down the back, on one side of which a dark light-edged spot stood out (see illustration). Its limbs were faintly barred with dark brown and the lower lip was white. Underneath it was mottled brown and white. This was nothing very remarkable at first glance, but closer inspection revealed some curious features which distinguished it from other South American toads with similar head crests. In August 1969 a similar toad was found in the same area, this time a youngster only 12 mm long.



Female toad found by Ridout and Warren in August 1968.

To the curators of herpetology at the British Museum and at Leiden these toads are unique. They are reluctant to dub them a new species and describe them in the scientific literature because the Echerak specimens have certain similarities to a rare eastern Andean species, *Bufo ceratophrys*, that is known only from males and from no farther east than Marahuaca in Venezuela. Significant differences between this species and the Guyanan toads are the spine on the eyelid, which is present in *B. ceratophrys* but not in the Guyanan form, and skin texture. These could be sexual differences, and until further collecting in Guyana yields the sexually mature male of this strange toad, and a comparison can be made with the males of *B. ceratophrys*, the problem of the identity of the Echerak toads must remain unresolved. Perhaps the answer will come from the area stretching from the interior of Surinam to the Gran Sabana in Venezuela where little herpetological collecting has been done.

TUMOUR VIROLOGY

Transformation and Transcription

from our Cell Biology Correspondent

IN permissive hosts polyoma and SV40 virus cause a lytic infection characterized by the release of many progeny viruses and ultimately death of the host cell. Non-permissive hosts, on the other hand, are transformed; the transformants have new antigenic and growth properties and are tumorigenic. Moreover, they contain one or more copies of the viral genome stably integrated into one or more chromosomes. What distinguishes permissive from non-permissive hosts? One fashionable explanation suggests that the non-permissive host lacks the biochemical environment necessary for the complete and ordered expression of the viral genome. For example, it might be imagined that the non-permissive host lacks a sigma factor necessary for the transcription of part of the virus genome.

At first sight, the observation that the expression of polyoma genes in transformed cells is only 40 per cent of that in cells supporting lytic growth corroborates this model. But polyoma virus has not been rescued from these transformed cells, and so maybe they only contain 40 per cent of the polyoma genome. SV40 virus, however, can be rescued from transformants by fusing them with permissive cells. The transformants must therefore contain a complete set of SV40 genes, and Martin and Axelrod (*Proc. US Nat. Acad. Sci.*, **64**, 1203; 1969) have shown recently that in some SV40 transformed cell lines all regions of the genome are transcribed. In other words, transformation of these cells does not seem to be a consequence of failure to transcribe part of the SV40 genome.

Using a specially devised saturation hybridization technique, they compared the extent of transcription of the SV40 genome in a permissive cell and five lines of mouse cells transformed with SV40. During lytic infection the entire genome is apparently transcribed whereas in the various transformed cell lines between 30 per cent and 100 per cent of the genome is transcribed. There is apparently no correlation between transformation and the gross extent of transcription of the SV40 genome. There is a correlation, however, between the extent of transcription and the extent of SV40 virus rescue on fusion with a permissive cell. SV40 virus is more readily rescued from transformants in which all the SV40 genome is transcribed, and the two transformed lines from which virus has never been rescued are the two lines in which SV40 transcription is lowest (30 to 40 per cent of the entire genome).

Of course, the saturation hybridization technique does not have the resolution necessary to prove that a few crucial RNA molecules are or are not made in the transformants. Nor does it reveal differences in the relative amounts of the various SV40 RNAs or the timing of their sequential appearance. Nevertheless, Martin and Axelrod's experiments seem to rule out the idea that the extent of SV40 transcription in permissive and non-permissive cells is necessarily very different. Perhaps therefore the difference between the permissive and non-permissive environment is at the translational rather than the transcriptional level.

Defective SV40 virions containing less than a complete genome appear spontaneously during passage of the virus. Uchida and his colleagues have shown that some of these defective viruses produce T antigen but not virus coat protein, and moreover the tumorigenicity of the defective virus in hamsters parallels closely the ability to induce T antigen in permissive cells. Uchida and Watanabe (*Virology*, **39**, 721; 1969) have reported that these defective SV40 which can induce T antigen can transform mouse cells *in vitro* with the same efficiency as plaque forming virus. The defective virus cannot, however, be rescued by fusion of transformed cells with permissive cells. The two transformants used by Martin and Axelrod from which virus cannot be rescued and in which only 30–40 per cent of the SV40 genome is transcribed may have been produced by SV40 defectives.

GENETICS

How Genes are Controlled

by our Botany Correspondent

THE well known adage of molecular biology that what is true for *Escherichia coli* is also true for elephants may be far from proven, but encouraging facts are beginning to collect. Some of them were discussed at a meeting on gene expression and its control at the Royal Society, London, on February 19 and 20. Dr D. J. Cove (University of Cambridge) produced evidence that the fungus *Aspergillus nidulans* has similar gene regulatory mechanisms to those of the familiar bacteriophages. Using mutants with deficiencies in the nitrate reductase and other enzyme systems, Cove and his colleagues have found evidence of induction and repression, and even some suggestion of linked genes that may form an operon. He sees no reason to suppose that eukaryotes have regulatory mechanisms much different from those of the prokaryotes—viruses and bacteria.

Moving nearer to the elephants, Dr J. Paul (Beatson Institute for Cancer Research, Glasgow) is investigating the masking of chromosomes in mammals. He has found patterns of hybridization between RNA and DNA which indicate that there must be specific restrictions on the transcription of messenger RNA from the chromatin of different organs in the mouse. This leads to the conclusion that some regions of DNA are masked in the chromatin. More nucleic acid hybridization experiments have indicated to Paul that the masking is done by the histones of the chromatin, which, when the masking is removed, are displaced by non-histone proteins which allow access to RNA polymerase to make messenger RNA. The all important non-histone component, with its regulatory function, apparently has a very complex chemistry, but Paul knows that it is acidic. Replying to a question, Paul said that there was no evidence of any relationship between his non-histone protein and the sigma factor which forms an essential part of the RNA polymerase of λ phage.

Dr J. B. Gurdon (University of Oxford) has used another technique — nuclear transplantation — to demonstrate repression and derepression in the early development of the amphibian *Xenopus laevis*. He described how, in spite of the stability of a normal differentiated cell of *Xenopus*, its nucleus can be transferred to the cytoplasm of an egg to give rise to a normal tadpole. Nuclear transplantation thus results in a change in the expression of the genes.

Recent work in Gurdon's laboratory has revealed some of the metabolic changes that follow nuclear transplantation. When a nucleus is taken from a late blastula and put in egg cytoplasm, its pattern of RNA synthesis changes within a few hours from that of a blastula to that of an egg. These rapid changes in gene expression are apparently brought about by the cytoplasm. When Gurdon injected pure *Xenopus* DNA into egg cytoplasm he obtained a result very similar to the effect of injecting a whole nucleus. Clearly other nuclear material was not needed to change the expression of the genes.

Labelling experiments have shown that cytoplasmic proteins enter a nucleus of *Xenopus laevis* after it has been transplanted. Although he cannot give an overall scheme for the gene regulation involved here, Gurdon assumes that the entry of cytoplasmic proteins influences the activity of the nucleus in some way so that it is quite derepressed. He intends to go on to find out what it is that restricts the activity of the nucleus of a fully differentiated cell.

ANTIBIOTICS

Jamming the Message

from our Molecular Biology Correspondent

MUCH progress has in recent years been made in sorting out at just what point different antibiotics jam the cycle of protein synthesis. A new example of the precise localization of a site of attack on the ribosome comes from Bollen and Herzog (*FEBS Lett.*, **6**, 69; 1970), who have identified a protein in the 30S subunit of *E. coli* that is implicated in sensitivity to the antibiotic, spectinomycin. Resistant mutants from two different strains were obtained and the 30S ribosomal proteins were fractionated on an ion-exchange column. Both mutants had, by comparison with the products from sensitive cells, a single aberrant protein component. This was made still clearer when proteins from resistant and sensitive cells, labelled respectively with tritium and carbon-14, were eluted together. The function of the protein in question is not known, neither is it yet established which activity of the ribosome is hindered by spectinomycin.

At the same time the cataloguing of antibiotics in terms of their mode of action continues. Pestka (*Arch. Biochem.*, **136**, 80; 1970) has examined the effect of a range of antibiotics on the puromycin reaction, which involves the formation of a peptidyl puromycin bond, and so serves as a convenient prototypic protein synthesis model. It seems that chloramphenicol and sparsomycin function as competitive inhibitors of puromycin, whereas six other antibiotics are noncompetitive inhibitors. Sparsomycin has been previously reported to promote the association of aminoacyl-tRNA with the ribosome and may therefore make it unavailable for reaction with puromycin. Whether chloramphenicol operates in a similar manner, or by specific inhibition of the peptidyl-transferase step, is not yet clear.

In a second report (*ibid.*, 89) Pestka examines whether the antibiotics disturb the translocation reaction by analysing the product of a poly-U-stimulated system for phenylalanylphenylalanine, and oligophenylalanines with chain length three or more. The relative amounts of these in the mixture then give a measure of the extent to which translocation—the ability of the ribosome to shift from one coding triplet on the messenger to the next—is inhibited. The presence of GTP and the protein factor *G* is another variable which can be controlled. The steroid antibiotic, fusidic acid, turns out to be the only one that unequivocally blocks the capacity of the *G* factor to induce translocation, though two others have a lesser, and probably secondary, effect. The remaining antibiotics tested inhibit oligopeptide synthesis, but their action is manifested in the absence of the *G* factor and GTP. It is most likely—and indeed in some case has been established previously—that these antibiotics operate by preventing the attachment of incoming aminoacyl-tRNA to the ribosome.

How such effects on the ribosome are physically accomplished by a single molecule of antibiotic is another issue, but it has been widely supposed to involve some steric disturbance, local or gross, of the ribosome structure. The first direct evidence for such an effect has been described by Sherman and Simpson (*Proc. US Nat. Acad. Sci.*, **64**, 1388; 1969). It is known from tritium exchange experiments that a considerable proportion of the exchangeable hydrogen atoms in intact ribosomes is inaccessible, but when the ribosomes are dissociated into their subunits by withdrawal of magnesium all exchange essentially instantaneously. The addition of streptomycin to *E. coli* ribosomes induces a considerable alteration in the tritium exchange kinetics: with low ratios of antibiotic to ribosomes there is a marked increase in exchange, suggesting a fairly extensive conformational loosening (or diminution in the strength of association between the subunits). In these conditions there is little inhibition of poly-U-directed polypeptide synthesis, or misreading (a familiar and striking effect of this antibiotic). When the molar ratio of antibiotic to ribosomes exceeds 0·1, however, both effects are progressively and strongly manifested, and at the same time the rate of tritium exchange begins to diminish, and falls to something considerably lower than the value for the pristine ribosome. Sherman and Simpson suggest that there are two completely different modes of interaction. With ribosomes from streptomycin-resistant cells neither type of effect can be observed.

HEALTH

Unusual Cause of Impotence

from our Social Medicine Correspondent

CIRCUMSTANTIAL evidence has been recently found of a possible link between impotence and the use of certain herbicides and pesticides (Espir *et al.*, *British Medical Journal*, **1**, 379; 1970). Between April and November 1967, four out of five members of a team of farm workers who had used these chemicals complained of difficulty in achieving and maintaining an erection, having previously been perfectly normal in this respect. None had any other symptom and none experienced an appreciable fall-off in libido.

The possibility of a toxic cause was not suspected immediately in the first patient, but fortunately he stopped using the chemicals of his own accord and recovered completely within 2 months of the onset of impotence. When a second patient of similar occupation visited the same general practitioner 7 months later, suspicion fell on the chemicals. He and two subsequent patients were advised to avoid further contact with the pesticides, and except for the third patient, who took a year to recover completely, all recovered their potency within 2 to 3 months. Each patient was treated with methyltestosterone, but Espir *et al.* say there is no clear evidence that this enhanced recovery, which may have occurred spontaneously after the men stopped using the chemicals.

Nine groups of compounds were used on the estate in question during 1967: organophosphorus, substituted phenols, dipyridyls, organochlorides, substituted phenoxy compounds, triazines, carbamates, dithiocarbamates and ureas and uracils. All were used either during early spring and/or late summer and autumn—coincidental with the reported impotence. The men had occasionally disregarded regulations concerning the safe use of chemicals because of the discomfort from the lack of ventilation with protective clothing.

According to Espir *et al.*, remission of impotence, as in the cases described, is not consistent with many of the possible organic diseases. Though multiple sclerosis could not be excluded on this basis, there were no other signs of any neurological disorder and neither was there any evidence of psychological, endocrinological or local structural disease. In view of the circumstantial evidence, and having been unable to find any alternative cause, Espir *et al.* conclude that the reversible impotence was probably due to the toxic effects of the chemicals to which the men were exposed, though there was no evidence of poisoning with these compounds. Organophosphorus compounds were originally thought to be responsible, but Espir *et al.* could not find previous reports of impotence as an isolated manifestation. They therefore cannot say whether the reversible impotence was caused by a single substance or by two in combination.

Additional support for the proposed link is provided in an article in the December issue of the *Medical News Tribune* (**19**, 21; 1969). Referring to this in their addendum, Espir *et al.* say the case in question was an agricultural labourer who, for 3 years, complained of impotence, nausea and some indigestion which started each year in March and lasted for 6 weeks—the time of year when he used insecticides and herbicides. The sprays which the labourer thought upset him were 'Metasystox 55', 'Gesatop' and 'Tecane'.

WORTHINGTON

RNase-free DNase, DNase-free RNase...

the cleanest, sharpest tools for molecular biology come to you direct from Worthington

Unlike other biochemical supply houses, mere re-sellers, we make all our own enzymes. We have adapted such specialized analytical techniques as column chromatography, free-flow electrophoresis, and disc gel electrophoresis to routine enzyme production. From our efforts come enzymes with the purity and high activity required for demanding research work.

- For example, our chromatographically-prepared pancreatic ribonucleases, RAF and RASE, are free of that last 1% impurity found in other preparations. Even though we sacrifice half our yield in final purification, our RNA materials are priced competitively.
- Another ribonuclease for nucleic acid chemists, our RT_1 has twice the activity of any other commercially-available product.
- Our standard once-crystallized DNase and our chromatographically-prepared alkaline phosphatase both are upgraded electrophoretically to eliminate trace RNase.

The preparation of each of our 200-plus enzymes is carried through by the one person who best understands the process. His records provide the complete history of each batch of every enzyme. If necessary, we can trace any material back to its source.

Re-sellers can't do this. They merely slap a new label on the bottle and stick it on the shelf.

Distributed in the United Kingdom by Cambrian Chemicals, Limited.

DIEHL sigmatron

Electronic Calculating System with Pre-programmed Statistical functions

DIEHL sigmatron is the first calculating system specifically designed for Statistical calculations. By pre-programmed functions, Statistical calculations are reduced to one key operations. For instance, to obtain the Arithmetic Mean and Standard Deviation enter data on the keyboard and touch the pre-programmed key. After entry of the data is completed you need only touch the same pre-programmed key to obtain the results immediately. Linear Regression, Chi Square, Coefficient of Correlation are all reduced to the simplicity of one key operation. DIEHL sigmatron also gives you a powerful and effective calculating performance with ten separate memories, automatic square root, automatic decimal selection up to 8 places and a complete check of each figure, each step and each result.

If you prefer to make your own programs, DIEHL combitron S has 10 Program/Memory registers providing a capacity of 120 steps with branching and looping.

For external input of data, DIEHL dilector – punched tape reader – is available.

Brain Mechanisms and Motivation

by
KEITH OATLEY
Laboratory of Experimental Psychology,
University of Sussex,
Brighton

Mechanisms in the brain generate specific patterns of motivated behaviour concerned with such matters as hunger, thirst and sex. These mechanisms contain models of relevant aspects of the internal and external environment which enable an animal to direct its behaviour appropriately and purposefully.

DARWIN[1] was one of the first biologists to deal with the problem of purposeful behaviour in animals. He proposed that specific instincts, which gave direction to behaviour, were shaped by natural selection just as surely as were anatomical characteristics. Although he explicitly disclaimed any understanding of the mechanisms which gave rise to instinctive behaviour, this did not prevent many who came after him from using the idea of instincts as if the mere existence of a name for each instinct could explain how the behaviour was produced. Aggressive behaviour, for example, would be attributed to an aggressive instinct.

Brain Areas and Behaviour

Clearly, names such as aggression which act as labels or shorthand descriptions of categories of motivated behaviour have no real explanatory value. Nevertheless the existence of brain mechanisms which generate specific behaviour patterns is beyond doubt. Hess[2] was the first to show that instinctive patterns could be elicited by electrical stimulation of the brain through chronically implanted electrodes. Stimulation of parts of the hypothalamus of cats produced signs of aggressive behaviour such as a defensive posture, hissing, and usually a well directed attack on any convenient target. Subsequently other behaviour patterns, including eating, drinking and sexual behaviour, have been elicited by stimulating hypothalamic and limbic regions in many species. In the same way that chronic electrodes can be implanted intracranially, cannulae made of fine gauge hypodermic tubing can also be directed into almost any area of the brain. Application of transmitter substances through a cannula, like electrical stimulation, can elicit well defined patterns of motivated behaviour from unanaesthetized animals. Grossman[3] found that acetylcholine and related substances, applied directly to the hypothalamus of rats, selectively induced drinking. Noradrenaline applied through the same cannula evoked eating. The most plausible interpretation was that neurones subserving these different types of behaviour were very close together, but used separate transmitter substances. Testosterone and other sex hormones have also been injected directly into the brain[4]. Maternal patterns such as nest building and repeated grooming of the young have been elicited in this way, as have exaggerated sexual responses. The regions from which the various motivational behaviours can easily and reliably be obtained are chiefly the hypothalamus and related structures of the limbic system (Fig. 1). It has further been demonstrated[5] that animals will learn to press a small lever which turns on electrical stimulation to an electrode implanted in parts of these same regions. This learned behaviour has indicated that the stimulation has rewarding properties. In spite of early claims, however, the effect seems not to be one of unalloyed pleasure. The stimulation has aversive aspects as well.

Lesions of the hypothamalus and limbic system also have striking effects. Hetherington and Ranson[6] showed that bilateral destruction of the ventromedial nucleus of the hypothalamus in rats was followed by gross overeating and obesity. Conversely, lesions of the nearby lateral

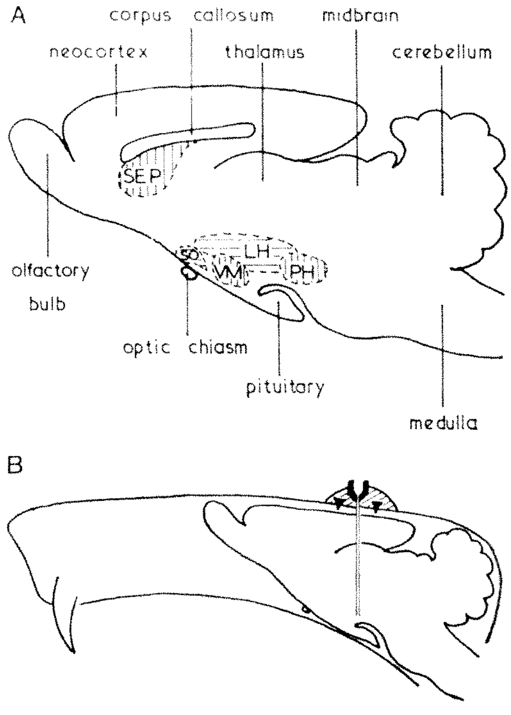

Fig. 1. (*A*) Semi-schematic view of the rat's brain in the sagittal plane. Areas shown with horizontal hatching are further lateral than those with vertical hatching. SEP is the septal area, one of the major parts of the limbic system. SO is the supra-optic nucleus of the hypothalamus. Here or further forward is a probable site for osmoreceptors important in the control of thirst. LH and VM are the lateral hypothalamus and the ventromedial nucleus of the hypothalamus which have been proposed respectively as "appetite" and "satiety" centres for hunger. PH is the posterior area of the hypothalamus, one of the regions from which aggressive behaviour has been elicited. The loci from which specific behaviour patterns can be affected by lesions or stimulation do not always correspond closely to anatomically defined nuclei. (*B*) Diagram illustrating permanent implantation of a cannula (or an electrode) in the rat's hypothalamus. The cannula is aimed using a stereotaxic apparatus, and anchored to the skull by means of jeweller's screws and acrylic cement.

hypothalamic area resulted in a complete cessation of eating and drinking[7].

These findings provoked an explosion of research on the behavioural effects of brain lesions and stimulation. Here it seemed were data that directly related structure to function. Stellar's[8] theoretical treatment unified a growing number of observations in this field, and a schematic diagram illustrating his hypothesis is shown in Fig. 2. Stellar proposed that each type of motivation was controlled by two bilateral brain centres. An excitatory centre turned on behaviour appropriate to some specific motivation, and an inhibitory centre turned the excitatory centre off. Each centre was supplied with internal and external stimuli, and learned and unlearned influences. In the case of hunger, because lesions of the ventro-medial hypothalamus increased eating and electrical stimulation stopped it, this region was identified as the inhibitory or "satiety" centre for eating.

Fig. 2. Stellar's[8] diagram illustrating his hypothesis about the type of mechanism underlying motivated behaviour.

Difficulties have arisen in connexion with this analysis. Proliferation of experiments has led to a slightly unwelcome proliferation not only of the anatomical extent of these putative hypothalamic centres, but also of their properties. It now seems, for example, that lesions of the lateral hypothalamus (thought to be the excitatory eating centre) do not lead to permanent aphagia. If the lesioned rats are fed by stomach tube, they eventually start to eat again[9]. They also exhibit characteristic and abnormal dietary preferences as recovery proceeds. It has been found[10] that although electrical stimulation of the lateral hypothalamus will induce a rat to eat if food is offered, stimulation by means of the same electrode can also elicit other types of behaviour. Rats, which in some initial tests were found specifically to eat when stimulated, subsequently had food removed during periods of stimulation but were still allowed water, and pieces of wood which they could gnaw. After this experience they were all found either to drink or to gnaw when stimulated without food present, and when it was present in addition to water and wood they distributed their responses between food and at least one of the other substances offered. These results on the lateral hypothalamus, together with several other recent experiments involving the behavioural effects of direct manipulation of the brain, have revealed discrepancies which are not adequately resolved by the notion of centres that simply turn on and turn off different types of behaviour.

Logical Basis of Behaviour

Experiments involving lesions and stimulation have demonstrated dramatic effects on behaviour. They have certainly revealed the presence and location of mechanisms which generate the specific and largely innate behaviour patterns which characterize several types of motivation. But the behaviour that has been produced has not revealed how these mechanisms work. This needs a different line of attack, in which the nature of the system capable of generating the observed behaviour is inferred from experiments where physiological and environmental variables which usually affect the system are manipulated and behaviour is measured carefully.

Claude Bernard[11] deduced the important principle that physiological mechanisms act to maintain constancy of the internal environment of the body in spite of changes in the outer world. Cannon called this principle homeostasis[12], and Richter[13] emphasized how motivated behaviour, such as eating and drinking, contributes to homeostasis just as much as does internal regulation.

Earlier workers had only the vaguest ideas as to how homeostatic mechanisms might work. The advent of control systems in engineering made possible a much greater understanding of the matter. To the extent that behaviour contributes to homeostasis, the mechanisms generating behaviour must be control systems of the kind known as regulators. From this it is possible to postulate a logical basis for behaviour. The essential components of a regulator show how such a system will display the purposiveness so characteristic of motivation. The minimal regulator must have (*a*) a specification of the desired state of the system, (*b*) a means for detecting deviation of the system from this desired state, and (*c*) a means whereby the measurement of deviation shall drive the system in such a direction as to minimize the deviation. The system works by feeding back some aspects of its output to control the system by means of the measurement (*b*).

If behaviour results in the regulation of some variable, then a feedback control device with these characteristics represents the underlying mechanism, and it then remains to be decided which part of the brain corresponds to each of the essential components. If the system is more complicated than first suspected. this will become clear in the course of enquiry. The essential nature of the mechanism as a control system will remain.

The concept of regulation made it possible to organize theories of motivation on a framework which gave apparently satisfactory explanations of behaviour. Thus Hull[14] proposed that needs (departures from optimal bodily states) induced drive, the energizer of behaviour. Responses, produced under the influence of the drive which led to drive-reduction, were reinforced, and their probability of recurrence was increased.

One implication of the theory was that some behaviour is built directly on needs such as hunger. All other types of behaviour, not directly related to deviations of the body from its optimal physiological state, were thought to be learned secondary drives arising by association with primary needs. In an experiment illustrating this, chimpanzees, instead of being rewarded by food for performing a task, learned to work just as hard for tokens which they could subsequently exchange for food in a slot machine[15].

Not all attempts to relate motivation ultimately to physiological needs have been convincing. An alternative version, also using a homeostatic framework, involved some optimal neural state. Hebb[16] and several others have proposed that the level of cortical arousal produced by the reticular activating system rises above its desired level during intense fear and falls below it during boredom. In the normal course of events it is regulated near some optimal level by behaviour such as curiosity and exploration (Fig. 3).

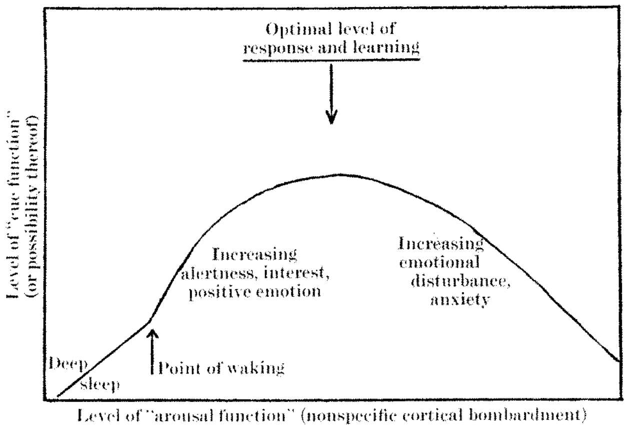

Fig. 3. Hebb's[16] graph of the effectiveness of cue function, the attribute of stimuli used in guiding behaviour, related to the level of arousal, or general energizing influence on behaviour.

Hull's and Hebb's explanations of motivation were successful partly because they were formulated on the plausible basis of homeostatic regulation. Both theories, however, held that drive was the engine impelling behaviour, but not the steering gear. They stated that behaviour was undirected at first and would be learned if it led to drive reduction. Then the learning mechanism determined the direction of behaviour. Several predictions were based on this hypothesis. For example, separate means of inducing drive should be cumulative in their effect on the vigour of response. These predictions have not been confirmed unequivocally, and consequently the general drive idea has not played a large part in more recent theoretical treatments of motivation[17]. Instead emphasis has turned away from drives that push behaviour from behind, towards external incentive events that draw behaviour forward. Such theories seem especially appropriate for motivations like exploration and sex.

Models of the Environment

Further justification for rejecting general drive theories comes from the lesion and stimulation work I have discussed. Behaviour elicited by electrical or chemical stimulation is clearly generated by mechanisms which specify not only the quantitative vigour of response, but also its direction. The conclusion echoes Lashley's[18] suggestion that problems of motivation would not involve libido or general drive but the manifestation of very specific sensori-motor systems.

An experiment by Petrinovitch and Bolles[19] illustrates this. They trained rats that were either hungry or thirsty in a T maze. Thirsty rats learned to find water always in one place in the maze more easily than hungry rats learned to find food there. On the other hand, hungry rats were superior in a task in which reward was placed on alternate sides of the maze on successive trials. Presumably brain mechanisms of rats have evolved in such a way as to match the tendencies of the environment to maintain a source of water in a constant place while varying the location of food.

This experiment also demonstrates that, as well as specificity, motivational mechanisms have features appropriate to the nature of the environment. A similar argument was put in a rather different context by Craik[20]. He proposed a hypothesis on the nature of human thought. In order to generate behaviour appropriate to the environment, Craik argued that the brain must itself contain a model of that environment. The model would represent in a neural symbolism the objects, events and relationships that occur in the world. Evidently animals, including man, conduct their affairs with apparent knowledge of the kinds of things that occur in the world. They predict the outcome of events, and the results of their own actions. A man will say "If I leave now I can just catch the train". A rat behaves as if he knows that the left turn in a maze leads to food. It is difficult to see how behaviour could be appropriately directed towards the environment if the brain did not contain, in some sense, a model of the world.

Though important, Craik's hypothesis has not been exploited much. A suitable application for this type of idea is the problem of motivation. Motivational or, as Darwin called them, instinctive mechanisms must have been shaped during evolution to take account of and represent those aspects of the environment relevant for eating, sleeping, breeding and so forth. Aspects of the environment have come to determine the logical structure of the model contained in the brain. If this is true, then a fundamental method of reaching an understanding of brain mechanisms is to discover what objects, events and relationships are relevant to some category of behaviour. If it is possible to represent formally how these objects, events and relationships are articulated in the environment, evidence can be sought that the brain has a symbolic representation of these same environmental processes.

On this formulation it would not be possible to explain all motivation with a single type of mechanism. The use of hunger as the prototype for motivation has led to theoretical difficulties, as well as the spread of mistaken ideas such as that of an aggressive drive which grows stronger if the opportunity for aggression is denied[21]. The homeostatic principle should be applied when behaviour is directed towards the regulation of some internal variable. The paradigm is useful because it specifies the nature of the mechanism generating behaviour. This advantage should not allow behaviour to be explained by homeostasis when internal regulation is not involved. Instead the role of each type of behaviour should be sought in the life of the animal, as well as the environmental events that need to be represented and symbolically manipulated by the brain.

The characteristics of motivational systems are usually as follows. (1) The mechanisms include a means for generating specific consummatory behaviour closely matched to the properties of the goal object, and released by and guided towards this object. (2) There is some means of controlling the quantity of consummatory behaviour. In some cases this may be by homeostatic regulation. (3) There are mechanisms for generating suitable appetitive behaviour. This behaviour is not entirely random, but involves strategies appropriate to the properties of the goal object. A cat, for example, hunts in a very systematic way. All three of these are innate. In addition learning enters as follows. (4) What is learned about the environment during appetitive behaviour may be partly determined by component (3). (5) Motivation can be induced and reduced by learned stimuli, particularly (for example) in the case of fear, somewhat less so in the case of sex, and probably much less in the case of thirst.

Sexual behaviour illustrates the interaction of several component processes[22,23]. Anatomical and behavioural patterns displayed by an animal will identify it to a partner of the same species and opposite sex. The partner also displays patterns, and each evokes in the other sequences of courtship and copulation, but only if hormonal conditions in both are right. Hormones in this context act as a timing device, encouraging only mature individuals to mate, and stimulating fertilization at a time of the year which suitably anticipates the best season for rearing young. The motivational mechanism represents in its model both a suitable partner and a suitable season, relating these in such a way as to produce behaviour which will continue the species.

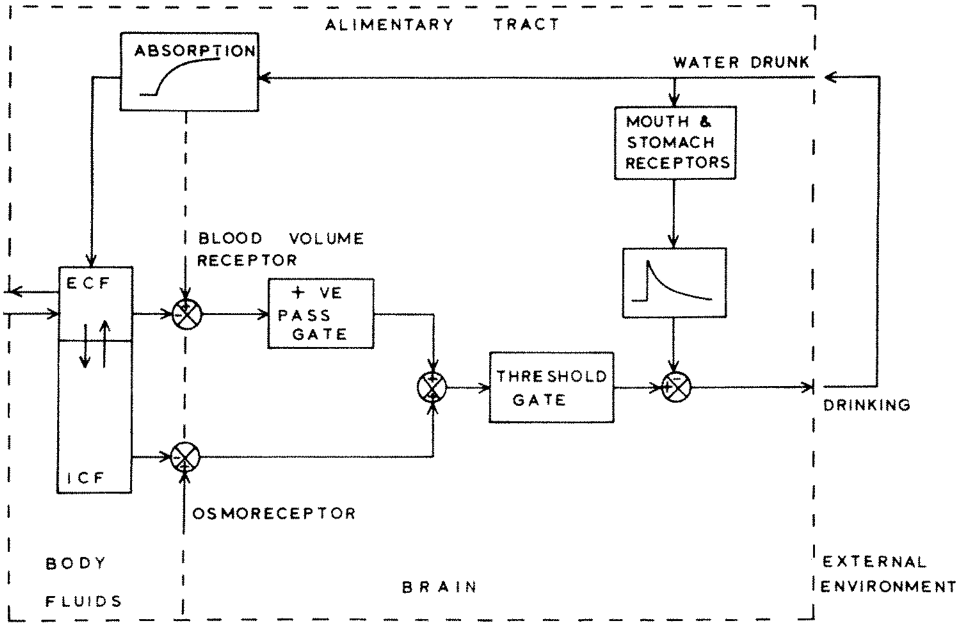

Fig. 4. A model of the control of thirst (simplified from ref. 30). Arrows represent signals, boxes are mechanisms or transfer functions operating on the signals, and the circles containing diagonal crosses are summing junctions which add signals according to the signs given. Deficits of body fluid produce a positive thirst signal. Though only deficits of ECF are taken into account, both deficits and excesses of the cellular space reach the summing unit.

The ability of animals to choose a healthy diet[13] also shows how the mechanism of motivation is matched to the nature of the environment. It was originally thought that animals might be able to discriminate the presence of vitamins in food, and that they might have specific (homeostatic) hungers for each of these. It now seems instead that animals detect in themselves a state of illness or good health, and can associate these states with foods that they have eaten. Thus rats avoid a food with a discriminable taste or smell if illness follows eating that food. This can occur after only a single exposure to a toxic food and even when the eating and illness are separated by several hours. This type of learning contrasts sharply with learning of contingencies in the external world, where associations between events are only made if the events occur within a few seconds of each other. Furthermore, in learning about the external world stimuli affecting the somatic receptors (visual, auditory, tactile) are effective. For learning about the onset of illness these stimuli are ineffective and only tastes and smells can be learned[24]. Eating a balanced diet is the reverse of avoiding illness. Here vitamin-deficient animals avoid foods which do not relieve their illness. A rat suffering from thiamine deficiency offered a choice of diets will try them systematically, one at a time, with intervals of several hours. If the diets have distinctive tastes and any of them contain the vitamin, he will eventually find that one and keep eating it, again as a result of learning[25].

Here again the brain mechanisms of a specific motivation have features which model the workings of the environment. For the learning of most external processes the constant temporal conjunction of events reflects a high probability of causality. In becoming ill or recovering because of the diet, causality has a longer time course, and this must be reflected in learning mechanisms that will make associations over a longer period.

Thirst and Water Balance

Thirst has both homeostatic and non-homeostatic features[26], which indicate the way in which the brain represents the environment. Homeostatic regulation of thirst occurs when body water falls below some desired level. Body fluids are distributed in two principal compartments, cellular and extracellular. Water shifts between the two along osmotic gradients, while solutes are confined to their own compartment. Diminutions of either the cellular[27] or the extracellular space[28] will provoke thirst and receptors exist whereby the brain monitors these changes. Osmoreceptors act as a sample of the cellular space and blood volume receptors measure a sample of the extracellular compartment. When deficits of both fluid

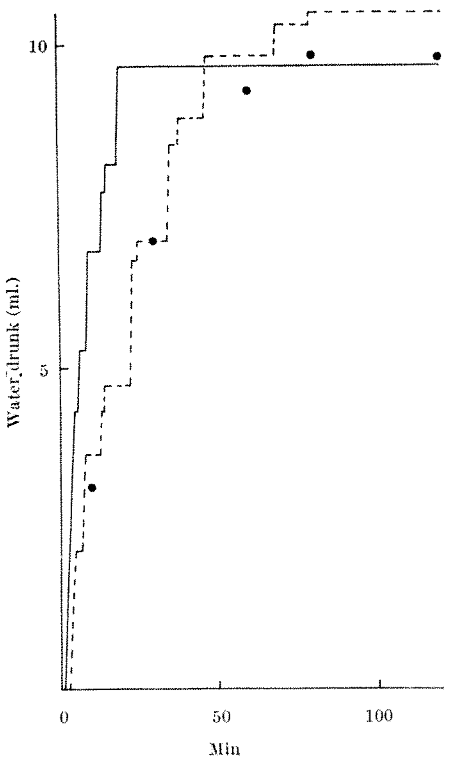

Fig. 5. Unpublished result (myself and Toates) of the output from a computer simulation (solid line) compared with drinking of an individual rat (dotted line) and the mean of a group of rats (solid spots) in response to an intravenous injection of sodium chloride. The simulation parameters and time constants were all fitted to physiological data for individual components of the system, and this overall response gives a good fit. The computer response is slightly faster than that of the rat because the rat responds partly in a non-homeostatic way by spending some of its time grooming instead of drinking.

spaces occur together they are additive in their effect on thirst[29]. This occurs, for example, when an animal is deprived of drinking water. I proposed the additive arrangement[30] in a model of thirst (Fig. 4). This model, which explains the quantity of consummatory behaviour, was simulated on a computer in collaboration with F. M. Toates. Fig. 5 shows an example of a comparison between the output of the simulation and drinking by rats.

The variables and calculations used by the computer follow a physiological understanding of each component process in the system. Distribution of water between cellular and extracellular compartments, for example, is thought to be determined by osmotic gradients. Accordingly, concentrations on either side of the cellular membrane were calculated. A rate of flow of water between the compartments was made proportional to the difference, or gradient between them, and the integral of the rate added to and subtracted from the appropriate fluid spaces. The time constant for this and other component processes was fitted to published data and not further adjusted. The simulation contains three principal parts. The first is the computer representation of the body fluids, including the absorption of water and solutes from the gut. The other two parts are the systems for control of the kidneys and of thirst (which is an elaborated version of the scheme of Fig. 4). Renal and thirst systems embody Claude Bernard's concept of homeostatic regulation within the formal context of feedback control.

The thirst system simulates the brain's model of the body fluids. It exhibits the kind of structure that the brain's model (in Craik's sense) must have in order to be able to act appropriately towards the environment; in this case the internal environment, the body fluids. The brain measures two relevant events, the two compartment volumes, and represents the exchange of water between compartments as a neural addition process. Also represented in the brain's model is the delay of alimentary absorption after water is drunk. This exponential lag in the feedback loop would lead to instability were it not for additional short-term feedback signals. To compensate precisely for absorption the brain represents the delay by a memory of the amount drunk which decays with the same time constant as that of absorption. This decaying memory is added to the absorptive feedback to calculate the total amount drunk.

This homeostatic mechanism represents the brain's working model of the internal environment, and the means of controlling it. Other aspects of thirst are not homeostatic and relate instead to the external environment. The diurnal rhythm of drinking, for example, seems to be independent of changes in body fluids[31]. It is exhibited when rats allowed to drink freely are found to drink about 80 per cent of their total water at night. The rhythm is probably driven by an endogenous oscillator, which is synchronized to, but not entirely dependent on, the external lighting cycle. Mechanisms that determine diurnal rhythms simulate and predict the natural alternation of light and darkness and generate behaviour at the time of day that is suitable for the ecological niche of the animal.

Motivation in animals is beginning to be understood in terms of kinds of mechanisms necessary to generate the appropriate behaviour. The next step is to put this essential component of understanding together with knowledge of the anatomical location of the mechanisms in the brain, and determine, perhaps by micro-electrode recording, the neural embodiment of these systems which represent and control their environment.

I thank Professor N. S. Sutherland for helpful criticism.

Amino-acid Sequence of Porcine Pancreatic Elastase and its Homologies with other Serine Proteinases

by
D. M. SHOTTON[*]
B. S. HARTLEY

University Postgraduate Medical School,
Hills Road, Cambridge

The primary structure of porcine elastase has been determined by classical procedures of enzymatic digestion and chemical sequence analysis and shown to be closely related to those of chymotrypsins A and B and trypsin. Differences in side-chains offer an explanation of the differences in substrate specificity.

THE proteolytic enzyme elastase (EC 3.4.4.7) can digest a wide variety of protein substrates[1], but is distinguished from the other pancreatic endopeptidases by its ability to digest elastin, the elastic fibrous protein of connective tissue[2], and by its specificity for substrates with uncharged non-aromatic side-chains[3]. The specificity of elastase thus complements those of the trypsins and the chymotrypsins for substrates with basic and aromatic side-chains, respectively. Elastase is formed in the duodenum by tryptic activation of the zymogen, proelastase, which is secreted by the acinar tissue of the pancreas[4,5]. It consists of a single polypeptide chain of 240 residues, with a molecular weight of 25,900, which is homologous with the single chain of trypsin and the B and C chains of the chymotrypsins. The amino-acid composition is shown in Table 1. In common with all other serine proteinases[6], elastase possesses a serine residue at the active centre which is readily inhibited by diisopropyl phosphorofluoridate[7]. The amino-acid sequences around the active centre serine and histidine residues, the disulphide bridges and at the amino-terminal region have been shown to be closely homologous with the corresponding regions of bovine trypsinogen and chymotrypsinogen A (refs. 8, 9). We wish now to report the determination of the complete amino-acid sequence.

Table 1. AMINO-ACID COMPOSITION OF ELASTASE

Amino-acid	No. of residues	Amino-acid	No. of residues
Lysine	3	Glycine	25
Histidine	6	Alanine	17
Arginine	12	Cysteine	8
Aspartic acid	6	Valine	27
Asparagine	18	Methionine	2
Threonine	19	Isoleucine	10
Serine	22	Leucine	18
Glutamic acid	4	Tyrosine	11
Glutamine	15	Phenylalanine	3
Proline	7	Tryptophan	7

Total: 240 residues.

Determination of Amino-acid Sequence

Highly purified elastase was prepared from 'Trypsin 1–300', an acetone powder of porcine pancreas (Nutritional Biochemicals, Cleveland, Ohio)[1,8], using crystallization rather than chromatography as the final stage in the purification[10,50].

The complete amino-acid sequence was determined by studies of the peptide fragments produced by digestion of the elastase molecule by various proteolytic enzymes. The peptide mixtures thus obtained were fractionated by column chromatography and then by high voltage paper electrophoresis and paper chromatography. The sequences of the purified peptides were determined by the most appropriate current techniques.

In the first instance peptide fragments were obtained from reduced and aminoethylated diisopropyl phosphoryl elastase (DIP-elastase) by digestion with trypsin. This procedure had the advantage that the conversion of cystine to aminoethyl-cysteine residues provided extra sites of tryptic cleavage in regions of the molecule where the sequence was already known[9], resulting in a greater number of smaller, more soluble and more easily sequenced peptides than would otherwise have been obtained. This digest was fractionated on a 'Zeo-Karb 225' (×2) ion-exchange column with a pyridine–acetate gradient, and from it peptides accounting for almost all of the elastase molecule were isolated and sequenced.

The missing fragments were obtained by subjecting reduced and ^{14}C-carboxymethylated DIP-elastase to cyanogen bromide cleavage at the two methionine residues. The three fragments produced were separated by gel filtration on 'Sephadex *G*-50', as were the soluble tryptic peptides obtained from them. Fourteen of the fifteen tryptic peptides of elastase were isolated in this way, further purified by high voltage paper electrophoresis and, where necessary, subjected to sequence analysis.

The missing tryptic peptide was that from the carboxyl terminus of the molecule. It contained fifteen amino-acid residues. It was insoluble in most normal solvents, including 8 M urea, and was isolated by prolonged tryptic digestion of the purified carboxyl-terminal cyanogen bromide fragment of sixty-eight residues, followed by removal of the soluble peptides by washing in 8 M urea. Its sequence was determined from studies of the overlapping soluble peptides obtained by peptic digestion of this insoluble core. Nine of its amino-acid residues occupy an α-helical conformation in the three dimensional structure of tosyl-elastase[11], which may explain its peculiar solubility properties.

In order to overlap the tryptic peptides to determine the complete sequence, peptides containing internal arginine residues were isolated from a peptic digest of native elastase, fractionated on 'Sephadex *G*-50' and purified by high voltage paper electrophoresis, as were several other peptides used to determine or confirm the sequence at various positions. Peptides containing internal lysine residues were obtained from a combined tryptic plus chymotryptic digest of reduced and aminoethylated DIP-elastase which had been fully acetylated with ^{14}C-acetic anhydride, this digest being fractionated on a 'Zeo-Karb 225' column with a pyridine–acetate gradient. These lysine peptides were prepared and purified by Dr K. J. Stevenson during other studies (H. Kaplan, K. J. S. and B. S. H., manuscript in preparation).

In determining the sequences of the purified peptides, much use was made of the dansyl–Edman procedure for stepwise sequential analysis[12], and larger peptides were frequently subjected to secondary digestion either by the enzymes trypsin, α-chymotrypsin, papain, pepsin or thermolysin, or by partial acid hydrolysis. The amide groups of asparagine and glutamine residues were unambiguously located by measurements of the electrophoretic mobilities of peptides containing them[13]. It is noteworthy that extensive deamidation occurred at each of the four -Asn-Gly- sequences in elastase, the deamidated varieties of peptides containing these sequences being isolated in much greater yields than the amidated varieties, as also noted by Ambler[47]. This suggests that the amide groups of asparagine are made much more labile by an adjacent glycine residue, and that evidence for -Asp-Gly- sequences should not be uncritically accepted at face value.

The numbering is that of chymotrypsinogen A. "Insertions" in the sequences of other enzymes are numbered 36A, 36B, etc. "Deletions" are indicated thus —. Only those residues of chymotrypsinogen B which differ from chymotrypsinogen A are indicated. At each sequence position residues which are chemically similar (defined as Arg = Lys, Asp = Glu, Asn = Gln, Asp = Asn, Glu = Gln, Ser = Thr, Val = Ile, Ile = Leu and Tyr = Phe = Trp) between any pair of enzymes are shown in capitals. Residues which are identical are underlined, except for identities between chymotrypsinogen A and chymotrypsinogen B which are not shown. Residues whose sidechains are internal, judged to be inaccessible to water molecules in the molecular models of both elastase[11] and α-chymotrypsin[36], are indicated by circles round the residue numbers. PE = porcine elastase; BT = bovine trypsin[17]; BCA = bovine chymotrypsin A[19]; BCB = bovine chymotrypsin B[21]; PCC = porcine chymotrypsin C[34]. Disulphide bridges[48] are as follows: E, T, CA and CB: 42–58, 136–201, 168–182 and 191–220; T only: 22–157 and 128–232; CA and CB only: 1–122.

Only residues which differ from the sequence in porcine trypsinogen or porcine chymotrypsinogen A are indicated. PT = porcine trypsinogen[29]; TAO and OTB are two ovine trypsinogens[30] and BT = bovine trypsinogen[16]. PCA = porcine chymotrypsinogen A[31]; PCB = porcine chymotrypsinogen B[27]; BCA = bovine chymotrypsinogen A[18]; BCB = bovine chymotrypsinogen B[21]; PCC = porcine chymotrypsinogen C and BCC = "bovine chymotrypsinogen C" (procarboxypeptidase fraction II)[32].

These and the previous studies[8,9] have led to the complete determination and unambiguous overlapping of the amino-acid sequence of elastase (Table 2). Confirmation of the accuracy of this determination is given by three independent lines of evidence. First, tryptic peptides produced from each of the purified cyanogen bromide fragments of elastase have all been identified and agree with those predicted from the local overlaps. Second, there are extensive sequence homologies between elastase, trypsin and the chymotrypsins. These are not fortuitous, but are closely related to the functions and three-dimensional structures of the enzymes, and would be lessened by any re-ordering of the elastase peptides. Third, the three-dimensional electron density map of tosyl-elastase[14] contains detailed information about the order of large, small, polar, nonpolar and aromatic amino-acid residues along the polypeptide chain, many of which can be unambiguously identified from their electron density alone. A model of the elastase molecule built from the sequence data (Table 2) satisfactorily accounts for all the electron density in the map, there being no point at which the crystallographic and sequence evidence are in conflict[11,15].

The sequence of elastase shown in Table 2 aligned with those of bovine trypsinogen[16,17], bovine chymotrypsinogen A (refs. 18-20) and bovine chymotrypsinogen B (ref. 21) in a way which maximizes the homologies between the four enzymes and introduces only two extra sequence positions into the table. Three corrections have been made to the previously published elastase sequence data[9]. Between Cys-168 and Tyr-171 there are four, not five, serine residues; residue 186 is asparagine, not aspartic acid; and between Asn-204 and Glu-206 there is a glycine residue, Gly-205. (To aid in the comparison between the various serine proteinases we have, throughout this paper, used the numbering of the amino-acid residues in the chymotrypsinogen A sequence to describe the position of corresponding amino-acid residues in these homologous enzymes: see Table 2.)

The ambiguity in the previously published sequence of residues 197 and 198 has been resolved, the sequence being -Gly-Pro-, and the overlap between Asn-186 and Gly-187 has been established. The table also shows recent corrections to the sequences of bovine trypsinogen (residue 189 is aspartic acid, not asparagine[22]) and bovine chymotrypsinogen A (residue 102 is aspartic acid, not asparagine[23]) which are of great importance for a correct understanding of the nature of the specificity and catalytic mechanism of those enzymes[11,22-24].

Homologies between Pancreatic Endopeptidases

Bovine pancreatic juice contains, in roughly equal amounts, the zymogens of trypsin, chymotrypsin A, chymotrypsin B (ref. 25) and a fourth serine endopeptidase, less well characterized, which is part of the procarboxypeptidase A complex[26]. In porcine juice, trypsinogen, chymotrypsinogen A and chymotrypsinogen B appear to resemble their bovine counterparts, while chymotrypsinogen C may be very similar to the "procarboxypeptidase endopeptidase" of the cow[27]. In neither of these studies was proelastase or elastase discovered. The enzyme undoubtedly exists in good yield in acetone powders of pig pancreas, and the apparent discrepancy may arise from the fact that the enzyme precipitates as a complex with another acidic component when extracts of pancreas are dialysed free of salt[1]. It might therefore be accidentally removed before ion-exchange chromatography, and for this reason one cannot be certain that elastase is absent in bovine pancreatic juice, though its biological value for a herbivore, such as the cow, is less obvious than for an omnivore like the pig. Early reports of elastase activity in bovine pancrease[1,28] deserve greater credence than they have sometimes received, and it seems likely that both bovine and porcine pancreatic juice contain five serine proteinase zymogens: trypsinogen, proelastase and three chymotrypsinogens, A, B and C.

Table 3 shows the homology which exists between the N-terminal sequences of the chymotrypsinogens and trypsinogens of various species. The N-terminal sequences of porcine chymotrypsinogens A and B are identical to that of bovine chymotrypsinogen A except that Pro-7 replaces Gln-7 of the latter. Bovine and porcine chymotrypsinogen C resemble each other quite closely but are less homologous with chymotrypsinogens A and B both in sequence (Tables 2 and 3) and in activity[33]. They are, nevertheless, best classified as chymotrypsinogens. Some further sequences[34] of porcine chymotrypsinogen C around the active centre His-57 and Ser-195 are included in Table 2. The sequence of the small activation peptide of proelastase is as yet unknown[5]. Splitting of the bonds between residues 15 and 16 activates each zymogen, releasing activation peptides in the case of proelastase and the trypsinogens.

In Table 4 a general analysis is made of the degree of homology* between those enzymes the sequence of which is completely established. It shows that bovine chymotrypsin A and chymotrypsin B, which show almost identical substrate specificities[35], are closely related isoenzymes showing a degree of homology (78 per cent identity) which is much higher than that between the α and β chains of human haemoglobin (44 per cent identity). On the other hand, the chymotrypsins, trypsin and elastase are clearly enzymes of different specificity, but show between 35 per cent and 43 per cent identity in amino-acid sequence (contrast, for example, sperm whale myoglobin and human haemoglobin α chain, which show 18 per cent identity), suggesting that they too have been produced by divergent evolution from a common ancestor following gene duplication events.

Table 2 shows that these amino-acid side-chain homologies are not uniformly distributed throughout the polypeptide chain, but tend to be concentrated around those residues that are important for catalysis and in those parts of the molecule that are internal, as judged by the apparent inaccessibility of the amino-acid side-chains to water molecules in the molecular models of both elastase[11] and α-chymotrypsin[36]. Table 5 gives an analysis of this distribution of homologous residues between internal and external positions. 71 per cent of the internal positions, but only 19 per cent of the external ones, are homologous

---

* Homologous residues are those which are identical or chemically similar to their counterparts in the other enzymes. Chemical similarity is defined in this paper as Arg = Lys, Asp = Glu, Asn = Gln, Asp = Asn, Glu = Gln, Ser = Thr, Val = Ile, Ile = Leu, and Tyr = Phe = Trp.

Table 4. OVERALL HOMOLOGIES BETWEEN SERINE PROTEINASES

	Total No. of residues	Per cent identity (or per cent chemical similarity*) to†, and mutation distance‡ from: Trypsin	Chymotrypsinogen A§	Chymotrypsinogen B§	Any other of these four
Elastase	240	35% (48%) 244	39% (51%) 215	38% (47%) 220	51% (68%)
Trypsin	223		43% (53%) 211	38% (49%) 220	56% (67%)
Chymotrypsinogen A§	230			78% (85%) 62	59% (69%)¶
Chymotrypsinogen B§	230				53% (64%)‖

* Defined as for Table 2.

† Calculated as per cent of the minimum length required to accommodate the sequences being compared when aligned as in Table 2, discounting common deletions.

‡ Minimum number of nucleotide base changes required to convert the gene for one sequence into that for the other, based on the genetic code as reported by Crick[49], computed with a program kindly written by Miss Joyce Cox. Deletions are scored as being two bases different from any amino-acid residue.

§ Residues 16–245 only.

¶ Excluding chymotrypsinogen B.

‖ Excluding chymotrypsinogen A.

Table 5. HOMOLOGIES IN INTERNAL AND EXTERNAL POSITIONS BETWEEN SERINE PROTEINASES*

	No. of residues	Per cent residues identical (or chemically similar†) in all four enzymes	Per cent residues showing no homology between any pair of enzymes‡
In internal positions†	75	56% (71%)	4%
In external positions†	167	10% (19%)	30%
Overall	242	24% (35%)	22%

* Porcine elastase, bovine trypsin and bovine chymotrypsinogens A and B (residues 16–245 only).

† Defined as for Table 2.

‡ Except between chymotrypsinogen A and chymotrypsinogen B.

in all four enzymes, while only 4 per cent of the internal positions show no homology between any two enzymes of different specificities, compared with 30 per cent of the external positions. Of the one hundred residues suspected of being internal by Smillie *et al.*[21] on the basis of their being hydrophobic in both trypsin and the chymotrypsins, sixty are in fact in internal positions, along with another fifteen residues which were thought to be external.

The sequence homologies (Table 2) allow one to build models of trypsin and elastase based on the principle that the conformation of the polypeptide chains are identical to that of α-chymotrypsin. Such models were built[22], and showed no obvious steric or chemical defects. For example, the internal side-chains could be close packed with no distortion of the main chain and no charged groups replaced uncharged groups which are internal in the α-chymotrypsin structure. These models suggested that the differences in specificity between the enzymes could be explained by relatively minor side-chain substitutions on the enzyme surface. In the trypsin model, the replacement of Asp-189 for Ser-189 in the substrate binding site of chymotrypsin[24] provides a negative charge perfectly placed to form an ion-pair with the positive charge of lysyl or arginyl substrates[22]. In the elastase model the bulky side chains of Val-216 and Thr-226, replacing Gly-216 and Gly-226 of chymotrypsin, block the entrance to this substrate binding cavity. This enzyme should not, therefore, demonstrate marked specificity for large basic or aromatic side-chains on the amino-acid residue N-terminal to the bond split, as do trypsin and chymotrypsin. The available data on the specificity of elastase[3,52,53] support this conclusion. The X-ray data[11,14] justify these conclusions from the hypothetical model of elastase and thereby add weight to the conclusions from the trypsin model.

The distribution of the amino-acid side-chains of elastase is shown in Fig. 1. With the exception of the two buried aspartic acid residues (102 and 194) the functions of which are discussed in the third article of this series[11], all the charged amino-acid residues occupy surface positions in the molecule. The other hydrophilic residues show a similar but less marked tendency. By contrast the hydrophobic amino-acids are fairly evenly distributed between the inside and the outside of the molecule, but while those on the surface are mostly found in non-homologous positions, most of the internal ones are similar to, if not identical with, their counterparts in the other three enzymes. Such analysis of the side-chain distributions in trypsin and the chymotrypsins yield essentially similar results and will not be detailed here. A more detailed discussion of the organization of the tertiary structure of elastase and the conformation of those residues important for its activity is given later in the series[11].

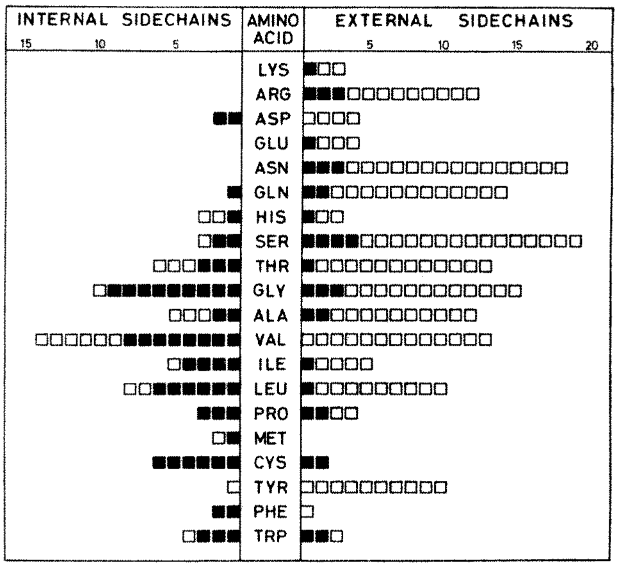

Fig. 1. The distribution between internal and external positions of the side-chains of the amino-acid residues in the porcine elastase molecule. ■, Residues homologous with (identical or chemically similar to) corresponding residues in bovine trypsin, chymotrypsinogen A and chymotrypsinogen B. □, Residues not homologous with all three other enzymes. "Internal", "external" and "chemically similar" are defined as for Table 2.

Evolution of the Serine Proteinases

The five pancreatic endopeptidases thus seem to be a single family of enzymes with almost identical tertiary structures, this identity being attributable to the homology of their amino-acid sequences, especially of the internal hydrophobic residues. The differences in specificity between the chymotrypsins, trypsin and elastase seem to result from relatively few amino-acid replacements at the substrate binding sites, which are accompanied by quite extensive but relatively unimportant changes in the rest of the enzyme surface. The same pattern of organization probably exists in all the mammalian serine proteinases, because thrombin, secreted as prothrombin by the liver into the blood stream, exhibits a high degree of sequence homology with the pancreatic enzymes in positions which would be expected from similar tertiary structures[22,27].

Serine proteinases from other organisms, the spiny Pacific dogfish[38], the turtle[39], a sea anemone *Metridium senile*[40], a mould *Streptomyces griseus*[41] and a soil bacterium *Sorangium* sp.[42] have been shown to possess some homologies with the mammalian serine proteinases in substrate kinetics and specificity and in amino-acid sequence, notably the possession of an -Asp-Ser-Gly- sequence at the serine residue of the active centre. This suggests that these enzymes of the "chymotrypsin" type may be of common distant evolutionary origin, the products of gene duplication events followed by divergent evolution. Another class of serine proteinases exists which is characterized by a -Thr-Ser-Met- sequence at the active centre serine residue and is represented by the bacterial extracellular proteinases subtilisin BPN′ from *Bacillus amyloliquofaciens* and subtilisin Carlsberg from *B. subtilis*, and probably by a proteinase from a mould *Aspergillus oryzae*[43]. While homologous with one another, these enzymes show no homology in sequence[44] or in tertiary structure[45] with the mammalian serine proteinases, and yet have a similar grouping of an aspartic acid, a histidine and a serine residue at the catalytic site and seem to function by a similar enzymic mechanism produced by convergent evolution. Yet another class of serine proteinases may exist in yeasts and plants[46]. In addition the mammalian serine esterases are a separate class of enzymes which display active centre sequence homologies with the mammalian serine proteinases. Further sequence studies on these various types and classes of enzymes from widely divergent species are needed to reveal the degree of similarity which exists between them and to clarify and substantiate our present rudimentary knowledge about their classification and evolutionary origins.

We thank Mr R Jakes for technical assistance. One of us (D. M. S.) acknowledges the financial support of a Medical Research Council scholarship and a Beit Memorial medical research fellowship received during the course of this work.

Hills Road, Cambridge

X-ray diffraction data have been collected from four isomorphous crystalline derivatives of the proteolytic enzyme elastase, and a map of the three-dimensional electron density of the tosyl derivative has been calculated by Fourier synthesis of 2,750 independent terms. It shows clearly the conformation of the elastase polypeptide chain, the size and orientation of the amino-acid side-chains, and the position of the tosyl group which labels the active centre of the enzyme.

PORCINE pancreatic elastase (EC 3.4.4.7) is a serine proteinase[1] homologous with trypsin and the chymotrypsins[2]. Preliminary studies[3] showed that elastase could be easily crystallized in the orthorhombic spacegroup $P2_12_12_1$, with unit cell dimensions $a = 51{\cdot}5$ Å, $b = 58{\cdot}0$ Å and $c = 75{\cdot}5$ Å, corresponding to a unit cell of four molecules, with one molecule per asymmetric unit. The large and well ordered crystals diffracted X-rays strongly out to a resolution greater than 2 Å and were very stable to X-irradiation, suggesting that elastase was ideally suited for high resolution X-ray crystallographic studies.

The determination of the structure of elastase, as well as providing a significant contribution to our knowledge of protein conformation in general and of the relationship between amino-acid sequence and tertiary structure in particular, would, by comparison with the known structure of α-chymotrypsin[4,5], answer the longstanding question as to whether related enzymes with different but homologous sequences possess very similar tertiary structures, and would explain the common catalytic mechanism exhibited by these two enzymes. Besides providing information about the detailed conformation of elastase itself, which would make possible the correlation and interpretation of the various chemical, kinetic and physicochemical data obtained on this enzyme, it would also reveal in atomic terms the structural differences responsible for the different substrate specificities and activities exhibited by elastase and α-chymotrypsin.

---

* Present address: Molecular Enzymology Laboratory, Department of Biochemistry, University of Bristol, Bristol B58 1TD.

We describe here the preparation and evaluation of isomorphous crystalline derivatives of elastase, and the determination of the three-dimensional electron density distribution of one of these derivatives, tosyl-elastase, at a resolution of 3·5 Å. Details of the three-dimensional conformation of the elastase molecule, determined by interpreting the crystallographic data in terms of the amino-acid sequence of the enzyme[3], are given in the third article in this series[6], which also contains a comparison of the structures of elastase and α-chymotrypsin.

Preparation and Characterization of Elastase Derivatives

The scheme used for the preparation of derivatives of elastase for three-dimensional crystallographic study is shown in Fig. 1. The inhibited derivatives *p*-toluenesulphonyl elastase (tosyl-elastase) and *p*-chloromercuribenzenesulphonyl-elastase (PCMBS-elastase), in each of which the sulphonyl group is covalently attached to the active centre serine residue of the enzyme, were prepared following the techniques developed by Sigler *et al.* for the synthesis of similar derivatives, which were used in the structural determination of α-chymotrypsin[7,8]. Although these derivatives could be prepared by soaking crystals of elastase in high concentrations of inhibitors, they were routinely prepared by inhibition in solution using the procedure described in Fig. 1. There was more than 98 per cent inhibition with this method, giving virtually full occupancy of these single site derivatives. Crystals were prepared from 0·5–1·0 per cent solutions of the dialysed and freeze dried derivatives that had been redissolved in 0·01 M sodium acetate, *p*H 5·0, by the addition of sodium sulphate to a final concentration of 0·02–0·1 M. Good crystals, isomorphous with crystals of the native enzyme, grew overnight to a size of 1–2 mm and were then transferred to a standard working solution of 1·2 M sodium sulphate–0·01 M sodium acetate (*p*H 5·0), in which they were stable. Sodium, rather than ammonium, sulphate was used in order to avoid the preferential complexing with ammonia of metal ions used to prepare further heavy atom derivatives by conventional soaking techniques[9,10]. The tosyl and PCMBS derivatives form a perfect isomorphous pair which differ only in the replacement of a methyl group in tosyl-elastase by a chloromercury group in PCMBS-elastase. Throughout this work tosyl-elastase, rather than the native enzyme, was used as the parent structure in order fully to exploit this high isomorphism, and to provide an active site marker to aid in the interpretation of the three-dimensional electron density map. Further heavy atom derivatives suitable for use with the multiple isomorphous replacement technique[11] were prepared by soaking crystals of tosyl and PCMBS-elastase in uranyl nitrate solutions (Fig. 1). This heavy atom salt, which proved very useful in solving the structure of hen egg white lysozyme, was chosen because of the good X-ray scattering properties and high anomalous scattering component of the uranyl ion, probably $UO_2(OH)_n^{(n-2)-}$, bound in such derivatives[12]. Four other derivatives of tosyl-elastase were investigated but not used. Uranyl pentafluoride[13] at 30 mM concentration produced weak binding at the same sites as 5 mM uranyl nitrate, 5 mM phenylmercury acetate gave a usable multisite derivative, and both potassium chloroplantinite and mercury acetate at 5 mM concentration caused extensive crystal deterioration as a result of excessive binding, while at 0·5 mM negligible binding was observed.

X-ray diffraction photographs of the principal reciprocal lattice planes of these crystalline derivatives were taken on a Buerger precession camera using CuKα radiation from a rotating anode X-ray tube, and were measured by a computer-controlled flying spot microdensitometer[14]. Easily interpretable difference Patterson projections at 2·8 Å or 3·5 Å resolution were calculated from these data, as shown, for example, in Fig. 2. The accuracy of the interpretations and the potential usefulness of these derivatives in providing three-dimensional phase information was evaluated by calculating difference Fourier projections, using the phase information from one derivative to phase the amplitude data of another. From the results of these studies, details of which are given elsewhere[15], it was evident that the PCMBS group occupied the same single site as the tosyl group with full occupancy, unlike the situation encountered with this derivative of α-chymotrypsin[8], and that in both uranyl derivatives the uranyl ions bound to another single site with almost full occupancy. All three heavy atom derivatives were therefore excellent for use in determining the structure of tosyl-elastase. The difference Fourier projections also suggested the presence of a secondary uranyl binding site of relatively low occupancy, but because the corresponding peaks failed to appear in subsequent three-dimensional difference Fourier syntheses this site was omitted from the three-dimensional phase calculations. The reliability factors of the centric 0*kl* reflexions, calculated after parameter refinement by the Hart process[16], were 42 per cent and 43 per cent for the single site mercury and uranyl derivatives respectively.

Fig. 1. Preparation of elastase derivatives.

* Covalent inhibition was achieved by slowly adding a two-fold molar excess of sulphonyl fluoride in dioxane, to give a final dioxane concentration of 5 per cent, to a 0·5 per cent solution of elastase in 0·05 M sodium phosphate buffer (*p*H 7·2) containing 2·5 per cent dioxane, and stirring for 18 h at 0° C.

† Uranyl derivatives were prepared by soaking selected crystals of the sulphonyl derivatives in 5 mM uranyl nitrate–1·2 M sodium sulphate–0·01 M sodium acetate (*p*H 5·0) for 2 weeks at 20° C.

Three-dimensional Data Collection

Atoms which are separated by more than the Van der Waals radii are resolved by an accurate structure determination at 3·5 Å resolution. Although confident interpretations of the positions and orientations of many of the amino-acid side-chains could not be made from the 3·5 Å electron density maps of ribonuclease S[17] and lysozyme (personal communication from D. C. Phillips), the overall configuration of the polypeptide chains of these enzymes could be easily discerned. In spite of the greater molecular size of elastase, it was considered that the quality of the heavy atom derivatives was such that the structure of tosyl-elastase at 3·5 Å resolution could be determined with sufficient accuracy to permit a meaningful comparison to be made with the known structure of α-chymotrypsin[4,5].

The stability of elastase crystals to X-irradiation was assessed by collecting two complete sets of 3·5 Å resolution three-dimensional diffractometer data in sequence from a single crystal of tosyl-elastase by the method described below. This involved approximately 11,000 measurements over an irradiation time of about 200 h. The agreement residual of the structure amplitudes of Bijvoet pairs of reflexions

$$R_{(+,-)} = 2 \cdot \frac{\Sigma(|\mathrm{F}|_{hkl} - |\mathrm{F}|_{hk\bar{l}}}{\Sigma(|\mathrm{F}|_{hkl} + |\mathrm{F}|_{h\bar{k}l})}$$

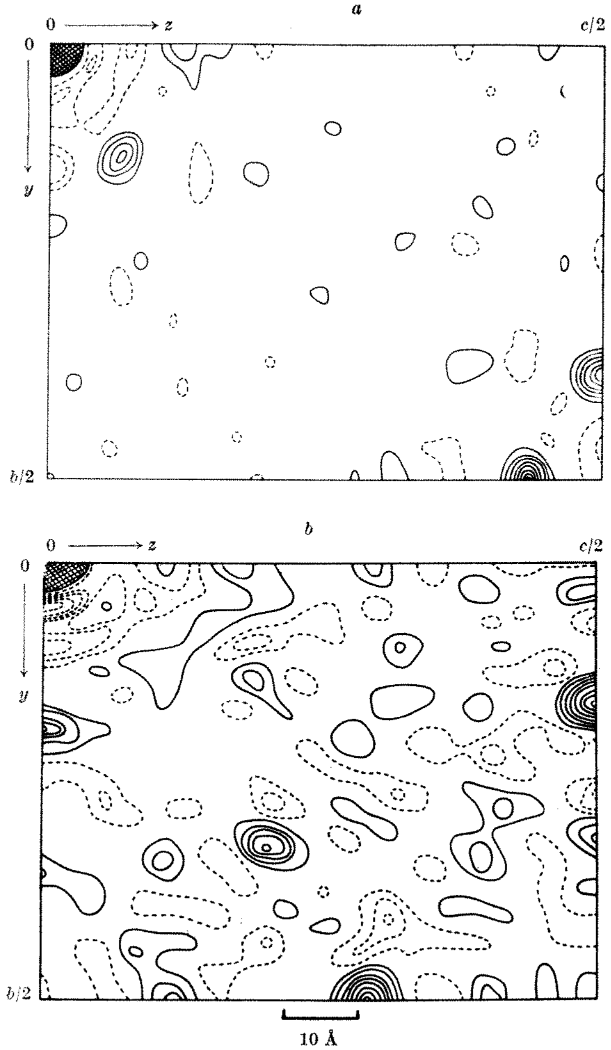

Fig. 2. $0kl$ difference Patterson projections, calculated using tosyl-elastase as the parent structure, (a) of PCMBS-elastase at 2·8 Å resolution, and (b) of uranyl tosyl-elastase at 3·5 Å resolution.

was 1·8 per cent for each data set, while the standard deviation of the averaged values of Bijvoet pairs between the first and the second data set was 3·3 per cent. It was therefore clear that complete 3·5 Å data could be collected from a single crystal without introducing significant errors due to radiation damage. The use of a single crystal of each derivative eliminated several sources of error inherent in the normal practice of collecting three-dimensional data from several crystals of each derivative, including variability in isomorphism, salt concentration and heavy atom site occupancies between crystals, and scaling and weighting errors introduced when data from several crystals are combined.

A complete set of three-dimensional data to 3·5 Å resolution was measured from a single crystal of each of the four elastase derivatives, each crystal used being approximately 0·8 mm in length along each axis. The 5,300 X-ray diffraction intensities within one complete quadrant of the reciprocal sphere of radius 3·5 Å^{-1}, comprising 2,800 independent reflexions, were measured on a Hilger and Watts four-circle diffractometer, which was fitted with helium filled input and output collimators and connected on line to a time-shared Ferranti Argus 312 computer, using CuKα radiation from a Phillips sealed fine focus X-ray tube run at 40 kV and 25 mA. Each reflexion was measured by an ordinate analysis procedure using a diffractometer control program especially written for this study by one of us (H. C. W.) with the help of Mr J. F. W. Mallett. (Programs supplied with the Hilger and Watts PDP8-controlled diffractometer system (Y290) (ref. 18) have now been modified for this ordinate analysis procedure and are available from the authors.) By this procedure the crystal was moved, in steps of 0·02° on the ω circle of the diffractometer, through the setting calculated to satisfy the Bragg angle requirements for the reflexion, the recorded intensity ordinates for the steps being temporarily stored, and then analysed as illustrated in Fig. 3 to produce values for the peak and background intensities. The total scan width (typically 0·8°) was initially set to be twice the previously determined maximum peak width of the strongest reflexions.

The reflexion counting times for each of the four crystals were adjusted to reduce the mean errors from counting statistics to approximately 2 per cent. The counts recorded for corresponding reflexions from the four crystals were thus approximately equal, and in subsequent refinement processes the contributions from the various derivatives were, with proper justification, given equal weight. After each measurement had been made, the reflexion indices, the peak and background intensities, and the position of the peak within the scan were recorded on paper tape.

In comparison with conventional computer controlled background–peak–background counting methods this ordinate analysis procedure, which requires very little extra computer memory, enables a substantial reduction of the reflexion counting time, and hence radiation damage, while retaining the same counting statistics. (A further improvement can be effected by using the more sophisticated ordinate treatment proposed by Diamond[19], although this process requires approximately 4 K more computer memory. Our experience suggests, however, that the Diamond method produces a significant improvement over the method described here only when the data set contains a large number of very weak reflexions.) Using this procedure the complete 3·5 Å data sets from the four elastase derivatives were collected on one diffractometer during July 1968.

Data Processing and Phase Refinement

The measured X-ray intensities were corrected for Lorentz, polarization and absorption[20] factors using a

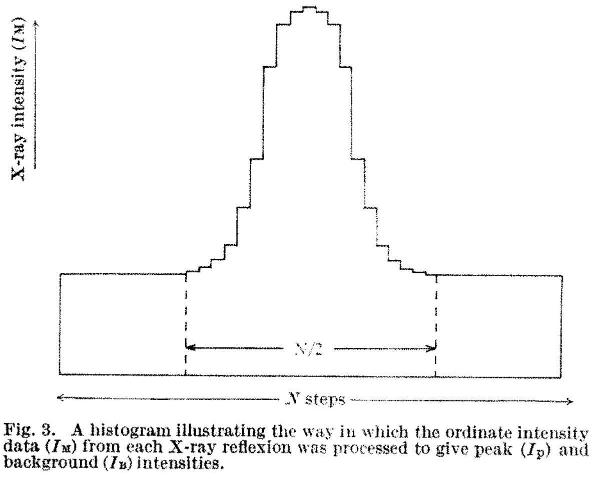

Fig. 3. A histogram illustrating the way in which the ordinate intensity data (I_M) from each X-ray reflexion was processed to give peak (I_P) and background (I_B) intensities.

$$I_P = \left(\sum_{M=n+1}^{M=n+N/2} I_M \right)_{\text{Max}}, \text{ where } n = 0,1,2,---N/2$$

$$I_B = \sum_{M=1}^{M=N} (I_M) - I_P$$

slightly modified version of a general diffractometer output processing program written by Mr T. Gossling. Measurements were rejected if either peak edge was within four steps of a scan extremity. No attempt was made to recover the hundred and fifty or so very weak reflexions rejected from each data set by this procedure, nor the much smaller number of good reflexions which were accidentally rejected because of paper tape punching errors.

The data were checked for internal consistency by comparing the measurements of individual Bijvoet pairs, a very small number of pairs being rejected when the differences were greater than would be expected from anomalous scattering effects. Unpaired reflexions were not rejected by this procedure.

One of the reasons for collecting the X-ray diffraction data from the "double" derivative, uranyl PCMBS-elastase, was to provide an alternative source of the phase information lost by the rejection of reflexions from the data sets of the single heavy atom derivatives, PCMBS-elastase and uranyl tosyl-elastase, thus avoiding the necessity of recollecting this data.

The agreement residuals between Bijvoet pairs for each derivative, $R_{(+,-)}$, which show clearly the effects of anomalous dispersion on the data sets of the heavy atom derivatives, are given in Table 1. This table also includes the values of the scale and temperature factors required to equate the derivative data to that of the parent, and the mean observed differences in structure amplitudes between parent and derivative data, which were calculated by a least squares procedure on 1,400 selected medium intensity reflexions chosen in equal numbers from equal ranges of $\sin^2\theta/\lambda^2$.

Table 1. EXPERIMENTAL DATA STATISTICS

Derivative	$R_{(+,-)}$	c	b	$\overline{\lvert\Delta F_H\rvert}$
Tosyl-elastase (parent)	0·018	1·00	0·00	
PCMBS-elastase	0·031	1·09	−4·36	3·5
Uranyl tosyl-elastase	0·050	0·86	−0·84	5·1
Uranyl PCMBS-elastase	0·054	0·91	−3·13	6·3

$R_{(+,-)}$ is the agreement residual between the structure amplitudes of Bijvoet pairs of reflexions, defined as in the text, calculated from the complete 3·5 Å data sets. c and b are the scale and temperature factors required to equate the derivative data to that of the parent, defined by the expression $F_{H\,\mathrm{corr}} = c \times F_{H\,\mathrm{obs}} \cdot e^{-b\cdot\sin^2\theta/\lambda^2}$. $\overline{\lvert\Delta F_H\rvert}$ is the mean difference in corrected structure amplitudes between parent and derivative data, the mean observed structure amplitude of tosyl-elastase, $\lvert\overline{F_P}\rvert$, being 31·0. The values of c, b, $\overline{\lvert\Delta F_H\rvert}$ and $\lvert\overline{F_P}\rvert$ were calculated from 1,400 medium intensity reflexions selected in equal numbers from equal ranges of $\sin^2\theta/\lambda^2$.

Three-dimensional difference Patterson syntheses, including that of the "double" derivative, were easily interpretable and were used to check the mercury and uranyl single site coordinates derived from the two-dimensional studies described here. These coordinates, plus heavy atom occupancies and isotropic temperature factors, were then refined using alternate cycles of phase determination and least squares refinement[21–23] on the 1,400 selected reflexions, anomalous scattering being ignored. Difference Fourier syntheses were calculated for all three heavy atom derivatives to identify possible subsidiary binding sites, but none were found. The parameters derived from the last cycle of the least squares refinement are given in Tables 2 and 3.

To determine the correct structural enantiomorph, the anomalous dispersion data were included in the phase determination of the 1,400 selected reflexions in the two possible senses[22,27]. The results of these calculations are summarized in Table 3. Because the heavy atom derivatives used contained only two independent heavy atom sites, the mean figure of merit[21] increased for both structural enantiomorphs, although the correct enantiomorph produced the better value. The root mean square lack of closure for the phase triangles of each derivative[21,22,24] became worse for the wrong enantiomorph, however, but improved significantly when the anomalous scattering was included correctly, suggesting that this factor distinguishes more effectively between the two possibilities than does mean figure of merit.

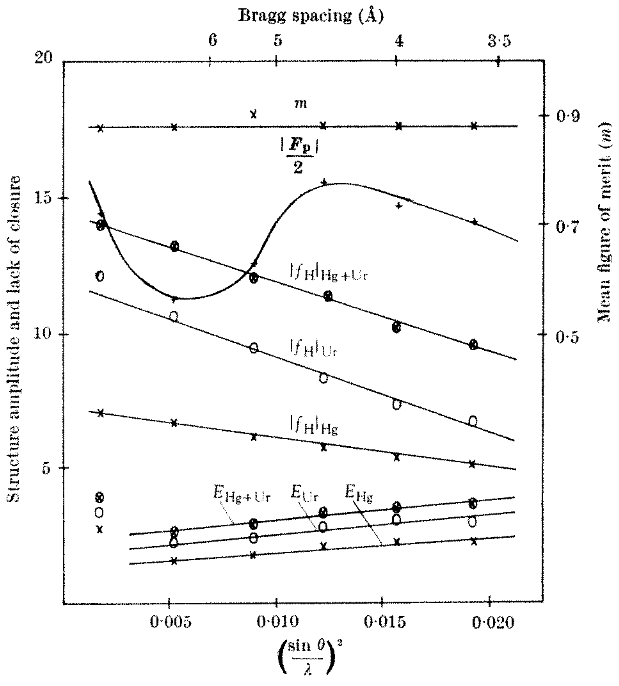

Fig. 4. The variation in the mean structure amplitudes of the parent structure and of the heavy atoms, and in the accuracy of the phase determination as a function of $\sin^2\theta/\lambda^2$. m, $\lvert\overline{F_P}\rvert$, $\lvert\overline{f_H}\rvert$ and E are defined as in Tables 2 and 3. The values of m are given by the right ordinate, and those of $\lvert\overline{F_P}\rvert$, $\lvert\overline{f_H}\rvert$ and E, which are on the same non-absolute scale, by the left ordinate.

The centroid phases[24] of all 2,750 independent tosyl-elastase structure amplitudes were then calculated from the final heavy atom parameters, incorporating the anomalous scattering data[27]. Fig. 4 shows the variations of the mean parent and heavy atom structure amplitudes for the complete data sets, and of the accuracy of the phase determination as a function of resolution. The mean figure of merit averaged over all reflexions, which remained constant over the range of $\sin^2\theta/\lambda^2$ studied, was 0·88, corresponding to a mean error in phase angle of 28°. The figure of merit would have been greater had the centrosymmetric reflexions not been treated in the same

Table 2. PARAMETERS FROM THE LAST CYCLE OF REFINEMENT

Derivative	Heavy atom	x	y	z	k	Z	B	$\lvert\overline{f_H}\rvert$
PCMBS-elastase	Hg	0·910	0·313	0·487	1·007	3·68	22	5·8
Uranyl tosyl-elastase	Ur	0·120	0·585	0·398	1·008	6·48	37	8·8
Uranyl PCMBS-elastase	Hg	0·915	0·315	0·468	0·999	4·65	28	11·5
	Ur	0·121	0·585	0·398		5·85	25	

x, y and z are the fractional co-ordinates of the heavy atom sites in one elastase molecule. k is a scale factor by which the derivative structure amplitudes are multiplied to put them on the same non-absolute scale as the parent structure amplitudes. Z and B are the values of the heavy atom occupancies and isotropic temperature factors obtained from the refinement, the occupancies being on the same arbitrary scale. $\lvert\overline{f_H}\rvert$ is the average value of the root mean squares of the heavy atom structure amplitudes, the mean observed structure amplitude of tosyl-elastase $\lvert\overline{F_p}\rvert$, on the same scale, being 31·0. The data in this table were obtained by refinement of the 1,400 selected reflexions.

Table 3. EFFECT OF INCLUSION OF ANOMALOUS DISPERSION DATA ON THE PHASE DETERMINATION

Anomalous dispersion data	$\bar{m}$	E_{Hg}	E_{Ur}	E_{Hg+Ur}	R_{Hg}	R_{Ur}	R_{Hg+Ur}
Not included (from last cycle of refinement)	0·778	2·10	3·31	4·03	0·40	0·41	0·38
Included incorrectly	0·837	3·38	3·54	4·27	0·61	0·45	0·42
Included correctly	0·913	1·98	2·84	3·19	0·37	0·34	0·30

$\bar{m}$ is the mean figure of merit[21]. E is the average root mean square lack of closure of the phase triangles for each derivative[21,22,24]. $R = \Sigma\frac{\lvert(F_D - F_P) - f_H\rvert}{\Sigma\lvert F_D - F_P\rvert}$

The values of E and R for PCMBS-elastase, uranyl tosyl-elastase and uranyl PCMBS-elastase are indicated by the subscripts Hg, Ur and Hg + Ur respectively. The data in this table were obtained by refinement of the 1,400 selected reflexions. The values of the ratios of the imaginary part to the real part of the heavy atom scattering factors were taken from the *International Tables for X-ray Crystallography*, **3**, 215 (1962).

way as the non-centrosymmetric reflexions. The achievement of such accurate phases was greatly facilitated by the $P2_12_12_1$ spacegroup of elastase, which has a uniquely defined origin and gives a large number of centric reflexions. The mean heavy atom structure amplitude, $|f_H|$ decreased, and the root mean square lack of closure for each derivative, E, increased as $\sin^2 \theta/\lambda^2$ increased, but even at the highest limit of this study the values of $|f_H|$ were significantly greater than the respective values of E, indicating that all three derivatives were providing accurate phase information at 3·5 Å resolution. It is significant that while uranyl tosyl-elastase contributed more than PCMBS-elastase to the phase determination at low resolution, the convergence of the $|f_H|$ and E curves in Fig. 4 indicates that PCMBS-elastase will continue to provide accurate phase information to a higher resolution than will uranyl tosyl-elastase, because of its extremely high isomorphism with the parent compound, tosyl-elastase.

Electron Density Map

The "best" Fourier synthesis[24] of tosyl-elastase was calculated, in sections perpendicular to the a axis, at intervals of $a/60$, $b/60$ and $c/60$, using a Fortran program written especially for protein structure calculations by Dr R. A. Crowther. These sections were displayed in contour form on a computer controlled oscilloscope, and recorded on 35 mm film[25]. They were enlarged by back-projection and copied onto perspex sheets to the scale 2 cm = 1 Å for subsequent interpretation and model building.

The molecular boundaries of the tosyl-elastase molecules are clearly visible in the electron density map, each molecule being an oblate ellipsoid having approximate dimensions 53 Å along the x axis, 40 Å along the y axis and 38 Å along the z axis. Neighbouring molecules have relatively few points of contact and are separated by wide interstices filled with salt solution in which no strong features appear in the electron density map. By contrast, the density associated with the atoms of tosyl-elastase stands out clearly. The course of the single polypeptide chain can be traced unambiguously from one end to the other as a column of continuous high density, which is on average three to four contours above the general background level. At regular intervals along the chain side-chains can be seen branching out in various directions. The peaks of the main chain density are located at these branch points, which clearly correspond to the α-carbon atom positions, and not at the positions of the peptide carbonyl groups[12,26]. At no point is the course of the polypeptide chain less well defined than at any other, except for one small loop near the amino terminus which projects outwards from the surface and has no contacts with neighbouring molecules. Although the electron density of this loop is only two contours above the general background level it is nevertheless easily interpretable. Several of the amino-acid side-chains are sufficiently well defined for them to be identified unambiguously. The four cystine disulphide bridges are each clearly visible as a column of high density, on average six contours above the general background level, linking two parts of the main chain, while both methionine residues can be recognized by their high sulphur peaks. The positions, orientations and characteristic planarity of the aromatic rings of the tryptophan, tyrosine, phenylalanine and histidine residues are in most cases clearly defined. Glycines are usually distinguishable from residues bearing side-chains. The side-chains of the other residues appear as stalks or bulges of various sizes, and in general cannot be identified from the electron density alone. Fig. 5 is a stereophotograph of the central part of seven sections from the complete three-dimensional electron density map of tosyl-elastase, which illustrates many of these features. It shows clearly the low background density of the intermolecular interstices and the clearly defined electron density of the several short stretches of extended chain which traverse these sections. The positions of the prominent sulphonyl group of the tosyl group, which is attached to the active centre serine residue, and of other residues of catalytic importance are indicated. An illustrated discussion of the detailed interpretation of the whole map, and of the relationship between conformation and

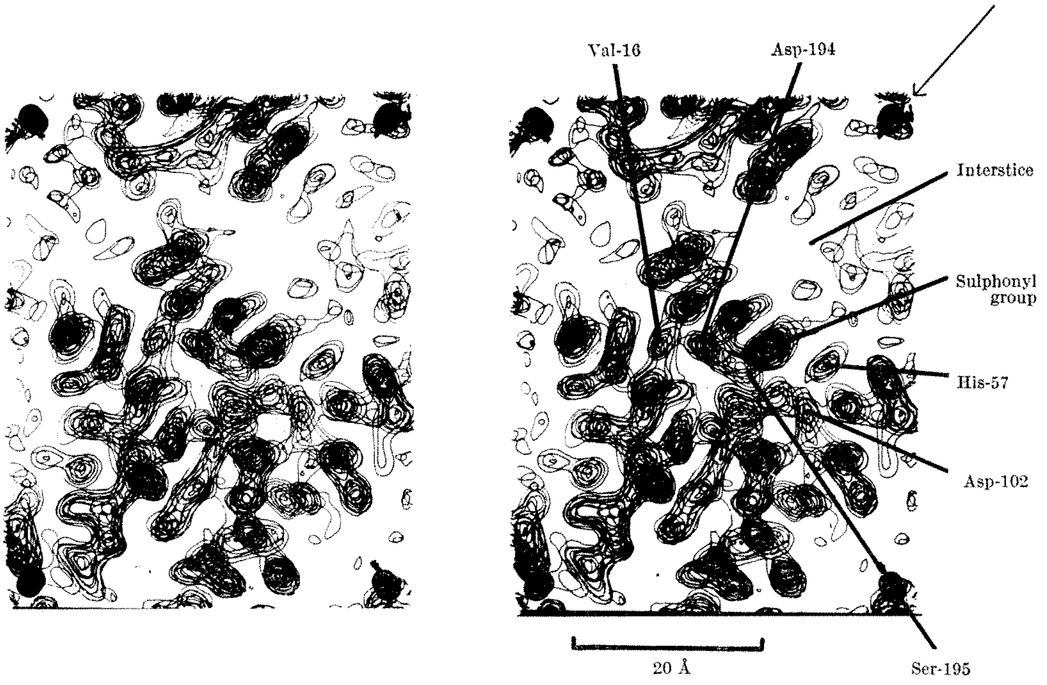

Fig. 5. A stereophotograph of the central region ($y = +10/60$ to $+50/60$, $z = +10/60$ to $+50/60$) of a stack of seven sections ($x = -13/60$ to $-7/60$) from the complete three-dimensional electron density map of tosyl-elastase. The positions of the large intermolecular interstice adjacent to the active centre, the dense sulphonyl group of the tosyl inhibitor attached to the γ-oxygen atom of the active centre serine residue, Ser-195, and the side chains of some of the catalytically important residues, Val-16, His-57, Asp-102, Asp-194 and Ser-195, are marked. The arrow indicates the direction, perpendicular to the x axis, from which the configuration of these catalytically important residues is portrayed in Fig. 4 of the third article of this series[6]. The chymotrypsinogen A numbering scheme has been used[2].

function of these catalytically important residues is given in the third article of this series[6].

By contrast with the situation found in α-chymotrypsin[5], the active centre of the elastase molecule is not blocked by intermolecular contacts, but faces one of the largest interstices in the crystal structure, this cavity being approximately 18 Å in diameter. It is hoped to exploit the accessibility of the active centre of elastase in future studies, at a higher resolution, of enzyme–substrate complexes and of "small" molecules the structures of which are difficult to determine by conventional methods.

We thank our numerous colleagues at the MRC Laboratory of Molecular Biology for their help and especially Dr B. S. Hartley for suggesting this project and for his continued encouragement, Dr P. B. Sigler for sulphonyl fluoride inhibitors, Dr C. C. F. Blake for advice on the synthesis of uranyl derivatives, and the directors and staff of the Computer Units of the Imperial College of Science and Technology, London, and the Institute of Theoretical Astronomy, Cambridge, for provision of computing facilities.

One of us (D. M. S.) acknowledges the financial support of an MRC scholarship and a Beit Memorial Medical research fellowship.

Three-dimensional Structure of Tosyl-elastase

by
D. M. SHOTTON
H. C. WATSON
Molecular Enzymology Laboratory, Department of Biochemistry, University of Bristol, Bristol, BS8 ITD

Amino-acid sequence studies and crystallographic evidence are used to construct an atomic model of elastase, which is compared with the structure of α-chymotrypsin. The single polypeptide chain of elastase is folded into two distinct and structurally similar halves displaying opposite polarity.

It has long been predicted that enzymes with homologies of amino-acid sequence and common catalytic mechanisms should have similar tertiary structures. For the pancreatic serine proteinases, there is experimental support for these predictions. Sigler *et al.* have found that the two disulphide bridges present in trypsin but absent in chymotrypsin and elastase can be built into the atomic model of α-chymotrypsin with little or no distortion of the polypeptide chain[1], Schroeder and Shaw[2] have observed an autolytic cleavage in trypsin between Lys-145* and Ser-146, a point immediately adjacent to the position of autolytic cleavages in δ-chymotrypsin, and Hartley[3] has shown that the trypsin and elastase side chains can be substituted for those present in a skeletal model of α-chymotrypsin with no gross distortion of the polypeptide chain.

This article describes a combination of the results of the chemical and crystallographic studies of porcine pancreatic elastase (EC 3.4.4.7), reported in the two preceding articles[4,5], which has led to the construction of an atomic model of this enzyme. The information thus obtained has allowed a comparison to be made between the structures of elastase and α-chymotrypsin, a homologous pancreatic serine proteinase[4], and has permitted a detailed analysis of the conformation adopted by the single polypeptide chain of elastase.

Interpretation of the Electron Density Map

Tosyl-elastase is an inhibited derivative of elastase which has a *p*-toluenesulphonyl (tosyl) group attached to the γ-oxygen of the active centre serine residue, Ser-195. A map of the electron density distribution of crystalline tosyl-elastase at 3·5 Å resolution was prepared as described in the second article in this series[5]. The entire course of the single polypeptide chain could be followed easily and unambiguously through the electron density map, and it was quickly apparent that the elastase molecule has the same general conformation as α-chymotrypsin. The N and C-termini of the chain, the four disulphide bridges and the sulphonyl group of the tosyl inhibitor residue were obvious features of the electron density distribution[5],

---

* To aid in the comparison between the various mammalian serine proteinases, we use the numbering of the amino-acid residues in the chymotrypsinogen A sequence to describe the position of amino-acid residues in these homologous proteins[4].

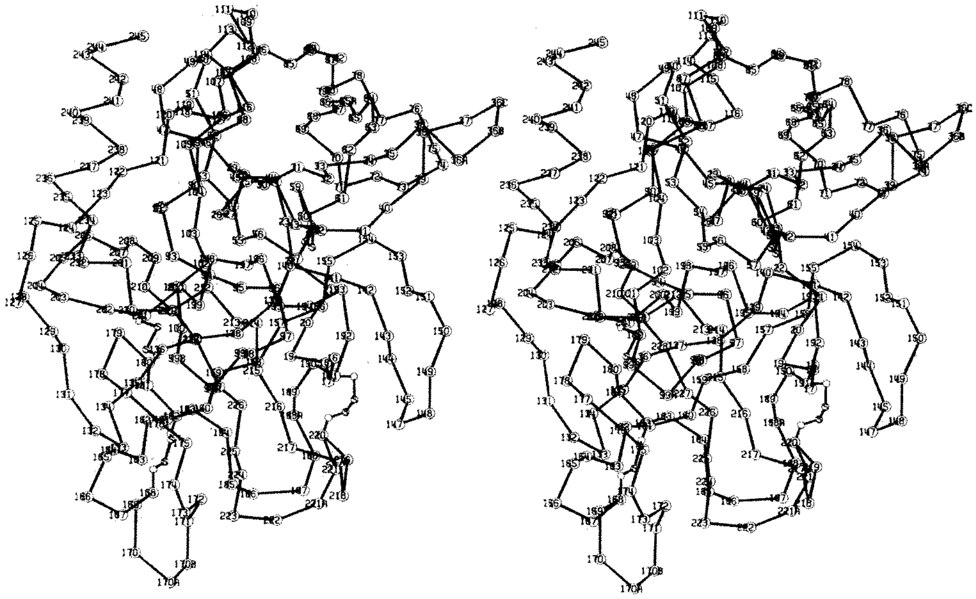

Fig. 1

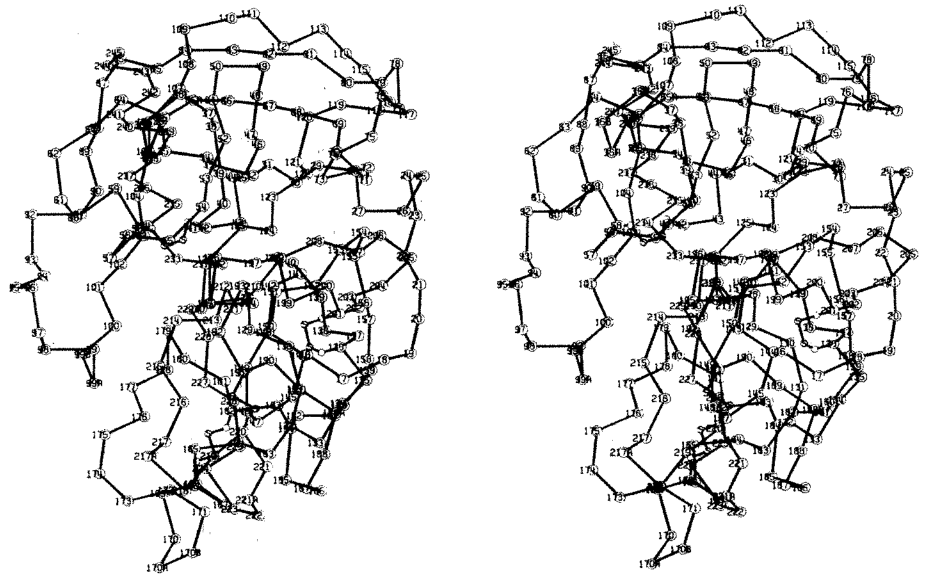

Fig. 2

Figs. 1 and 2. Computer-prepared stereo views of the conformation of the elastase polypeptide chain, prepared from the approximate α-carbon atomic coordinates of tosyl-elastase, measured from the preliminary model. Residues are numbered on the chymotrypsinogen A scheme, "insertions" relative to the chymotrypsinogen A sequence being numbered 36A, 36B and so on[2]. Residue 146 is not present in elastase. For clarity all side chains are omitted except those forming the four disulphide bridges. In both views the crystallographic x axis is vertical. Fig. 1 is a view down the y axis and Fig. 2 is a view from 90° to the right, down the z axis.

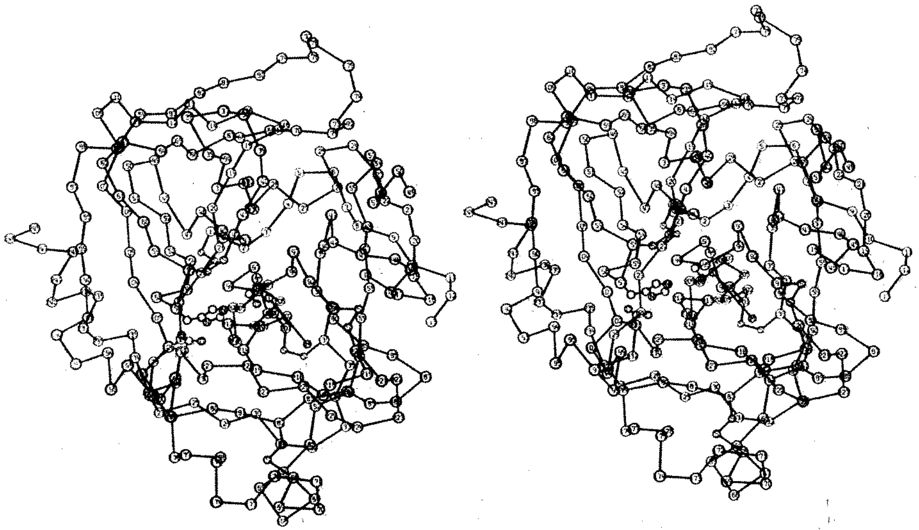

Fig. 3

Fig. 3. A computer-prepared stereo view of the conformation of the α-chymotrypsin polypeptide chain, prepared from the atomic coordinates of the tosyl α-chymotrypsin model of Blow and his collaborators[7-9]. The numbering scheme is that of chymotrypsinogen A[2]. The side chains of some of the important residues are shown, and the position of the tosyl inhibitory group in the substrate binding cleft is indicated by the line joining the positions of the methyl carbon (M) and the sulphonyl sulphur (I). The molecular orientation is similar to that of tosyl elastase shown in Fig. 2, and the similarity of three-dimensional conformation can be readily seen.

providing reference points from which to start a detailed interpretation. Although some of the amino-acid side chains could be identified with reasonable certainty from their electron density alone[5,6], we relied heavily on our knowledge of the amino-acid sequence of elastase[4] for the detailed interpretation of the electron density distribution of tosyl-elastase. This interpretation was made without knowledge of, or reference to, the detailed structure of α-chymotrypsin determined elsewhere by Blow and his collaborators[1,7-9].

With the aid of a half-silvered mirror device similar to that described by Richards[10], a skeletal model of tosyl-elastase was constructed on the scale 2 cm = 1 Å, using standard components designed by one of us (H. C. W.) in conjunction with Dr J. C. Kendrew. Throughout the building process the accuracy of the interpretation was checked and confirmed by the excellent correlation obtained between the expected amino-acid side chain[4] and the observed electron density[5,6]. The aromatic side chains formed very obvious markers which greatly facilitated the interpretation. This model satisfactorily accounts for all the electron density in the map, there being no point where the chemical and crystallographic evidence are in conflict. The distal parts of some long side chains, especially those of arginines and lysines, are not represented in the map, due to a degree of free-rotational disorder in these groups rather than to lack of resolution. As expected at 3·5 Å resolution, the dimpling of aromatic rings and forking of the side chains of valine, threonine, leucine and isoleucine residues are not apparent, and the carbonyl oxygens of the peptide bonds are not resolved from the rest of the main chain density. We are therefore unable from the 3·5 Å resolution map to determine the exact orientation of peptide groups, and thus can only discuss hydrogen bonding patterns within the molecule in general terms.

General Conformation and Comparison with α-Chymotrypsin

The elastase polypeptide chain is folded on itself in a series of large loops to form a compact globular molecule in which there are only two small regions of α-helical conformation, between residues 164 and 170 and at the C-terminus between residues 237 and 245, the rest of the chain tending to be fully extended. This is shown in Figs. 1 and 2, which are computer-prepared stereo views of the conformation of the elastase polypeptide chain, in which the single polypeptide chain can be traced from the buried N-terminal residue, Val-16, which forms an internal ion pair with the carboxyl group of Asp-194, to the α-helical "tail", terminating in residue Asn-245.

Elastase shows extensive amino-acid sequence homologies with the B and C chains of α-chymotrypsin[4]. We have been able to directly compare the three-dimensional structures of elastase and α-chymotrypsin. (To do this, our skeletal model of elastase was taken to the MRC Laboratory of Molecular Biology, Cambridge, where direct comparisons were made with the model of α-chymotrypsin built by Blow and his collaborators.) These comparisons show that the conformations adopted by the single polypeptide chain of elastase and the B and C chains of α-chymotrypsin are extremely similar, as are also the orientations of the amino-acid side chains of corresponding residues within these chains, thus confirming the predictions referred to in the introduction. This similarity can be seen by comparing the stereo view of the elastase structure given in Fig. 2 with a stereo view of the α-chymotrypsin molecule in a similar orientation, given in Fig. 3.

Where differences between corresponding internal residues in the two enzymes do occur, these are generally of a most conservative nature and do not involve charged residues. Where the size difference between dissimilar residues is great, compensating substitutions are found in adjacent regions so that the identity of tertiary structures is preserved. For example, the difference at position 29 between a serine residue in elastase and a tryptophan in α-chymotrypsin is offset by the occurrence of a histidine residue in elastase and a valine in α-chymotrypsin at position 200.

Because the elastase polypeptide chain contains twelve more residues than the B and C chains of α-chymotrypsin[4], some differences in local conformation in the vicinity of these "insertions" must occur. Fig. 5 (described in detail in the last section) shows that the insertions in elastase relative to α-chymotrypsin all occur on the molecular surface, usually at the ends of loops which "expand" to accommodate these changes without disturbing the identity of conformation of the rest of the chain.

The analyses of the sequence homologies between the pancreatic serine proteinase given in the first article in this series[4] help to explain the remarkable similarity of tertiary structure exhibited by these two enzymes. While the overall identity of corresponding residues in elastase and α-chymotrypsin is only 39 per cent, the degree of homology in the molecular interior is 81 per cent. Most of the differences which exist between them are therefore located on the molecular surface, which is fairly hydrophilic in nature, and seems merely to provide an insulating layer one polypeptide chain thick serving to shield the hydrophobic interior from the disruptive hydrating effects of the solvent.

These results suggest that the mammalian serine proteinases are a family of very similar enzymes built to a basic plan which has been conserved during divergent evolution. It therefore seems almost certain that the three-dimensional structure of trypsin will closely resemble those of elastase and α-chymotrypsin, for it shows roughly the same degree of amino-acid sequence homology to these two enzymes as they do to each other[4]. As in the α-chymotrypsin model[1], the two "extra" disulphide bridges of trypsin can be built into the elastase model with scarcely any distortion of the polypeptide chain. The distance in the elastase model between the α-carbon atoms of residues 22 and 157 is 6·6 Å, and between those of residues 127 and 232 is 6·2 Å, while the mean distance between α-carbons of the four cystines is 5·8 Å.

Elastase is produced from its zymogen, proelastase, by a tryptic cleavage which removes a small activation peptide from the N-terminus of the polypeptide chain, in an activation process resembling that of trypsinogen[11]. Proelastase binds specifically to elastin, a natural substrate for elastase[11], showing that the substrate binding site is already formed and accessible in the zymogen. It is therefore likely that the conformation of the proelastase chain is very similar to that of the active enzyme.

Substrate Binding Site

Steitz *et al.*[12] have shown that N-formyl-L-tryptophan binds to α-chymotrypsin so that the aromatic side chain lies in a deep hydrophobic cleft adjacent to the catalytic site, while the carboxyl group lies next to the active centre serine residue, Ser-195. They have concluded, therefore, that this cavity, which is also the site occupied by the toluene group of tosyl-α-chymotrypsin, is the binding site for the aromatic side chains of chymotrypsin substrates. This cavity is also present in the elastase molecule, but its mouth is partially occluded by the side chain of a valine residue at position 216, which is absent in trypsin and the chymotrypsins, where the corresponding residues are glycines. Further, the bottom of the cavity in elastase is partly filled by the side chain of Thr-226, again absent in the chymotrypsins and trypsin, where the corresponding residues are also glycines. These extra side chains in elastase make it sterically impossible for bulky aromatic side chains to be accommodated in this cavity, explaining the complete lack of activity of elastase towards such substrates[13]. Elastase has a substrate specificity directed towards uncharged non-aromatic amino-acids[14,22], especially alanine[15,16]. It is clear from the tosyl elastase model that N-formyl-L-alanine is able to bind to elastase in an identical fashion to that in which N-formyl-L-tryptophan binds to α-chymotrypsin[9,12], with the amido-nitrogen able to form a hydrogen bond with the carbonyl group of Ser-214, and the side chain methyl group lying above and in Van der Waals contact with the side chain of Val-216. These substrate interactions would position the carbonyl group of the peptide bond to be split in a favourable position for a nucleophilic attack on its carbonyl carbon by the γ-oxygen of the active centre serine residue of elastase. It seems likely that the binding of peptides to elastase also involves several other sites of weak interaction.

These findings support the explanation of the substrate specificity of trypsin given by Hartley[3], who has shown that residue 189, a serine residue in elastase and the chymotrypsins, which lies at the bottom of this cavity, is an aspartic acid residue in trypsin. It is suggested that the large basic side chain of a trypsin substrate enters the substrate binding cavity of trypsin to form an ion pair with the carboxyl group of this buried aspartic acid, explaining the strong specific binding of substrates observed for this enzyme.

One obvious prediction which can be made from these studies is that a trypsin-like serine proteinase, which contained a basic residue at position 189 instead of an aspartic acid, and glycine residues at positions 216 and 226, would be an excellent enzyme for cleaving peptide bonds on the C-terminal side of aspartic and glutamic acid residues.

Catalytic Site

Crystals of native elastase show substantial activity towards N-benzoyl-L-alanine methyl ester (about 40 per cent that of the enzyme in solution) (D. M. S., manuscript in preparation) and are also inhibited by soaking with various sulphonyl fluoride derivatives[5]. In the crystal lattice the active centre is not obstructed by intermolecular contacts with neighbouring molecules, in contrast to the situation found in crystals of bovine α-chymotrypsin[1], but faces one of the largest interstices in the crystal lattice. In addition, the differences in conformation between crystalline native elastase and tosyl-elastase, determined by difference Fourier projections, are very small and confined to the local environment of the tosyl group[6]. These findings indicate that the conformation of crystalline tosyl-elastase closely resembles that of the uninhibited enzyme in solution. This provides the justification for making deductions about the catalytic mechanism of elastase from the crystallographically determined structure of tosyl-elastase.

In elastase, as in α-chymotrypsin, the active centre is formed in a slight groove where catalytically important residues from different regions of the sequence are brought into close spatial proximity. Blow *et al.*[17] have proposed that in α-chymotrypsin a "charge relay system" exists between a buried aspartic acid residue, Asp-102, and the active centre serine residue, Ser-195, mediated by the imidazole ring of the active centre histidine residue, His-57, whose ring nitrogen atoms are within hydrogen bonding distance of the carboxyl group of the aspartic acid and the γ-oxygen atom of the serine. This would enable charge to be transferred from the buried aspartic through a hydrophobic environment to the serine γ-oxygen atom, explaining the extraordinary nucleophilicity of the active centre serine residue. In the three-dimensional structure of tosyl-elastase the α-carbon atoms of Asp-102, His-57 and Ser-195 occupy the same relative conformation as those in α-chymotrypsin, suggesting that in native elastase a similar charge relay system exists. The common catalytic mechanism of these two enzymes[18] is thus explained simply to be the result of the catalytically functional groups occupying identical configurations. The presence of the side chain of Val-216 in elastase, however, prevents the tosyl group of tosyl-elastase occupying the same relative conformation as it does in tosyl-α-chymotrypsin[9]. Instead of being tucked into the substrate binding cavity near the catalytic site, it points in the opposite direction, interacting with the imidazole ring of His-57 and displacing it outwards from its presumed native configuration by a rotation of about 180° around its α—β bond (see Figs. 3 and 4). In this position the imidazole ring lies almost parallel to and in Van der Waals

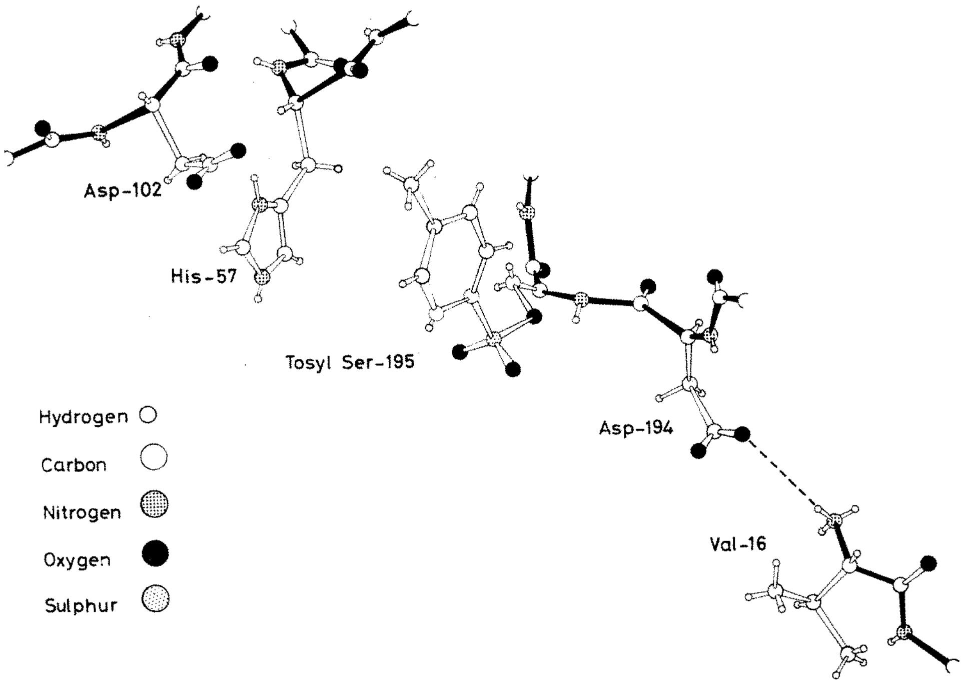

Fig. 4. A diagram showing the positions and orientations of the side-chains of the three catalytically important amino-acid residues of tosyl-elastase and of the two residues which form the internal ion pair. In native elastase, where the bulky tosyl group is absent, the imidazole ring of His-57 is thought to lie between the side chains of Asp-102 and Ser-195, rather than pointing out into solution.

contact with the toluene ring of the tosyl group, and is thus unable to form a charge relay system. The carboxyl group of Asp-102 points towards Ser-195, but forms a hydrogen bond with another nearby side chain, that of Ser-214, instead of with the imidazole ring of His-57. The relative positions of these groups can be seen in the electron density sections of the tosyl-elastase Fourier shown in the second article[5], and are illustrated in Fig. 4 and elsewhere[6]. In the isomorphous PCMBS elastase derivative[5] the chloromercuri group, which replaces the methyl group at the end of the toluene ring of tosyl-elastase, lies about 4 Å from the $N^{\delta 1}$ nitrogen atom of the His-57 side chain.

A similar grouping of a serine, a histidine and an aspartic acid residue has been observed at the active centre of subtilisin BPN′[19], a member of a separate class of bacterial serine proteinases, suggesting that the bacterial and the mammalian serine proteinases have independently acquired a common catalytic mechanism.

Hess and his collaborators[20] have shown that in acetylated δ-chymotrypsin, prepared by tryptic cleavage of the Arg-15—Ile-16 peptide bond in fully acetylated chymotrypsinogen, deprotonation of the α-amino group of the Ile-16, $pK_a = 8{\cdot}3$, results in loss of enzymic activity and in a conformational change, observed by changes in optical rotation, to a state resembling that of the inactive zymogen. Blow and his collaborators[1,7] have shown that in α-chymotrypsin the α-amino group of Ile-16 forms an internal ion-pair with the carboxyl group of Asp-194, adjacent to the active centre serine residue, and have proposed that this ion-pair stabilizes the active conformation of chymotrypsin. In tosyl-elastase at *p*H 5·0, Val-16 and Asp-194 form an internal ion-pair identical to that found in α-chymotrypsin (see Figs. 1–4). It might therefore be thought that the role of this ion pair in creating and maintaining the active conformation in these two enzymes is identical. The pK_a of the α-amino group of Val-16 in elastase has been determined as 9·7 (H. Kaplan, K. J. Stevenson and B. S. Hartley, manuscript in preparation), substantially higher than that of Ile-16 in chymotrypsin, and has been shown to have a very low nucleophilic reactivity, suggesting it is buried in the molecular interior, at all *p*H values up to 10·5, at which *p*H the protein starts to denature. Further, Kaplan and Dugas[15] have shown that, in contrast with the situation in chymotrypsin, the optical rotation does not change on deprotonation of the α-amino group, and that both native and fully acetylated elastase remain fully active towards N-benzoyl-L-alanine methyl ester at all *p*H values between 8 and 10. This indicates that, at least for this substrate, the rate-limiting step in the enzymic activity of elastase is independent of the state of ionization of the α-amino group of Val-16, and hence of the integrity of the Val-16–Asp-194 ion pair.

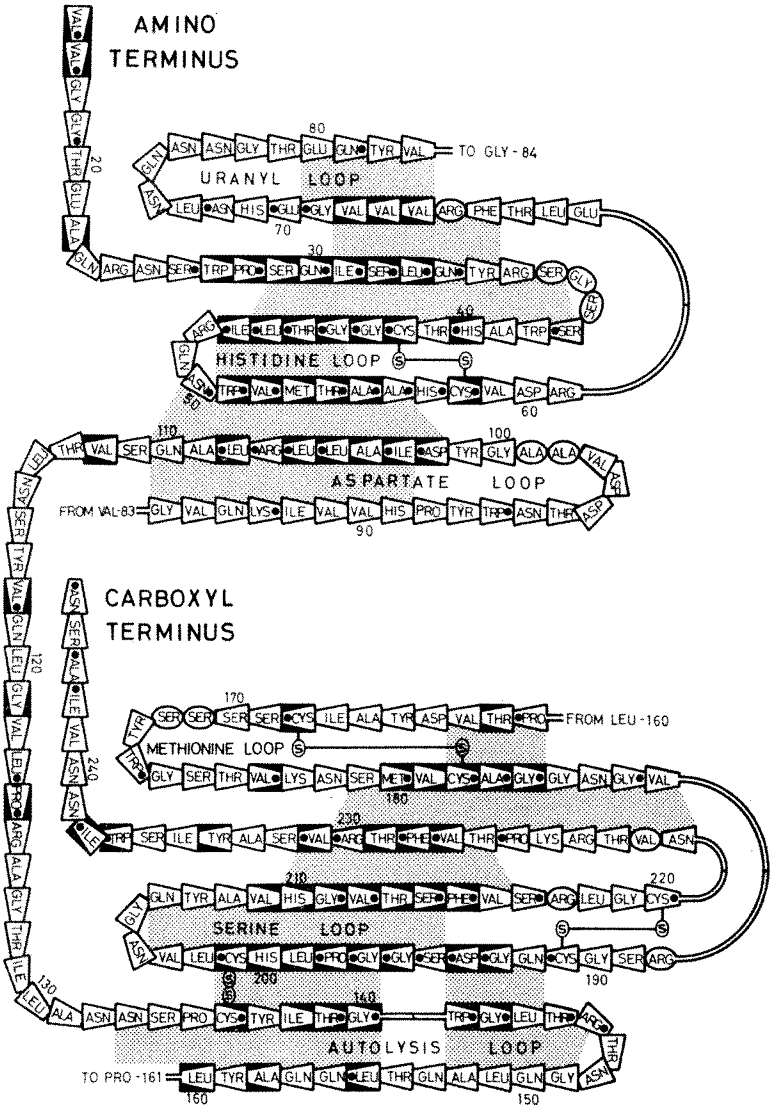

Fig. 5. A diagrammatic representation of the conformation of the elastase polypeptide chain, which is folded into two distinct halves in which looping of the chain brings neighbouring regions into close antiparallel contact. All neighbouring antiparallel regions in the molecule are represented as such in the diagram, those regions where chains run within hydrogen bonding distance of one another being shaded with spots. Internal residues, judged to be inaccessible to water molecules in the atomic models of elastase and α-chymotrypsin[3], are boxed with heavy outlines. Residues which are homologous in elastase, trypsin, chymotrypsin A and chymotrypsin B[2] are indicated by a black dot next to the residue name. Disulphide bridges are drawn. The numbering system is that of chymotrypsinogen A[2]. "Insertions" in elastase are indicated by ovals, and numbered 36A, 36B, etc. In elastase, residue 146 is a deletion, while in chymotrypsin A residues 147 and 148 have been removed by autolytic cleavages. Two breaks in the chain have had to be made in the diagram, between residues 83 and 84 and between residues 160 and 161, in order to represent the three-dimensional conformation of elastase on a plane surface. The diameter of the elastase molecule corresponds to about 10 residues length of extended polypeptide chain.

Organization of the Elastase Molecule in Two Similar Halves

The most striking feature of the general conformation of the elastase molecule is the manner in which the chain is organized into two clearly defined halves, in intimate contact and presumably held together in a stable conformation by hydrogen bonds and hydrophobic interactions. This can be clearly seen in Fig. 2, where the N-terminal half lies above and slightly to the left of the C-terminal half. Within each half of the elastase molecule the chain is folded into a series of large loops, in such a way that the chain runs antiparallel to neighbouring regions in the sequence at a distance of about 5 Å for several residues. These loops have also been noted in α-chymotrypsin[7], where the higher resolution of the structure determination permits the allocation of specific hydrogen bonds[8,9], which are of an irregular antiparallel β-pleated-sheet type. Five of the six most prominent loops in elastase are named in conformity with the usage of other workers[3,9] (see Fig. 5), and we have named the sixth loop, made by residues 66 to 83, the uranyl loop, because in two of the heavy atom derivatives of elastase it forms the principal binding site for a uranyl ion[5,6], which is bound within contact distance of the side chains of Val-67, Glu-70, Glu-80 and Tyr-82, and of the main chain carbonyl oxygen of Leu-73.

In order to clarify the principles of organization involved in the apparently aimless meanderings of the elastase polypeptide chain (Figs. 1 and 2), an attempt has been made in Fig. 5 to represent the conformation within the two halves of the molecule. To do this, all the neighbouring antiparallel regions of the molecule were first represented as such in the diagram, the alignment of the amino-acid residues being kept as close as possible to that observed in the elastase model, and then loops indicating the positions of the remaining stretches of the chain were added, giving reasonably accurate representations of the ends of the various loops in the molecule. The seventy-five internal residues, judged to be inaccessible to water in the atomic models of both elastase and α-chymotrypsin[4], and the eighty-two residues which are homologous in elastase, trypsin, chymotrypsin A and chymotrypsin B[4], are especially indicated in Fig. 5, and can be seen to be concentrated in the middle of the two parts of the diagram. These two regions thus clearly represent the hydrophobic internal homologous "cores" of the two halves of the molecule around which the rest of the molecule is folded.

It can be clearly seen in Fig. 5, which should be studied in conjunction with Figs. 1 and 2, that the two halves of the molecule are similar, each containing six areas of antiparallel interactions. The surprising result to emerge from this analysis is that the organization within the N-terminal half of the molecule, traced from the N-terminus to the middle of the chain, resembles that within the C-terminal half of the molecule, traced from the C-terminus to the middle of the chain. Loops possessing similar properties and positions within the elastase molecule occupy corresponding positions in the two halves of Fig. 5. For instance the histidine and the serine loops are both internal and tend to be both hydrophobic and highly homologous with the other serine proteinases (except at the ends of the loops, which protrude onto the molecular surface, where the hydrophobic homologous character is immediately lost). Both are slightly helical and are stabilized by disulphide bridges, and each bears one of the catalytically essential residue, namely His-57 or Ser-195.

Within each half of the molecule the antiparallel chains form a twisted sheet which curves round to unite with itself to form a "cylinder" around the surface of which the chains run in an oblique fashion. This can be visualized diagrammatically for the N-terminal half of the molecule by bending Fig. 5 so as to connect residues 83 and 84, and similarly for the C-terminal half by connecting residues 160 and 161, but it is much more easily seen in the stereo views of elastase (Figs. 1 and 2). This is especially clear in the N-terminal half of the molecule, where in Fig. 1 the twisted sheet of antiparallel chains can be seen spiralling away from the front left-hand chain of the aspartate loop (residues 84 and 91), and up to the right, to eventually reunite with the adjacent section of the chain (residues 80 to 83) where it forms part of the uranyl loop. In the C-terminal half of the molecule this same pattern is repeated upside down, but is more difficult to distinguish. These "cylinders" lie one above the other, and are oriented approximately at right angles to one another. It is obvious that to describe the elastase structure in these terms is a gross oversimplification, and has value only in as much as it permits an understanding of the basic similarity of organization exhibited by the two halves of the molecule.

Except where the histidine and serine loops run fairly close to one another for a few residues, there is no place in the molecule where adjacent chains run parallel rather than antiparallel. The tendency of antiparallel chains to spiral round one another to form slightly helical loops and twisted sheets has been observed in other enzymes, notably in carboxypeptidase A[21] and to a lesser extent in subtilisin BPN′[19], while the peculiar "cylindrical" arrangement of antiparallel chains described above for elastase has been previously observed in α-chymotrypsin[8,9]. The diagram used by Blow and his collaborators primarily to illustrate the hydrogen bonding pattern between the antiparallel loops, rather than to give an accurate representation of the three-dimensional conformation of α-chymotrypsin, differs significantly from Fig. 5, however. In that diagram the correspondence between similar loops is not clear, and an apparent similarity is shown between the arrangement of chains in the two halves of the molecule when both halves are traced from amino to carboxyl end, in contrast to the situation observed in elastase and illustrated in Fig. 5.

The similarity in conformation between the two halves of the elastase molecule is striking, especially because it cannot be accounted for by gene duplication. It indicates the existence of similar packing forces generated by two quite different stretches of polypeptide chain, in which the polarity of the chain is not of prime importance.

It is clear from the preceding discussion and Figs. 1, 2 and 5 that the proelastase polypeptide chain may be folded with equal ease from the N-terminal or the C-terminal end, but that both these procedures will necessitate threading either the serine or the histidine loop through pre-folded sections of the chain to achieve the native conformation, an intrinsically unlikely occurrence. It seems more likely, as has been suggested for chymotrypsin[7], that after synthesis folding occurs not as a one-step process but in stages, the internal hydrophobic homologous loops (Fig. 5) first forming to give nuclei of highly stabilized local conformation around which the more variable hydrophilic regions of the chain can then condense to give the specific conformation required for enzymic activity.

We thank Dr D. M. Blow and his collaborators for allowing us to make detailed comparisons between our preliminary elastase model and their α-chymotrypsin model and for permission to use the stereo view of α-chymotrypsin shown in Fig. 3, and Professor R. E. Dickerson, who prepared the drawings for Figs. 1, 2 and 3. We also thank Dr P. L. Wendell, Mr N. White and Mrs S. K. Watson for help in the construction of the model. One of us (D. M. S.) acknowledges the financial support of a Beit Memorial medical research fellowship received during the course of this work, which was also supported by a grant from the Science Research Council.

Monoamine oxidase exists in at least four molecular forms in different areas of the human brain. Variations in their enzymatic properties may have important clinical implications, perhaps reflecting their relative ability to degrade different monoamine substrates *in vivo*.

CERTAIN biologically active monoamines such as dopamine[1], noradrenaline[2] and 5-hydroxytryptamine[3] are present in the central nervous system of many animal species and may act as transmitter substances[4]. The function of cerebral monoamine oxidase (EC 1.4.3.4) (MAO) has yet to be fully elucidated although it is likely to provide one of the major intraneuronal mechanisms for inactivating these monoamines[4-6]. The part the enzyme and its substrates play in cerebral pathology is even less well understood, although evidence exists which seems to involve them unequivocally in certain diseases of the central nervous system; thus, high oral dosage of L-dopa will bring about clinical improvement in some Parkinsonian patients[7,8], presumably by replacing depleted dopamine stores in the basal ganglia[9]; some MAO inhibitors cause a lightening of affect in depressive illness[10,11].

Using polyacrylamide gel electrophoresis, we have separated rat brain mitochondrial MAO into several bands of activity[12] and suggested that the variable effects of MAO inhibitors in depressive illness might be a result of their ability to inhibit particular MAO isoenzymes of this type. The hypothesis was supported by the differing sensitivities that the bands of activity showed to the drugs investigated. Furthermore, each isoenzyme possessed a characteristic substrate specificity, heat stability and *p*H optimum. Our experiments have now been extended to human brain mitochondrial MAO and its multiple forms in whole brain and various constituent parts.

Preparation of Isoenzymes

Autopsy material was collected within 12 h of death. In five cases, the brain was sliced and samples were taken from the basal ganglia, cerebellar cortex, cerebral cortex, centrum ovale, hypothalamus and pons. The samples were placed in sterile screw-capped containers and frozen at −70° C until required. While dissection was careful, some white matter was included in the samples of cerebellar cortex. From two cases, the whole brain was frozen until assay.

Mitochondria were prepared by homogenization of 5–10 g tissue samples in ice-cold sucrose as described by Hawkins[13]. After washing in sucrose they were suspended in Tris-HCl buffer (0·05 M, *p*H 9·1) containing 1·0 per cent 'Triton *X*-100' and benzylamine[14]. The enzyme was then solubilized and purified as described previously[12]. In each enzyme preparation, four bands of activity were separated by polyacrylamide disc electrophoresis[12,15], respectively designated MAO_{1-4}; two migrated to the anode, one remained at the origin and a fourth migrated towards the cathode (Fig. 1). These results seem to be analogous with those reported for rat brain MAO[12], whereas pig brain MAO is homogeneous[16]. Protein fractions with enzyme activity were extracted from the gels[12] and stored at 4° C until required.

Properties of Human Brain MAO

A comparison was made between the specific activities of solubilized mitochondrial MAO from whole human brain and those of MAO derived from the brain areas chosen for investigation, using ^{14}C-tryptamine, ^{14}C-tyramine, ^{14}C-dopamine and ^{14}C-benzylamine as substrates[17] (Table 1). Whole brain mitochondrial preparations deaminated tryptamine least, and benzylamine most avidly.

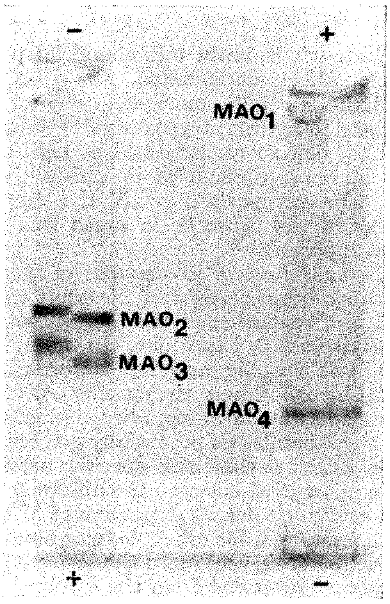

Fig. 1. Multiple forms of solubilized whole human brain mitochondrial monoamine oxidase (MAO) separated on 5 per cent polyacrylamide gel electrophoresis. MAO_{1-3} migrated from cathode to anode and MAO_4 from anode to cathode. 250 μl. of enzyme in 0·05 M Tris-HCl buffer, *p*H 9·1, was mixed with 'Sephadex *G*-200' and introduced on to the gel. Electrophoresis was continued at room temperature for 1–2 h at 6 mA per tube. The gels were developed for MAO activity with a solution containing 4 mg nitroblue tetrazolium, 1 mg sodium sulphate and 4 mg tryptamine-HCl in 5 ml. of 0·05 M phosphate buffer, *p*H 7·4 (ref. 41).

Table 1. SPECIFIC ACTIVITIES OF MITOCHONDRIAL MAO FROM VARIOUS AREAS OF THE HUMAN BRAIN

	Tryptamine	Tyramine	Benzylamine	Dopamine
Whole brain	0·729 ± 0·068	1·735 ± 0·184	5·607 ± 0·610	2·359 ± 0·183
Basal ganglia	0·573 ± 0·060	1·476 ± 0·161	2·848 ± 0·212	4·624 ± 0·371
Centrum ovale	0·899 ± 0·093	2·059 ± 0·300	5·277 ± 0·318	3·709 ± 0·381
Cerebellar cortex	0·613 ± 0·058	0·391 ± 0·052	1·502 ± 0·311	1·893 ± 0·212
Cerebral cortex	1·124 ± 0·111	2·218 ± 0·219	1·427 ± 0·218	1·714 ± 0·210
Hypothalamus	5·164 ± 0·702	7·719 ± 0·782	50·556 ± 8·172	36·148 ± 5·720
Pons	0·318 ± 0·034	0·080 ± 0·050	1·625 ± 0·199	1·972 ± 0·204

The specific activities are expressed as nmole of substrate deaminated per min incubation per mg of protein ± *S.E.*, and are the mean of between three and six experiments using at least two different brains. Protein nitrogen was measured[39] using bovine serum albumin as standard.

Table 2. SPECIFIC ACTIVITIES OF THE MULTIPLE FORMS OF HUMAN BRAIN MITOCHONDRIAL MAO

	^{14}C-Tryptamine	^{14}C-Tyramine	^{14}C-Benzylamine	^{14}C-Dopamine
Whole brain				
MAO$_1$	0·820 ($1·51 \times 10^{-5}$ M)	1·656 ($4·22 \times 10^{-5}$ M)	4·395 ($1·18 \times 10^{-4}$ M)	2·092 ($1·89 \times 10^{-5}$ M)

MAO$_4$	0·413	0·467 ($4·01 \times 10^{-5}$ M)	0·260 ($5·72 \times 10^{-4}$ M)	13·42 ($2·64 \times 10^{-6}$ M)

Each value is expressed as nmole of substrate deaminated per min incubation per mg protein and is the mean of at least two experiments from four different brains except for the whole brain where two only were used. The variation in activities between the brains did not exceed 20 per cent of the mean value. The figures in parentheses are the corresponding Michaelis constants measured graphically.

Compared with whole brain mitochondrial preparations, hypothalamic MAO deaminated all substrates more rapidly. Although high concentrations of both noradrenaline[2] and 5-hydroxytryptamine[18,19] are present in this brain area, neither amine could be used as substrate because of inherent difficulties in radioactive methods of assay[20]. In comparison with the hypothalamus, MAO activity of the other brain areas was low, as has already been reported[21,22].

The specific activities of isoenzymes of MAO prepared from the various brain areas were also determined (Table 2). The rates of oxidation of the four substrates by the bands of activity seemed to differ. In most areas, MAO$_1$ had the highest specific activity towards tryptamine, tyramine and benzylamine; the specific activity of MAO$_4$ toward dopamine was, however, always greater than that of the other three bands. Of potentially greater significance was the observation that the specific activity of the individual bands varied between the different brain areas. The specific activity towards dopamine of MAO$_4$ deriving from the basal ganglia, for example, was almost six times that of the whole brain and more than seventy times that of the same band prepared from the cerebral cortex. On the other hand, MAO$_4$ prepared from basal ganglia had a lower specific activity toward tyramine than that prepared from the whole brain. Similar differences occurred between the different brain areas with the other substrates.

Michaelis constants of the multiple enzyme forms prepared from whole human brain are also shown in Table 2. There seemed to be differences in the affinities of the bands for the four substrates. In contrast, the marked differences in specific activities of the bands between the brain areas were not accompanied by corresponding changes in the Michaelis constants (Table 2), so that $v_{\max}$ for the substrates would seem to differ between the brain areas investigated. It is unlikely that the lack of correlation between Michaelis constants and specific activities is a reflexion of differing purities of the enzyme samples, for not only were they electrophoretically pure but, before electrophoresis, all were submitted to gel filtration[12] to remove as far as possible proteins of differing molecular weights.

The thermal sensitivity characteristics of whole brain mitochondrial MAO, of MAO isolated from the brain areas under study and of the multiple forms from whole brain are shown in Fig. 2. A wide range of stabilities was displayed by the various brain preparations, hypothalamic MAO being most labile and that from basal ganglia most stable. From the stabilities of the individual enzyme forms, we might expect that hypothalamic MAO has a preponderance of activity in MAO$_1$ and MAO$_3$ whereas in the basal ganglia activity is confined mainly to MAO$_2$ and MAO$_4$.

With kynuramine as substrate[28], we measured the effect on the different brain enzymes of iproniazid and pargyline, two irreversible inhibitors of MAO[23,24]; of harmaline, a reversible inhibitor[25]; and of 'M & B 9302' (clorgyline), a non-hydrazine inhibitor which gives rise to an unusual biphasic inhibition curve with rat and human brain homogenates[26,27] (Table 3). There was little difference between the Ki values of enzyme preparations from the various brain areas. When the inhibition of whole brain

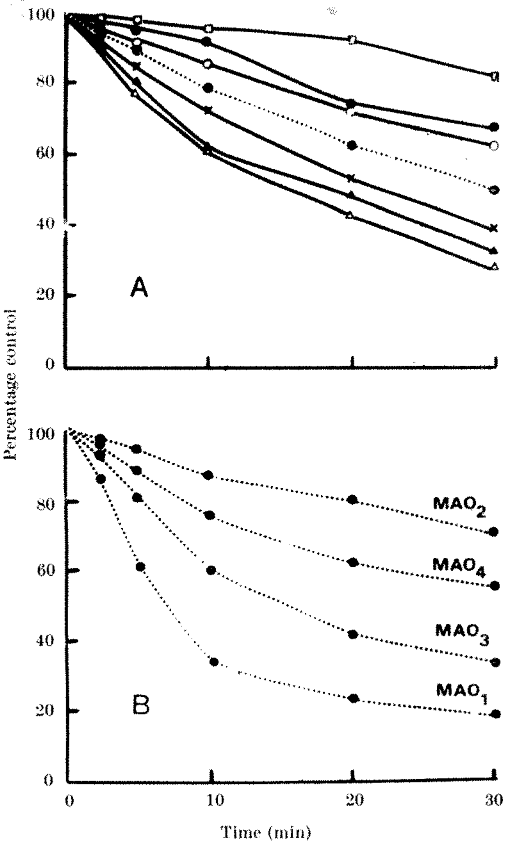

Fig. 2. The effect of temperature on human brain mitochondrial MAO activity. The enzyme was suspended in phosphate buffer (0·05 M, *p*H 7·4), heated to 50° C in a water bath and the residual activity measured using kynuramine as substrate[28]. *A*, Human brain MAO from various brain areas. Basal ganglia, □—□; cerebral cortex, ●—●; cerebellar cortex, ○—○; centrum ovale, ▲—▲; pons, × — ×; hypothalamus, △—△; whole brain, ● - - - ●. *B*, Multiple forms of whole brain MAO. The results are expressed as percentages of the activity of the unheated enzyme.

MAO by 'M & B 9302' was measured using ^{14}C-dopamine as substrate, however, a triphasic curve was obtained (Fig. 3), providing further evidence that human brain MAO exists in at least three forms; each plateau may represent inhibition of one of the isoenzymes. When ^{14}C-tyramine was substrate the plateaux were less distinct, whereas with kynuramine a normal sigmoidal dose–response curve was obtained. This result supports the conclusions of Collins and Youdim[29] that inhibition of the multiple forms of rat and human liver MAO is substrate dependent.

Interpretations

MAO seems to exist in multiple forms in many tissues[12,15,29–36]. We have now been able to show that MAO isoenzymes are similarly present in human brain and that their specific activities differ from one area to another, although the principles underlying these differences are not immediately obvious. Although there may be differences in affinity constants of systems isolated by physical means *in vitro*, the complete system, which could of itself act as an integrated enzyme protein, may differ markedly from the individual isoenzymes in its affinities for substrates or inhibitors.

Table 3. INHIBITION OF HUMAN BRAIN MITOCHONDRIAL MAO

	Iproniazid	'M & B 9302'	Pargyline	Harmaline
Whole brain	$5·68 \times 10^{-6}$	$1·64 \times 10^{-6}$	$2·09 \times 10^{-8}$	$1·25 \times 10^{-5}$
Basal ganglia	$9·89 \times 10^{-6}$	$1·34 \times 10^{-6}$	$3·45 \times 10^{-8}$	$1·59 \times 10^{-5}$
Centrum ovale	$4·90 \times 10^{-6}$	$2·04 \times 10^{-6}$	$2·42 \times 10^{-8}$	$2·81 \times 10^{-5}$
Cerebral cortex	$5·62 \times 10^{-6}$	$1·88 \times 10^{-6}$	$4·08 \times 10^{-8}$	$3·65 \times 10^{-5}$
Cerebellar cortex	$9·50 \times 10^{-7}$	$4·69 \times 10^{-6}$	$4·96 \times 10^{-8}$	$1·59 \times 10^{-5}$
Hypothalamus	$4·37 \times 10^{-6}$	$1·70 \times 10^{-6}$	$3·67 \times 10^{-8}$	$2·82 \times 10^{-5}$
Pons	$4·20 \times 10^{-6}$	$6·40 \times 10^{-7}$	$2·28 \times 10^{-8}$	$1·67 \times 10^{-5}$

The values represent inhibitor constants (K_i values) and are calculated from double reciprocal plots using at least two inhibitor concentrations[40].

If the amino-acid content of an isoenzyme differed in the various brain areas, then electrophoresis of whole brain MAO would separate many bands of activity; only four isoenzymes were, however, detected. Two of us (M. B. H. Y. and G. G. S. C.) have shown[37] for the multiple forms of rat liver MAO that they are conformational isoenzymes, that is, proteins differing only in the way the constituent polypeptide chains are folded[38]. If, as would seem a reasonable extrapolation, the bands of activity of human brain MAO also represent conformational isoenzymes, a unitary explanation of the differences in specific activities presents itself. It is possible that each amine substrate in the human brain interacts with one or more of the isoenzymes thereby causing small but not readily reversible changes in conformation with a corresponding alteration of specific activity but not of affinity for the substrate. The interaction could occur either during the folding of the polypeptide chain or, perhaps, during the catalytic process itself. We may therefore have a simple self-regulatory mechanism by which an increase in the intraneuronal concentration of a particular amine is accompanied by the activation of a relatively specific isoenzyme of MAO.

Our hypothesis receives support from the rates of oxidation of dopamine by MAO$_4$ in the different brain areas. The basal ganglia contain a high concentration of dopamine whereas the amount in the cerebral cortex is low[1]; the specific activity of MAO$_4$ towards dopamine is more than seventy times higher in the basal ganglia than in the cerebral cortex.

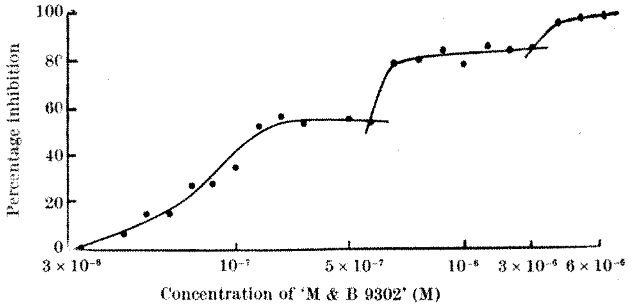

Fig. 3. The inhibition of whole human brain mitochondrial MAO by 'M & B 9302'. The enzyme preparation was incubated with the inhibitor for 20 min at 37° C before addition of the substrate (^{14}C-dopamine) to give a final concentration of $6·79 \times 10^{-4}$ M. The results are expressed as percentage inhibition of the control enzyme activity.

As we recently suggested for depressive illness[12], such an approach might lead to the synthesis of a specific inhibitor tailored to an individual isoenzyme band. Whether the therapeutic effectiveness of MAO inhibitors in depression arises from the localized accumulation of a particular substrate after preferential inhibition of a specific isoenzyme, perhaps at a particular anatomical site, can only be decided by future observation.

In conclusion, we suggest that our observation of high local specific activity of an isoenzyme band, in an area rich in its particular substrate, is unlikely to be an isolated phenomenon. Parallel observations with noradrenaline and 5-hydroxytryptamine are urgently needed.

We thank Dr D. R. Maxwell of May and Baker, Ltd, for a supply of 'M & B 9302'. Our work was supported by grants from the Medical Research Council, the Wellcome Trust and Hoechst Pharmaceuticals, Ltd.

Re-evaluation of the Synaptic Activation of an Electrogenic Sodium Pump

by

JacSUE KEHOE*

Department of Anatomy,

P. ASCHER*

Department of Pharmacology,
University of Cambridge

A hyperpolarizing synaptic potential observed in *Aplysia* neurones is shown to be the result of an increase in potassium permeability. A re-evaluation is made of the criteria used to implicate the activation of an electrogenic pump.

ELECTROGENIC explanations of ionic pumps have been proposed[1-5]. Such hypotheses imply that a change in the rate of pumping can lead to a change in membrane potential[6] and it has indeed been shown that some hyperpolarizations—for example, that following repetitive action-potentials[7-10] or intracellular injection of Na^+ (refs. 11 and 12)—could be accounted for by increased activity of the Na^+–K^+ pump. Is it possible that "pump" potential changes could be triggered independently of any change in ionic permeabilities? Such a hypothesis has been proposed to account for a variety of potential changes caused by synaptic transmitters[13-24], hormones[25] and light[26]. For example, the recent experiments of Pinsker and Kandel[21] seemed to imply activation of the Na^+–K^+ pump in a synaptic potential. The experiments we report show, however, that this potential is due to a change in K^+ permeability, and thus emphasize the need of re-evaluating many of the potentials attributed to the activation of an electrogenic pump.

The two-component, postsynaptic inhibition described by Pinsker and Kandel[21] occurs in identifiable cells of the abdominal ganglion of *Aplysia californica*. It consists of a rapid, early component (the "early IPSP") which is the result of a Cl^- permeability change and of a "late IPSP" which appeared to be due to the synaptic activation of an electrogenic Na^+–K^+ pump. We felt that it would be worthwhile to take a second look at this abdominal ganglion inhibition because it markedly resembles a pleural ganglion two-component inhibition—both phases of which were previously shown to be due to ionic permeability changes[27-30]. A list of the most important data published follows.

Pleural ganglion[27-29]	Abdominal ganglion[21]
Rapid component	*Early IPSP*
a. Inverts at −60 mV	*a.* Inverts at −65 mV
b. Cl^- dependent	*b.* Cl^- dependent
c. Selectively blocked by (+)-tubocurarine (dTC)	*c.* Selectively blocked by dTC
Slow component	*Late IPSP*
a. Inverts at −80 mV	*a.* Cannot be inverted
b. K^+ dependent	*b.* Not K^+ dependent
c. Selectively blocked by tetraethylammonium[28] and methylxylocholine[29]	*c.* Selectively blocked by ouabain, cooling and prolonged washing in K^+-free

The major discrepancy between the two sets of data concerns the interpretation of the slow phase of the two inhibitions. In the pleural ganglion it was attributed to an increase in permeability to K^+ ions because one could define an inversion potential which varied according to the Nernst equation when the external K^+ concentration was varied from 5 mM to 20 mM (ref. 27). In the abdominal ganglion, on the other hand, the "late IPSP" was attributed to the activation of an electrogenic pump because it (*a*) was not inverted by hyperpolarization of the postsynaptic membrane, (*b*) was not associated with a change in membrane conductance, and (*c*) was suppressed by prolonged washing in K^+ free seawater, by ouabain 2×10^{-4} M and by cooling to 7°–10° C (ref. 21).

---

* Visiting workers from Laboratorie de Neurophysiologie Cellulaire; Centre d'Etudes de Physiologie Nerveuse, CNRS, Paris.

The interpretation of the effects of ouabain and cold seems, however, subject to question in view of some of our own unpublished observations on the dTC-resistant component of the pleural inhibition.

The effects of ouabain on this component are shown in Fig. 1. In normal seawater, this response inverts at −80 mV. Ten min after the addition of 2×10^{-4} M ouabain, the inversion potential is shifted to −70 mV—indicating a decrease in the internal K^+ concentration after blockage of the Na^+-K^+ pump. It can be noted that if the effect of ouabain on the dTC-resistant inhibition had been analysed only at −70 mV, ouabain would appear to have completely eliminated the inhibition.

Cooling also has marked effects on the K^+ dependent inhibition of the pleural ganglion. The response is progressively reduced and slowed down by cooling and it disappears altogether when the temperature reaches 7°–10° C. The Cl^- dependent phase is considerably less affected. Both components of the synaptic inhibition can be mimicked by an injection of acetylcholine (ACh)[27] and, as seen in Fig. 2, cooling also selectively blocks the K^+ dependent phase of the ACh potential.

Because both ouabain and cooling have rather marked effects on a potential that is known to be due to membrane permeability changes, we thought it possible that their effects on the abdominal ganglion inhibition had been misinterpreted and we consequently felt it necessary to perform additional experiments on the abdominal cells.

In these experiments, both the "postsynaptic" neurones (L1, L2, L3, L4, L5, L6) and the presynaptic neurone (L10)[31] were penetrated with double barrelled microelectrodes filled with 0·5 M K_2SO_4. We could thus evaluate the synaptic potentials triggered by intracellular stimulation of L10 at different levels of polarization of the postsynaptic neurone. We found, as had Pinsker and Kandel[21], that it seemed often impossible to invert the "late IPSP" (see Fig. 3*A*). After dTC had eliminated the Cl^- dependent component, however, an initial hyperpolarization of the remaining multiphased response could be inverted around −90 mV (±5 mV). The terminal component, on the other hand, remained hyperpolarizing until −100 mV (±5 mV), at which level it was no longer detectable (Fig. 3*B*).

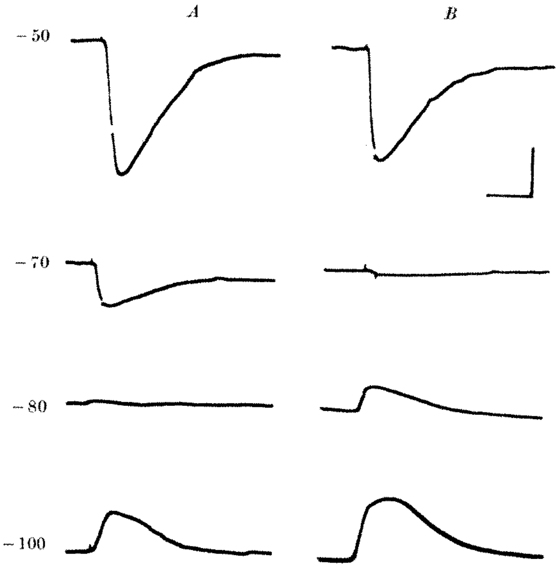

Fig. 1. Effects of ouabain (2×10^{-4} M) on the K^+ dependent dTC-resistant component of the synaptic inhibition of the pleural neurones. *A* shows the postsynaptic responses to intracellular stimulation of the presynaptic neurone[13,14] in a preparation where dTC chloride (10^{-3} g/ml.) has eliminated the chloride dependent component. Polarization of the postsynaptic neurone to the levels indicated on the left shows that normally the inversion potential of the dTC resistant component is −80 mV. In *B*, 10 min after the addition of ouabain, the inversion potential was shifted from −80 to −70 mV. Calibration: 5 mV; 4 s.

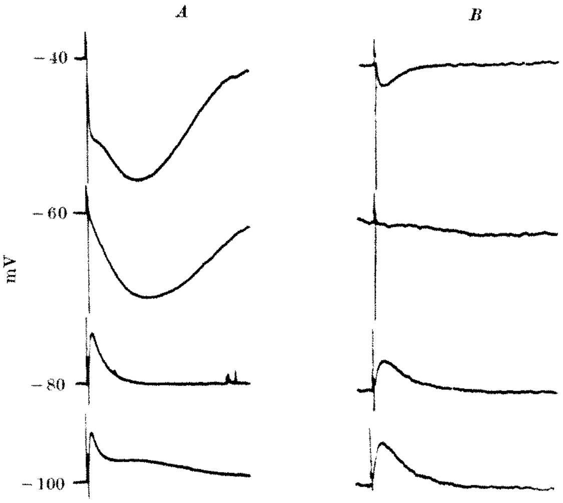

Fig. 2. Effects of cold on the ACh potential in pleural neurones. *A*, Responses to an electrophoretic injection of ACh (5×10^{-2} M) on the pleural neurones. The early component of the ACh potential inverts at −60 mV; thus only the slow component is visible at that membrane potential. The slow component inverts at −80 mV. *B*, Reducing the temperature from 22° to 8° C produces a complete suppression of the late component (effect best observed at −60 mV) whereas the rapid component is considerably less affected. Calibration (see *B*): 5 mV; 5 s.

Although in these respects the dTC-resistant abdominal ganglion inhibition differs slightly from that of the pleural ganglion, both react identically to a reduction in external K^+ concentration, as can be seen in Fig. 3*C*. In normal seawater (K^+ = 10 mM), at −95 mV the early hyperpolarization is inverted, while the late hyperpolarization is not detectable. When the external K^+ concentration is reduced to 5 mM, both phases become marked hyperpolarizations.

We found that the effects of ouabain on the abdominal ganglion inhibition are similar to those on the pleural inhibition. Ouabain does not eliminate either the early or late dTC-resistant hyperpolarizations, but merely changes their inversion potentials (Fig. 4).

Thus certain evidence given by Pinsker and Kandel[21] in support of their hypothesis must be re-evaluated. We find first of all that it is possible to invert at least part if not all of the dTC-resistant hyperpolarization. Second, this hyperpolarization is sensitive to changes in external K^+, and, finally, ouabain does not eliminate it but merely changes the inversion potential.

Further similarities between the abdominal and pleural inhibitions became evident when we tested the effects of ACh on the abdominal neurones. It has been shown previously[27] that the response of pleural cells to an iontophoretic injection of ACh mimicks the inhibitory input. The ACh potential consists of two components: the first inverting at −60 mV; the second, at −80 mV (Fig. 2*A*). These two elements respond in the same way as those of the synaptic input to ionic and pharmacological manipulations[27–29]. ACh also provokes a two-component hyperpolarization on the abdominal cells[21]. When we analysed this response at different levels of membrane potential, we found it identical to that recorded from the pleural cells. The two components invert at −60 and −80 mV, respectively; the early phase is Cl^- dependent and is blocked by dTC, whereas the late phase is K^+ dependent and is blocked by methylxylocholine. Both phases are associated with changes in conductance.

Thus no distinction can be made between (*a*) the ACh potential of the abdominal neurones, (*b*) that of the pleural neurones, and (*c*) the synaptic inhibition of the pleural postsynaptic cells. The similar behaviour of these groups of responses contrasts with that of the synaptic response in the abdominal cells. As mentioned here, the dTC-sensitive component of this synaptic response inverts at approximately −65 mV; the dTC-resistant component is

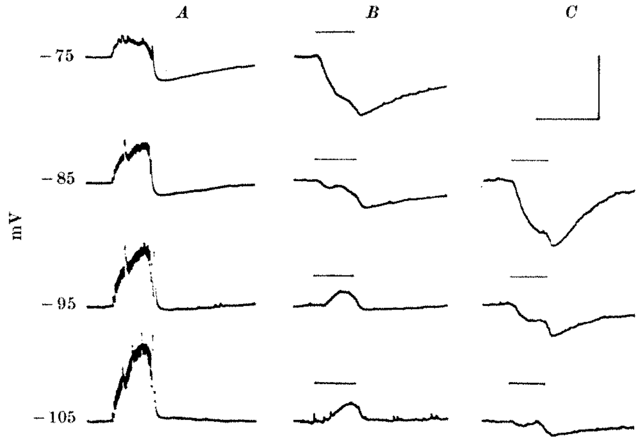

Fig. 3. Effects of a reduction in external K^+ on the dTC resistant synaptic inhibition of abdominal neurones. L10 was intracellularly stimulated so as to provoke a train of spikes. The duration of this train is indicated by the horizontal lines in *B* and *C*. *A*, These data correspond to those given by Pinsker and Kandel in Fig. 1*Ab*. No clear reversal of the "late IPSP" can be seen when the somatic membrane polarization is brought from −75 to −105 mV. *B*, After dTC chloride (10^{-3} g/ml.), the remaining response can be separated into two hyperpolarizing components. The first, seen during the period of presynaptic activity, inverts between −85 and −95 mV; the second appears after the train of presynaptic spikes has terminated and is no longer visible beyond −95 mV. *C*, Reduction of external K^+ from 10 to 5 mM causes a shift in the equilibrium potential of both phases of the dTC-resistant hyperpolarizations. These changes are most evident at −95 mV. Calibration: 5 mV; 10 s.

multiphasic (in contrast with the single phased response in the pleural cells—compare Figs. 1*A* and 3*B*), and its hyperpolarizing phases do not invert until at least −90 mV. Furthermore, whereas the combined application of dTC and methylxylocholine will completely eliminate the pleural synaptic responses and the ACh responses on both groups of cells, the abdominal synaptic response does not obey this rule. Although the rapid IPSP of the abdominal inhibition is indeed eliminated by dTC, and although part of the dTC-resistant hyperpolarization is blocked by methylxylocholine, there remains in the presence of both of these drugs a response to the activation of L10. It consists of an initial depolarization (which in many preparations is capable of triggering a spike in the postsynaptic cell) which is followed (usually at the termination of the presynaptic firing) by a hyperpolarization (Fig. 5). Although it is difficult to invert this later hyperpolarization it has been shown here that—like the early one—it is K^+ dependent and is not blocked by ouabain.

Thus it appears that the synaptic response in the abdominal cells is made up of (*a*) a two-component inhibition which differs from that studied in the pleural cells only with respect to the inversion potentials of the components (−65 mV versus −60 mV; 90 ± 5 versus −80 mV), and (*b*) a biphasic response which is not mimicked by ACh injection.

That the inversion potentials of both the Cl^- and K^+ dependent elements of the abdominal ganglion inhibition are more negative than those of the pleural inhibition can be understood if one assumes that the ACh liberated by the presynaptic terminals is acting on a distant or particularly fine part of the axon. The synapse of L10 on L3 and others has been, in fact, located at a great distance from the soma of the postsynaptic cell[31]. In experiments in which we entered both the soma and a distant region of the axon of L3, polarization of the soma to −100 mV polarized the axon to only −75 mV, and a similar attenuation was found in the other direction. That the polarization level recorded in the soma does not accurately represent that of the synaptic region is also suggested by experiments in which ACh was injected on the axonal region of the cell near the presumed synaptic region, while the recording and polarizing electrodes were in the soma. In these conditions, the early phase of the ACh response inverted at −65 mV rather than at −60 mV. (The same injection of ACh gave only a very small second phase, thus making it impossible to measure its potential of inversion which was, however, clearly more negative than −80 mV.)

If we then admit that the anomalous inversion potentials are due to the effect of a distant junction, it remains only to understand the biphasic synaptic potential which can still be observed after dTC and methylxylocholine have blocked the two components of the ACh-potential. While we cannot completely eliminate the hypothesis of a "chemical" synaptic effect (ACh acting on additional receptors that are not represented in the region of the soma, or the intervention of other transmitters) the fact that the hyperpolarizing component is never prominent as long as the presynaptic neurone is firing suggests that the biphasic potential is similar to that observed by Hughes and Tauc[32] and interpreted[33] as due to transmission of the presynaptic spike through an electrical junction which would favour the slow hyperpolarizing component (see also ref. 34).

The main conclusion from our experiments is that the synaptic activity previously attributed[21] to the stimulation of an electrogenic pump is in fact due to a change in K^+ permeability. The criteria used by Pinsker and Kandel[21] have been used for similar purposes in the interpretation of a number of hyperpolarizing potentials (salivary glands[13,14], salt glands[15], smooth muscle[16,17], sympathetic ganglion cells[18-20], molluscan neurones[22,23]) so it seems that these criteria must be carefully considered.

The interpretation of potential changes occurring without a change in membrane conductance and the interpretation of anomalous reversal potentials must be made cautiously if there is any possibility that the polarizing and recording electrodes might be distant from the membrane region where a conductance change could in fact be occurring. Diamond, for example[35], has shown that, when γ-aminobutyric acid is applied to the dendrites of Mauthner neurones, the conductance changes can be

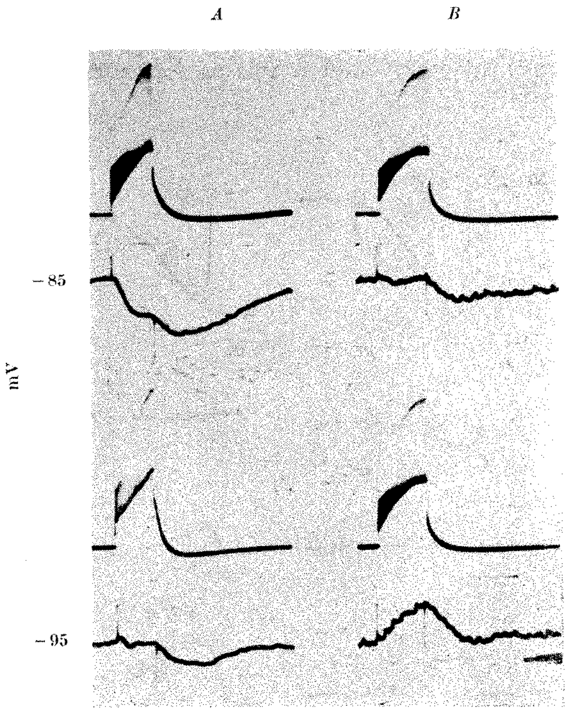

Fig. 4. Effects of ouabain (2×10^{-4} M) on the dTC-resistant hyperpolarization of the abdominal neurones. At each polarization level (−85 and −95 mV) both pre (L10) and post-synaptic (L5) records are presented. (Only the lower portion of the action potentials of L10 is visible.) The "early IPSPs" had been eliminated by dTC Cl (10^{-3} g/ml.), leaving a multiphased hyperpolarizing response. The earlier component inverted at −95 mV in the curarized preparation. When ouabain was added (*B*), its inversion potential was shifted 10 mV, as was that of the later hyperpolarization. Calibration: 5 mV; 10 s.

detected over only a few tens of microns, whereas there is very little decrement in potential changes over the same distance (see also ref. 36). Burke and Ginsborg[37], on the other hand, have shown how distance can introduce discrepancies between equilibrium potentials and reversal potentials measured with a single current microelectrode (see also ref. 38). Such effects of distance can be expected with axodendritic synapses (mammalian sympathetic ganglion cells) and with axo-axonic synapses (molluscan neurones, and possibly frog sympathetic ganglion cells), and similar difficulties arise in the case of "distributed innervation"[37] (smooth muscle, salt glands, salivary glands). Moreover, electrical junctions (known to occur in salivary glands, smooth muscle, and *Aplysia* neurones) will cause the same problems of measurement as are posed by distant junctions.

Ouabain can always be expected to reduce the ionic gradient for K^+, and any reduction of a synaptic potential must be evaluated in this respect. Such an evaluation might often be very difficult, however, for the effect of ouabain would be initially more pronounced in axonic or dendritic regions (where the surface/volume relation is high[39]) whereas measurement of the change in K^+ equilibrium potential is in general made in the tissue as a whole or in the cell soma. That a rapid fall in K^+ concentration in the synaptic region might occur without affecting the soma K^+ equilibrium potential is indeed suggested by another observation: an immediate depolarizing shift of the reversal potential of the late IPSP in the abdominal neurones can be observed following the triggering of only a few action potentials in the postsynaptic cells, and there is no corresponding shift for the reversal potential of the response to a somatically applied ACh injection.

K^+ free solutions and cooling stop the Na^+–K^+ pump, and can be expected to produce effects resembling those produced by ouabain. But the resulting shift of the K^+ equilibrium potential might be more difficult to detect. In K^+ free solutions, it will initially be masked by an inverse shift due to the immediate increase of the K^+ concentration gradient. This may account for the contradictory reports in K^+ effects on salivary potentials[40-42] or sympathetic ganglion potentials[43,44]. On the other hand, the effects of blocking the pump by cooling might be masked by direct suppressive effects such as those illustrated in Fig. 2. It is known that many "passive permeabilities" have a high temperature coefficient[45-48]; but the sensitivity of the K^+ potential illustrated in Fig. 2 appears exceptionally high and suggests an additional effect, which might occur in the sequence of events leading from the combination of ACh with its receptor to the change in K^+ permeability.

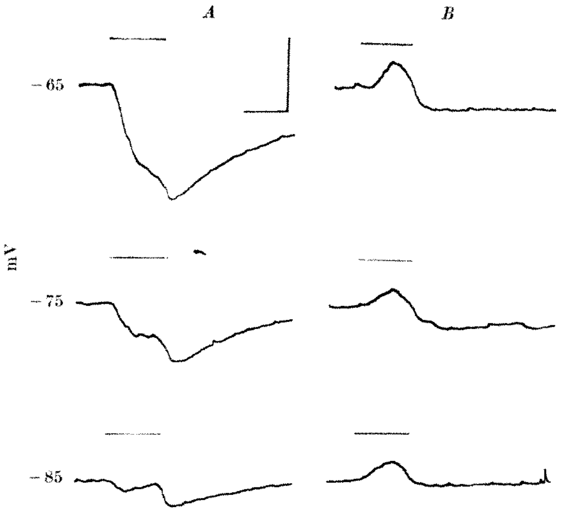

Fig. 5. Effects of methylxylocholine on the dTC-resistant components of the abdominal synaptic inhibition. *A*, As in Fig. 3*B*, the postsynaptic response has been recorded at different potential levels in a medium containing dTC chloride (10^{-3} g/ml.). It consists of two hyperpolarizing components (one starting during the presynaptic activity, the other after this activity terminates). *B*, Methylxylocholine (10^{-4} g/ml.) has been added to dTC seawater. This suppresses the first hyperpolarizing component (that which starts during the presynaptic activity) and unmasks a biphasic potential: the early component is depolarizing at all postsynaptic membrane potentials (and often triggers a spike at −50 mV); the late component is hyperpolarizing up to membrane potentials as high as −85 mV. In these pharmacological conditions, ACh injection will have no effect on the postsynaptic neurone. Calibration: 5 mV; 5 s.

Finally, we have observed on pleural neurones that Na^+ free solutions (Na^+ replaced by Li^+) had ouabain-like effects and progressively shifted the K^+ equilibrium potential.

Thus it seems that the criteria for establishing that a synaptic transmitter directly activates an electrogenic pump have in general not been used in such a way as to eliminate the hypothesis of a change in ionic permeability occurring at a distant junction and/or on the other side of an electrical synapse. On the other hand, there is no reason to doubt that the Na^+–K^+ pump might be activated after a synaptic potential, insofar as a change in cationic permeabilities will lead to a change in internal cation concentrations. It appears doubtful, however, that the minute changes involved in most synaptic potentials are sufficient to trigger a detectable "pump" potential change.

Neurotrophic Control of Protein Synthesis in the Regenerating Limb of the Newt, *Triturus*

Evidence is presented for the stimulation of protein synthesis in newt limb buds by an agent produced by nerve fibres.

AMPHIBIAN limb regeneration is a nerve-dependent process[1,2]. Denervation of early regenerates leads to the complete cessation of growth and restoration of the nerve supply results in renewed capacity to grow. Limb regeneration is but one of a number of biological processes for which a neurotrophic influence is invoked[1]. The possibility has been suggested that nerve fibres emit from their distal processes a chemical substance with trophic properties[2]. The proof of this mechanism would require the extraction from neurones of one or more substances capable of substituting for innervation in a system clearly requiring the trophic action of the nerve. The studies that there have been in this direction offer no clear proof that the origin of the physiologically active extract is nervous or that the activity induced by the extract is normally nerve-dependent. Hommes *et al.*[7] extracted an inductor of cartilage formation from homogenates of combined notochord and spinal cord of chick embryos, Kanatani[8] prepared nerve extracts capable of stimulating meiosis and release of gametes in starfish. Lesh and Burnett[9] concentrated from the growth medium of *Hydra* a factor which induces and maintains polarity in this animal.

We have examined the chemical nature of the neurotrophic action in a system which is clearly nerve-dependent, the regenerating salamander limb. Previously we were unsuccessful in sustaining gross regeneration of the missing part by infusions of nerve extracts. We have now sought a more sensitive assay of the neurotrophic effect by assessing biochemical changes in the regenerate resulting from denervation because innervation has been shown to exert a significant role in the regulation of some biochemical processes. (For example, transient glycogen storage and diminution in lipid turnover occur following denervation of the brown fat pad in mice[3]; and the activity of muscle sole plate cholinesterase is dependent on the nerve ending[4-6].) Our object here was to test whether innervation is required for protein synthesis during the early blastema stage of limb regeneration at a time when the growth is most dependent on the nerve; and, if so, to see whether nerve homogenates could support protein synthesis in the denervated blastema.

Adult *Triturus viridescens*, native to western Massachusetts, were maintained—before and after operation—at 25° C. All operative procedures were carried out under light 'Chloretone' anaesthesia (30 per cent saturated aqueous solution). Bilateral forelimb amputations were performed just proximal to the elbow joint. Care was taken to establish a flat amputation surface to provide a transverse base from which the blastema could later be separated from adult stump tissues. When the regenerate reached the moderate early to early bud stage of regeneration[1] (10 to 14 days after amputation) the left experimental limb was denervated; simultaneously, an identical sham control operation was performed on the contralateral limb. This phase of growth, characterized by the rapid accumulation of blastemal cells, is most dramatically suppressed by denervation. The regenerate was denervated in the brachial plexus; unless otherwise stated, denervation was total and involved resection of at least 1 mm of the third and combined fourth and fifth spinal nerves. For partial denervation, single nerves or combinations of the three nerves were severed so as to produce regenerates innervated with 500, 800, 1,800, 2,100 and 2,600 nerve fibres[10]. The sympathetic nerves which follow the brachial artery into the forelimb were not disturbed.

Protein Synthesis by the Regenerate

Amino-acid uptake was studied in control and denervated blastemas 48 h after denervation in all except one series of animals in which the influence of the duration of denervation was investigated. DL-1-^{14}C-Leucine or uniformly ^{14}C-labelled L-leucine (New England Nuclear) was adjusted to final specific activities of 7·03 and 1·43 mCi/mmole, respectively, and a final concentration of 10 mM by dilution with distilled water. Each animal was injected intraperitoneally with 0·04 ml. without anaesthesia. At varying times following leucine injection the blastemas were separated from the original amputation

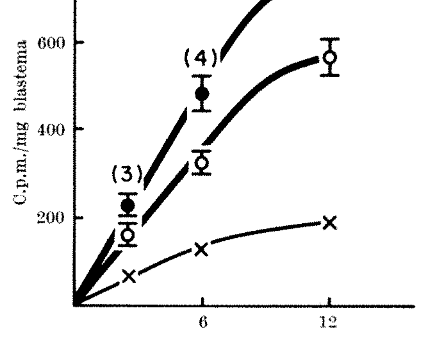

Fig. 1. Kinetics of appearance of leucine in innervated regenerates. Each animal received 0·40 μmoles of L-leucine (1·43 mCi/mmole) intraperitoneally at zero time. Blastemas were amputated for analysis of total radioactive leucine (●—●) and incorporated leucine (○—○) at the times indicated. Free radioactive leucine (×—×) was determined by subtraction. The bars correspond to *S.E.*; in parentheses are the number of regenerates in each series.

line with a sharp razor. Each blastema was blotted dry, weighed and immediately homogenized in 0·2 ml. of iced 5 per cent trichloroacetic acid (TCA). After transfer of the homogenate to another tube, the homogenizers were rinsed four times with a further 0·2 ml. of 5 per cent TCA and the washings combined with the homogenate. An 0·2 ml. aliquot of the TCA suspension was placed on a 'Millipore' filter (type *HA*, 0·8 μm porosity), washed with 10 ml. of iced 5 per cent TCA, and dried; radioactivity was counted either in a Nuclear Chicago proportional flow thin-window counter or in a Packard 'Tri-Carb' liquid scintillation spectrometer using a PPO–POPOP toluene scintillant. Neither additional washing with cold or hot TCA nor extraction of TCA precipitates with ethanol–ether–chloroform mixtures altered the counts significantly. In some cases, an 0·2 ml. aliquot of the TCA suspension was monitored directly without washing with cold TCA in order to obtain counts of the total leucine in the homogenate. An 0·4 ml. aliquot of each TCA suspension was centrifuged at 20,000*g* for 20 min, the precipitate taken up in 1M NaOH and its protein content determined by the method of Lowry *et al.*[11] using human serum albumin as a standard. The experimental and control blastemas of each animal were always processed simultaneously. Results are expressed either as c.p.m. of leucine incorporated per mg of blastemal protein; or in terms of percentage, based on specific activities, indicating incorporation in the denervated limb relative to 100 per cent incorporation in its contralateral control.

Preparation and Infusion of Nerve Homogenates

Newts whose forelimbs had been amputated 5 to 10 days previously served as a source of nerve. The animals were decapitated without anaesthesia, and placed on a bed of ice, and brachial nerves 3 and 4 were severed just distal to their spinal ganglia. The nerves and their branches into the upper arm were freed of perineurium, rapidly removed for weighing (weight was 1·5 to 1·7 mg), and then homogenized in a ground glass Potter–Elvehjem homogenizer at 0°–2° C containing 0·05 ml. of distilled water. The crude homogenates were either infused directly or as supernatants after centrifugation in a Sorvall 'RC2–B' for 1 h at 40,000*g*. The protein concentration of uncentrifuged homogenates was 2·8–3·1 mg/ml.; that of the centrifugation supernatant 0·8–0·9 mg/ml.[11]. Some homogenates were heated at 90° C for 10 min and were then infused to test for thermostability. Preparations were stored at –20° C for up to 24 h before use.

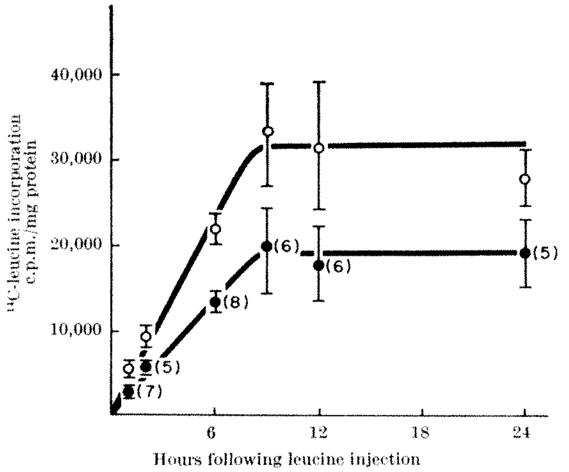

Fig. 2. Kinetics of incorporation of ^{14}C-leucine into protein of paired 48 h denervated (●—●) and contralateral sham operated control (○—○) regenerates. Each animal received 0·40 μmoles of leucine (7·03 mCi/mmole) at zero time intraperitoneally. Blastemas were amputated for incorporation analysis at the indicated times thereafter. The bars correspond to *S.E.* the mean; in parentheses are the number of animals in each series.

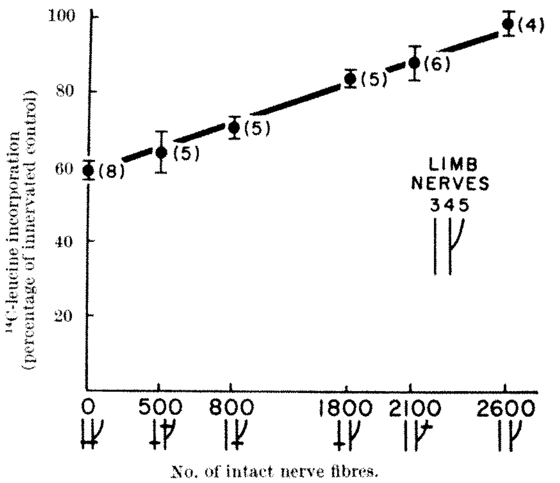

Fig. 3. Relationship between quantity of innervation and incorporation of ^{14}C-leucine into blastemal protein. Partial denervations were performed unilaterally as indicated; contralateral limbs were sham operated. Leucine was administered 48 h after denervation and blastemas removed 6 h later. The bars correspond to *S.E.*; in parentheses are the number of animals in each series.

Infusions of 0·005 ml. of homogenate were introduced directly into denervated blastemas with a Singer micro-infusion apparatus[12], 48 h after nerve transection. The infusion was always carried out for 1 h and was immediately preceded by an intraperitoneal injection of ^{14}C-leucine. Contralateral blastemas were infused with distilled water simultaneously or during the following hour. The tubing used in infusion of the homogenates was immersed in ice water.

Influence of Innervation and Denervation

Both innervated and denervated blastemas accumulate labelled leucine actively; although contributing only 0·04–0·07 per cent of the total body wet weight, each blastema accumulated at 6 and 12 h 0·1 per cent and 0·13–0·15 per cent, respectively, of the total administered leucine dose. Fig. 1 reveals that ^{14}C-leucine accumulates linearly in innervated blastemas for 8–10 h and then reaches a plateau. Similar kinetics of accumulation of total labelled leucine are seen in denervated regenerates (Fig. 2). In the innervated regenerate, approximately 70 per cent of the total label is in protein (Fig. 1), attesting to the vigour of protein synthesis in the growing regenerate.

Following a single dose of the labelled amino-acid, incorporation of leucine into blastemal protein (Fig. 2) increases linearly for approximately 8 to 9 h in innervated regenerates and in those denervated for 48 h; thereafter incorporation is maintained at a plateau for up to 24 h. Denervation has a profound effect on incorporation, reducing the rate and the final level attained by approximately 40 to 45 per cent. The parallel declines in accumulation of free radioactive leucine and in incorporation of leucine into protein in the innervated regenerate suggest that the inhibition of protein synthesis is a function of the decline in availability of unincorporated leucine. Further, the similarity of kinetics of accumulation of total labelled amino-acid in innervated and denervated regenerates indicates that the inhibition of protein synthesis by denervation does not arise from a diminution of available substrate.

To assess the specificity of neural control of protein synthesis, incorporation studies were undertaken in which the quantity of blastemal innervation and the duration of denervation were varied. As shown in Fig. 3 there is a linear inhibition of protein synthesis proportional to the extent of nerve destruction to a limiting value of 40 per cent inhibition attained in the fully denervated regenerate.

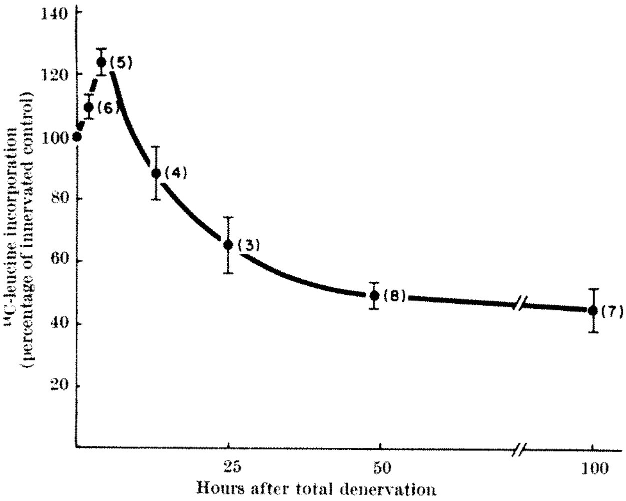

Fig. 4. Influence of duration of denervation on incorporation of ^{14}C-leucine into protein. Complete denervations were performed unilaterally and sham operations contralaterally. Leucine was administered at varying times. Blastemas were removed 1 h after leucine injection. For each series, points on the curve correspond to the time after denervation when leucine was administered plus the 1 h during which blastemas were exposed to the amino-acid. The bars indicate *S.E.*; in parentheses are the number of animals in each series.

The specificity of the neural effect was further explored by varying the time after complete denervation before leucine administration. Fig. 4 reveals that there is an initial transient stimulation of protein synthesis on transection of the nerves. A 10 per cent stimulation is evident by 2 h after denervation ($P < 0\cdot1$) and a 24 per cent stimulation by 4 h ($P < 0\cdot005$). Thereafter, incorporation recedes, falling below control levels by the tenth hour and reaching a baseline level of 45 to 50 per cent of control values about 50 h later. The burst of incorporation on nerve withdrawal is reminiscent of the initial heightened activity of muscle and other end organs which is observed after denervation—a phenomenon defined by Cannon's law of denervation[13].

Effect of Nerve Homogenates on Incorporation

The hypothesis that the neurotrophic influence resides in a substance extractable from nervous tissue was tested by assessing the ability of nerve homogenates to stimulate protein synthesis in regenerates denervated for 48 h. Fig. 5 demonstrates that the mean incorporation of leucine in denervated regenerates infused with nerve homogenate is 84·0 per cent that of paired contralateral control regenerates; that in similar non-infused or water-infused regenerates is only 62·0 and 58·2 per cent respectively, a result significant at $P < 0\cdot005$. Thus, on average, infusion of the homogenate abolishes about 60 per cent of the deficit in protein synthesis resulting from complete denervation. Further examination of the homogenate-infused series (Fig. 5) reveals that only three of thirteen regenerates overlap the range of incorporation of either non-infused or water-infused regenerates, while five of the thirteen regenerates synthesize protein at the normal control level. Clarified and non-clarified homogenates both stimulate leucine incorporation similarly.

Heating the nerve homogenate to 90° C for 10 min abolishes its capacity to stimulate protein synthesis, the mean incorporation in infused regenerates being 62·5 per cent of innervated control values, essentially the same as in non-infused or water-infused regenerates.

Partial Nerve Dependence of Protein Synthesis

We conclude that about 40 per cent of protein synthesis in the regenerating amphibian limb is nerve dependent. Protein synthesis, albeit depressed by denervation, does not cease. There are therefore other factors in addition to the neurotrophic one which also affect blastemal protein synthesis; presumably, total protein synthesis in the blastema is the sum of syntheses of many different proteins, each with its own control mechanism. Enzyme synthetic systems are known to be subject to hormonal regulation; and growth of the regenerate is influenced by the hormonal balance[14]. The blastema itself may exert control over the production of specific proteins; for example, after denervation a fibrocellular reaction develops with an increase in synthesis of collagen.

That control of protein synthesis is a function of neurotrophic action is indicated in our experiments by the proportionality between protein synthetic levels and extent of innervation and by the burst of protein synthesis which immediately follows denervation and which precedes the later decline. Autoradiographic findings that maximal incorporation of labelled methionine occurs in those cells of the regenerate in closest proximity to regenerating nerve fibres[15] further supports the specificity of the neural influence. The possibility that inhibition of protein synthesis might be a consequence of surgical trauma is ruled out by the sham operations on the control limb; nor is it the result of the immobility of the limb because significantly reduced protein synthesis is observed in partially denervated but fully motile limbs. Nor can interference with blastemal blood supply with consequent inequality of radioactive leucine pools be implicated, because autonomic nerves controlling blood flow in the newt do not travel with the brachial nerves and are not therefore severed; moreover, radioactive leucine pools do not differ significantly in innervated and denervated regenerates.

Our finding of a basal protein synthetic level not subject to neural control and above this a linear dependence of protein synthesis on the quantity of innervation resembles that of Guth *et al.*[4-6] on the muscle sole plate cholinesterase system of the rat.

The sensitivity of the response of the protein synthetic machinery in the regenerate to denervation is striking. Protein synthesis increases immediately, attains a peak by about 4 h, and thereafter declines, dropping below control levels by 10 h. By comparison, mitosis—also a nerve dependent function in the regenerate—exhibits a burst and reaches a peak within the first day but does not fall below control values for 3 to 5 days[16]. The rapid response of the protein synthetic machinery suggests that it may be a primary site of neurotrophic action on the amphibian limb regeneration system. But whereas protein synthesis is related linearly to the degree of innervation, gross

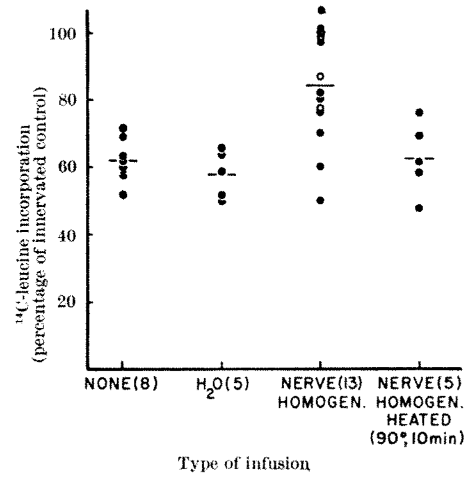

Fig. 5. Effect of infusion of water or nerve homogenates on incorporation of ^{14}C-leucine into protein of 48 h, fully denervated regenerates. Immediately following leucine injection, experimental regenerates were infused for 1 h with 0·005 ml. distilled water, a fresh nerve homogenate (○, unclarified; ●, 40,000*g* for 1 h) or a nerve homogenate heated to 90° C for 10 min; sham operated control regenerates were infused simultaneously or 1 h later with distilled water. Regenerates were removed for incorporation analysis 6 h after leucine administration. For comparison, incorporation in non-infused denervated regenerates is also presented. Cross bars denote the mean; in parentheses are the number of animals in each series.

regeneration is an all or none process requiring the presence of a threshold number of nerve fibres per unit area at the amputation surface. The explanation of this paradox may be that the initiation of gross regeneration requires the presence of certain minimal quantities of crucial proteins per unit area of the amputation surface, the syntheses of which are controlled in a linear manner by the quantity of innervation.

Physical Basis of the Regulatory Activity of Nerve Fibres

A second conclusion drawn from our experiments is that the neurotrophic influence is chemical in nature. This we conclude from the finding that nerve homogenates reverse about 60 per cent of denervation induced inhibition of protein synthesis. Indeed, in 40 per cent of the animals, the homogenates increased protein synthesis to control levels.

The agent of the nerve which stimulates protein synthesis in the regenerate may also reside in non-nervous tissues. Preliminary experiments with liver homogenates indicate the presence of a material, albeit less potent, which stimulates protein synthesis in the regenerate. The idea that the neurotrophic agent is common to other cells has already been suggested from experimental studies which showed that the extent of blastemal dependence on the nerve can be altered and also that limbs which develop in the embryo in the absence of the nerve can regenerate[1,17]. A similar widespread occurrence of an agent of growth has been demonstrated for the nerve growth factor which causes proliferation of sympathetic ganglion cells; it has been extracted from a variety of rat tissues—not merely from the salivary glands, its primary source[18].

Growth stimulating substances are diverse in nature: purified nerve growth promoting substance from rat salivary glands is a protein of medium size[18]; the meiosis stimulating and gamete shedding factor from starfish[8], isolated from neural tissue, and the hydra-polarization factor[9], presumably of nervous origin, seem to be small polypeptides; and the chondrogenic factor of chick embryo spinal cord and notochord contains nucleotide, amino-acid and sugar residues[7]. According to Brachet[19] the chondrogenic factor may be a glycoprotein. The thermolability of our neurotrophic agent rules out amino-acids, nucleotides and molecules such as histamine and acetylcholine, and suggests a polypeptide or protein. A nucleic acid, whose activity would be lost by heating, is another possibility. Indeed, the nerve cell body is a rich source of both protein and RNA: there is RNA in the axon[20], although its site of synthesis is not known; and it is widely accepted that proteins made in the cell body move down the axons to their endings[21-23] where they may be released to carry out metabolic functions.

One can only speculate on the mechanism by which the neural factor stimulates protein synthesis. It may act on the plasma membranes of the blastema cell; more probably, it may enter the cell and there affect the protein synthetic machinery.

During the completion of this manuscript a paper by Dresden[24] appeared in which denervation is shown to depress protein, RNA and DNA synthesis in the advanced regenerate (palette stage) at the time of tissue differentiation.

Characterization of the Germination Response to Temperature of Species and Ecotypes

by

P. A. THOMPSON

Jodrell Laboratory,
Royal Botanic Gardens, Kew

A new method of measurement gives more reliable data about the response of seeds to temperature in terms of their success in germination. This should help to answer many questions about plant distribution and seed performance.

During the course of evolution particular flowering plants have become adapted to grow in particular climatic conditions. One of the major factors influencing the establishment of a species in any locality is the season at which its seed germinates. This must occur at a time which is statistically favourable for the survival and eventual maturation of the seedlings, if the species is to maintain itself for any length of time. Each geographical area, and habitat, poses its own particular problems to plant survival and the flora of each area consists only of the species suitably adapted to survive these hazards. There have been many attempts to characterize the germination responses of seed to temperature, mostly based on trials in incubators set at particular temperatures. I have used a method which allows measurements to be made of germination responses for continuous ranges of temperature covering any desired span between 0° and 50° C.

Early work on seed germination responses was concerned very largely with the effects of temperature, and with ways of expressing the germination character of species or crop plants in relation to their behaviour at different temperatures. Sachs[1] first proposed the use of three cardinal points to describe the germination character, using the maximum and minimum temperatures at which any germination occurred, and the optimum temperature based on lengths of root or shoot growth within a particular period. His experiments were very short term and consequently masked the difficulties in definition of these cardinal points, which occur when more prolonged incubation periods are considered. Haberlandt[2,3] and deCandolle[4] investigated the effects of more prolonged incubation periods and their experiments provide early examples of the complexity of the germination responses of different species and the difficulties involved in them characterizing so as to permit simple comparisons one with another.

A review by Edwards[5] pointedly illustrates this problem. He cites, in a fairly detailed way, the results of many experiments done in incubators set to provide a range of temperatures. But, although the range covered is often wide, and the records made very detailed, it is practically impossible to coordinate the results to provide a simple basis for comparison of salient features of the germination characters of the species or crop plants concerned. The same criticism is applicable to more recent reviews on the effects of temperature on germination by Stokes[6] and Lang[7]. Neither of these reviews deals in any depth with the overall responses of different seeds to a range of temperatures. This omission can quite reasonably be considered a direct result of the problems inherent in such comparisons, which have stultified attempts to establish the germination character of different species to temperature, unless the criteria used are based on the broadest and most superficial interpretations of data.

Difficulty of Cardinal Points

The concept of three cardinal points seems to be simple and attractive. In practice it is complicated by variations in the approach of different workers (Edwards quotes seven different definitions of the optimum), and limited by dependence on the particular temperatures set up for the tests, and variations in the duration of incubation periods. These variations or inconsistencies of definition and conditions may be comparatively unimportant in artificial situations in which the prime consideration may be the provision of standard conditions at which to conduct routine tests of agricultural or horticultural seeds. In ecological studies, however, a sound method of comparing germination responses is essential before progress can be made in comparing responses of different species in relation to habitat or distribution. Such comparisons are essential for the study of the responses of populations or ecotypes, or for investigations on the adaptability of responses in relation to pressures exerted by climatic changes, or the consequences of introduction into cultivation by man. In these cases comparisons of germination responses depend on the definition of a germination character for each species or ecotype, which is as precise as possible, and which can be used to relate responses in different populations or species. As long as methods for the determination of cardinal points are linked closely to specific temperatures pre-set in incubators, and often almost arbitrarily selected, little progress can be expected in attempts to define germination responses.

Table 1 presents results obtained using a set of incubators in the traditional way to study germination responses of *Ajuga reptans* and *Fragaria vesca*. They are typical of many incubator experiments, and illustrate the difficulties of interpretation which may result from the use of such equipment. First, the range of temperatures provided failed to give any indication of maximum temperatures. Second, in spite of the provision of records made over a long term at weekly intervals optima are not defined and can be stated only in the most arbitrary terms. Third, although there is good reason in both species to suggest that 6° C is sub-minimal, no nearer estimation of the minimum temperatures for germination is possible. It seems to be somewhere near to 11° C for both species, but no closer estimate is possible and one can note only that the proportion of fruits germinating at 11° C is much higher for *F. vesca* than for *A. reptans*.

A more detailed comparison of germination responses is possible using thermo-gradient bars which can be set to provide controlled temperatures over a continuous range. Gradient bars constructed in this laboratory and described in greater detail elsewhere[8,9] have been used to examine temperature responses over the range 0° to 50° C. The bar consists of an aluminium alloy strip (60 cm long × 5 cm wide × 0·6 cm deep) heated at one end by a small ceramic electrical resistance, and cooled at the other end by a semi-conductor cooling module. This results in a continuous gradient of temperature from the hot end to the cold end of each bar, and the range and character of the gradient can be controlled by varying either the voltage supply to the ceramic resistance, or the d.c. current fed to the cooling module. These bars have been set up in units of six sharing common control and recording gear. Temperatures along the bars are monitored automatically using sets of matched thermistors inserted in each bar, and recorded at regular intervals on a chart recorder. Usually the bars are divided into 2·5 cm sections, the successive centre points of which differ from each other by from 1° to 2° C according to the overall temperature range. Fifty seeds sown in each section on pads of moist Whatman No. 3 *MM* filter paper overlying the bar are counted as a unit for recording purposes, so that detailed day to day germination response curves can be obtained for pre-set ranges of temperatures at intervals of 1° to 2° C. The results of an experiment using thermo-gradient bars to examine germination responses in the batches of *A. reptans* and *F. vesca* used previously are recorded in Fig. 1.

Table 1. COMPARISON OF PERCENTAGE GERMINATION OF *Fragaria vesca* AND *Ajuga reptans* AT DIFFERENT TEMPERATURES

Incubation period (weeks)	Temperature (°C) 26	21	16	11	6
(*a*) *Fragaria vesca*					
1	84	83	1	0	0
2	96	98	87	48	0
3	96	98	98	70	0
4	96	98	98	79	0
5	96	98	98	82	0
6	96	98	98	83	0
(*b*) *Ajuga reptans*					
1	61	53	16	3	0
2	73	77	38	11	0
3	74	80	50	13	0
4	75	81	65	15	0
5	75	81	77	16	0
6	75	81	77	17	0

Fruits were collected in early August from two populations growing close together at about 1,500 m.s.m. in the Alps at Serfaus in Austria. Tests were set up in incubators about 6 weeks after collection.

These curves provide a much more detailed and complete characterization of germination response than the incubator results in Table 1. In particular, they provide information about maximum and minimum responses unobtainable from the table and demonstrate that the transitions from temperatures which are favourable for germination and promote maximal levels, to unfavourable temperatures at which few if any fruits germinate, is abrupt and occurs within a range of only a few degrees centigrade. Fig. 1 also exemplifies the dilemma in quoting optimum temperatures, which can be resolved only by resorting to arbitrary criteria based on particular incubation periods or conditions. The graphs in Fig. 1 are too complex to provide a concise description of germination character suitable for simple comparisons between different species. The method adopted in this laboratory to simplify the complex of curves obtained in thermo-gradient bar experiments is to plot, for each successive day, the maximum and minimum temperatures at which a 50 per cent rate of germination is achieved. This resolves the curves into a single curve relating germination performance to both time and temperature. Curves obtained in this way for *F. vesca* and *A. reptans* plotted from Fig. 1 are shown in Fig. 2. These curves compare the germination character of the two species concerned, and reflect reasonably accurately, in view of the simplification involved, conclusions to be drawn from the complex of curves shown in Fig. 1. They also provide a full description of the positions of temperature maxima and minima, and pinpoint the differences in response between the two species. Although they are widely separated taxonomically, these species occupy geographical ranges and habitats which are rather similar, and often occur in association. It may not be surprising therefore that the germination characters of these two populations are, in general, rather similar, differing principally in the position of their minima for germination. Further comparisons, within genera, or between different species in particular habitats, are shown in Figs. 3 and 4. These figures illustrate ways in which the shape of the germination response curve can be modified to provide, for any particular sample of seed, a well defined curve in which particular salient features provide simple standards of comparison with the curves of other species. The major parameters responsible for the form of the curves can be defined as (*a*) the average time of incubation before germination—this may be relatively long as in the two *Primula* species (Fig. 3) or very short, for example, *Agrostemma githago* (Fig. 4); (*b*) the span of temperature within which germination occurs—this may be relatively narrow as in *Primula palinuri* (Fig. 3) and *Cistus creticus* (Fig. 4) or very wide, for example, *S. otites* and *S. nutans* (Fig. 3); (*c*) the position of temperature maxima and minima, for example, *Agrostemma githago* (Fig. 4) germinated to 50 per cent at temperatures down to 2° C, whereas *Primula farinosa* failed to germinate below about 11° C; (*d*) the range of temperature at which germination occurs—this naturally depends on the position of maxima and minima but its value as a character is well illustrated in a comparison of the curves for *P. palinuri* and *P. farinosa* (Fig. 3).

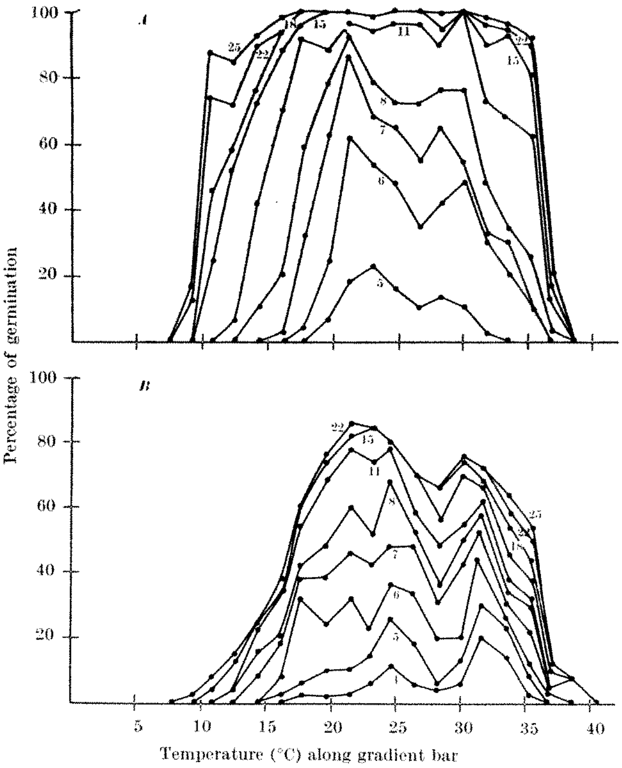

Fig. 1. Percentage germination at different temperatures of two species tested on a thermo-gradient bar. *A*, *Fragaria vesca* Linn. collected at about 1,500 m.s.m. in the Alps at Serfaus in Austria. *B*, *Ajuga reptans* Linn. collected in the same locality and in close proximity to the other species. Numbers on successive graphs indicate days of incubation before counting.

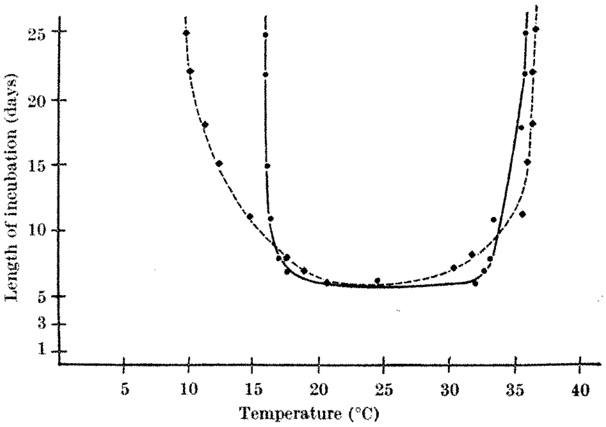

Fig. 2. Germination curves for *F. vesca* (◆- - -◆) and *A. reptans* (●——●), prepared from the graphs in Fig. 1 by plotting for successive days the maximum and minimum temperatures at which 50 per cent of maximum germination was reached.

S. otites and *S. nutans* (Fig. 3), with closely similar habitats and geographical ranges, were found to have markedly similar germination characters. Mediterranean species included in these tests all showed a marked adaptation to rapid germination at low temperatures and relatively low temperature maxima. These characteristics are apparent in a typical Mediterranean species, *Cistus creticus* (Fig. 4), in *P. palinuri* (Fig. 3) which is the only member of its genus occupying a truly Mediterranean habitat, and in a species of Mediterranean origin, *Agrostemma githago*, which has been widely dispersed as a weed of cultivation.

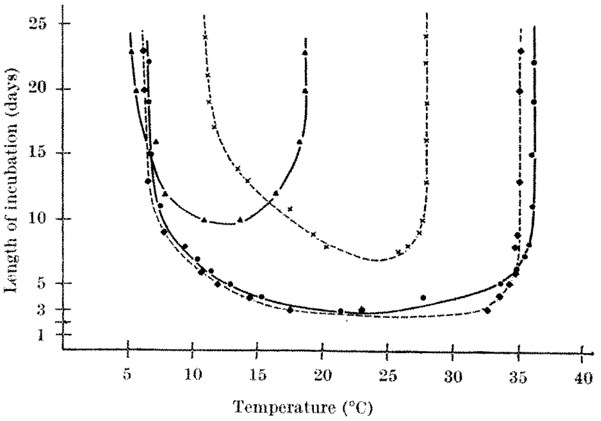

Fig. 3. Comparison of the germination responses of species from two genera; including two species of *Silene* with closely similar ranges and habitats, and two species of *Primula* with separate ranges and distinctively different habitat requirements. *a*, *Silene nutans* Linn. (●——●), collected near Dessau, German Democratic Republic; *b*, *S. otites* (Linn.) Wibel (◆- - -◆), also collected near Dessau; *c*, *Primula palinuri* Petagn (▲——▲), collected in Royal Botanic Gardens, Kew; *d*, *P. farinosa* Linn. (× - - - ×), also collected at Kew.

It is a characteristic of many species that germination of freshly shed seeds is restricted, and that the range of temperatures favouring germination becomes progressively wider as time from seed maturation increases. This phenomenon first noted by Harrington[10] and Munerati[11,12] has often been investigated, and Borriss[13] has proposed the term "relative dormancy" to describe the condition of restricted germination in freshly shed seed. It has been shown that after-ripening usually results in a progressive broadening of the span of temperatures within which germination occurs, accompanied by increased speed of germination and increases in percentage germination rates[14-16]. Seed collected from a stock of *Silene conoidea* (a Mediterranean species) was tested immediately after collection, 3 months and 1 yr later. The results plotted in Fig. 5 describe the nature of changes in response to temperature associated with after-ripening processes, and demonstrate the necessity of taking such changes into account when making comparisons between the germination characters of different species or populations.

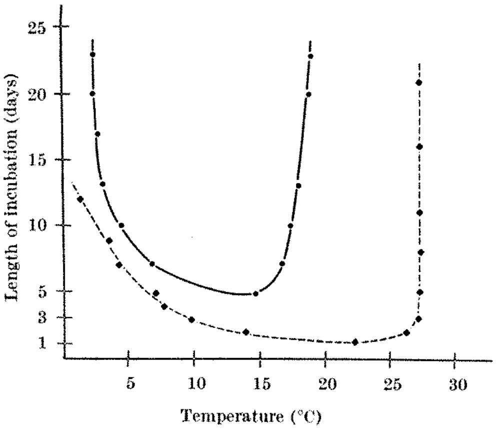

Fig. 4. Germination responses of two species of Eastern Mediterranean origin. *a*, *Cistus creticus* Linn. (●——●), using seed collected from plants growing in the Royal Botanic Gardens, Kew; *b*, *Agrostema githago* Linn. (◆– – –◆), using seed from a population growing as a weed species near Strykowo in Poland.

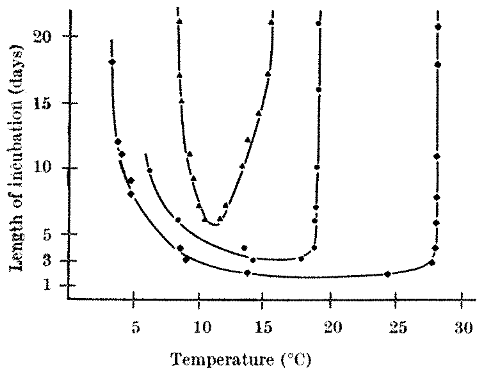

Fig. 5. Changes in germination responses of *Silene conoidea* Linn., occurring as a result of after-ripening in dry storage at laboratory temperatures. Seed collected from plants growing in the Royal Botanic Gardens, Kew. Tests were made (*a*) immediately (▲——▲); (*b*) 3 months (●——●); (*c*) 1 yr (◆——◆) after seed harvest.

Germination and Geography

Several of the early reports on seed germination[3,4,17,18] comment on the ability of seeds of some crop plants to germinate on blocks of ice or in ice stores at temperatures close to 0° C. Other reports[19,20] provide examples of seeds with rather high minimum requirements for germination sometimes in the neighbourhood of 20° C. Coffman[17] reported a wide variation in minimum germination temperatures for different crop plants, and it has been suggested[21] that the speed of germination at low temperatures, and the position of temperature minima for germination, may be correlated with the geographical distribution of different species of Caryophyllaceae. Germination tests on thermo-gradient bars were done with nine species of Caryophyllaceae using seed collected from wild plants in various parts of Europe. In Fig. 6 the results are plotted against a logarithmic time scale instead of the linear scale used before. This scale was adopted to separate more effectively relatively small differences occurring in incubation times before germination at median temperatures. Wide variations in the position of temperature minima for germination were found ranging from the three species with distributions in north-western and continental Europe, which failed to attain 50 per cent germination at temperatures below 12° to 15° C, to *Agrostemma githago* which germinated at a temperature of 0° C in less than 20 days; some of the seeds of the latter species were encased in ice by the time they germinated. The results confirmed previous observations relating germination behaviour at low temperatures to geographical distribution, showing that species with a more southern distribution germinated more rapidly and at lower temperatures than northern species. This result can be compared with Cooper's results on the effects of temperature on the induction of dormancy in various races of *Lolium perenne*[22]. The form of the curves was linear for a part of the temperature range of each species, but became markedly exponential as minima were approached. This exponential character would invalidate attempts, such as have been made[23], to determine minimum germination temperatures by extrapolation of results obtained at higher temperatures.

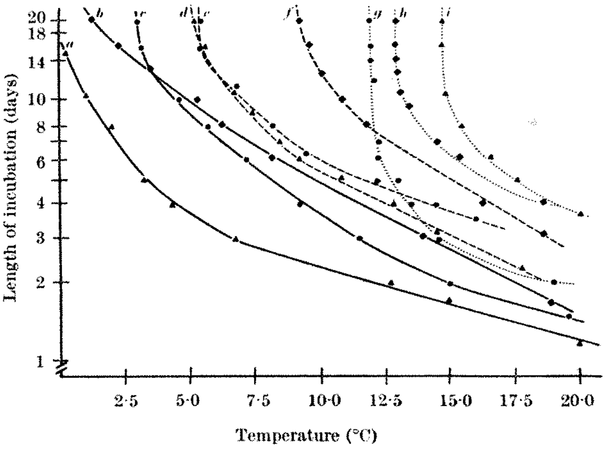

Fig. 6. Comparison, in the lower part of their ranges, of the temperature responses of species of Caryophyllaceae with different natural distributions in Europe. *a*, *Agrostemma githago* Linn., collected near Eisleben in the German Democratic Republic (▲——▲); *b*, *Silene coeli-rosea* (Linn.) Godron, collected from plants growing in the Royal Botanic Gardens, Kew (◆——◆); *c*, *S. secundiflora* Otth., collected from plants at Kew, raised from seed obtained near Almeria in south eastern Spain (●——●); *d*, *S. viscosa* (Linn.) Pers., collected near Budapest, Hungary (▲– – –▲); *e*, *S. nutans* Linn., collected near Feldkirch, Austria (●– – –●); *f*, *Lychnis viscaria* Linn., collected near Dessau in central Germany (◆– – –◆); *g*, *S. vulgaris* (Moechn) Garcke, collected near Bad Schwalbach in central Germany (● · · · · ●); *h*, *Lychnis flos-cuculi* Linn., collected in Øg, Sweden (◆ · · · · ◆); *i*, *S. alba* (Miller) E. H. L. Krause, collected near Sjklarska, Poland (▲ · · · · ▲).

Several studies have been published of attempts to interrelate the germination responses of populations of a particular species collected in different parts of its range. Haasis and Thrupp[24] and Stearns and Olson[25] working with coniferous species, and McNaughton[26] with *Typha* species all reported variations in germination of different ecotypes. Lauer[27], on the other hand, failed to distinguish notable differences between populations of *Agrostemma githago* and *Datura stramonium* collected in various locations in Europe. Results are shown here of experiments done on gradient bars with seed from three populations each of *S. otites* (Fig. 7) and *Lychnis flos-cuculi* (Fig. 8). Geographically the ranges of these two European species are predominantly quite similar, though *S. otites* has a significantly more continental and southern distribution than *L. flos-cuculi.* Habitat conditions, however, are quite different, for *S. otites* is a plant of dry sandy soils, requiring good drainage and relatively dry conditions in winter for survival in competitive conditions, whereas *L. flos-cuculi* is a plant of moist meadowland or even marshland. A comparison of Figs. 7 and 8 suggests that the principal differences in germination character between the two species derive from the much lower minima found for populations of *S. otites* and the more rapid overall germination of this species. The maxima for germination are broadly similar in both species with the exception of the population of *L. flos-cuculi* from Brno. Comparisons within and between Figs. 7 and 8 provide a broad indication of the level of similarities and differences between populations of the two species, and suggest that each has a dominant form of pattern, which may be modified in particular populations, but not to the extent of obscuring fundamental differences between the germination characters of the two species. The relationship between plant distribution and variation between populations of species of Caryophyllaceae is discussed in more detail elsewhere[8], and will not be elaborated here.

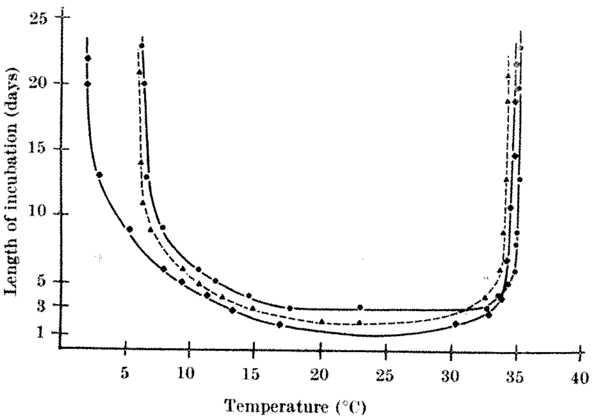

Fig. 7. Comparisons of the germination character of three populations of *S. otites* (Linn.) Wibel, collected in different parts of Europe. *a*, From Dessau, central Germany (●——●); *b*, from Budapest, Hungary (▲– – –▲); *c*, from Bouches du Rhone, France (◆——◆).

Went and Juhren[28,29,30] and Koller and Negbi[31] have presented results linking germination responses to temperature to particular ecological situations or seasons of germination, and on an *a priori* basis it is obvious that unless temperature responses are closely linked to the ecological requirements of a particular habitat a species has no prospect of establishing a persistent population. Harper[32] has already pointed out the vital and decisive importance of the season of germination as a factor dominating the prospects of the establishment of a species in an alien environment. But the germination character of a species would act as an impediment to the extension of its range only if it is a relatively fixed character, and therefore unable to adapt rapidly to the physical stimuli presented by a new or changing environment. There is a general impression, backed by little experimental evidence, that seed germination is highly adaptive as a character, and if this were so it would not be expected to act stringently as a curb to the extension of a plant's range of distribution. The question whether germination is a plastic, highly adaptive character, on the one hand, or a relatively fixed attribute characteristic of any particular species on the other, is still open, but vital to any understanding of the factors affecting plant distribution, and the extension or recession in range of particular species. Its solution depends first on a satisfactory method for defining the germination character of different species or ecotypes. It is believed that the method proposed here, and illustrated in Figs. 2 to 8, goes some way to solve problems inherent in making comparisons between different species or batches of seed tested in a wide range of different temperatures, in a way which allows a critical study of similarities and differences in germination character.

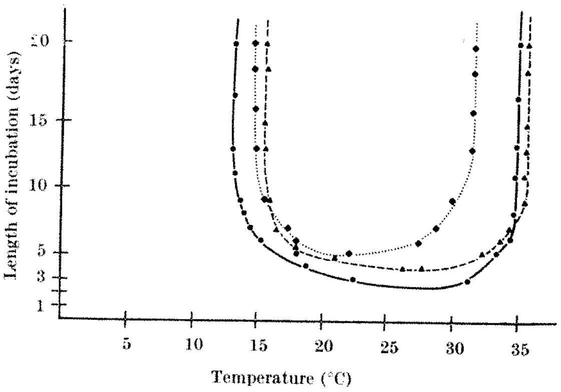

Fig. 8. Comparisons of the germination character of three populations of *L. flos-cuculi* Linn. collected in different parts of Europe. *a*, From Øg, Sweden (●——●); *b*, from near Brno, Czechoslovakia (◆ · · · · ◆); *c*, from Côte d'Or, France (▲– – –▲).

I thank Mr N. McAdam, Mrs D. Lower and Mrs P. Freeman for help with these experiments, and the directors and seed collectors of the following institutes for seed used in this work: Botanic Garden, University of Uppsala; Botanic Garden, Hungarian University, Budapest; Botanic Garden, University of Halle; Botanic Garden, Dijon University; Agricultural and Silvicultural University, Brno; Botanic Garden, University of Vienna; Botanic Garden, University of Liverpool.

PK 0048–09: a Possible Radio Variable Galaxy

OBSERVATIONS of sixty Parkes Catalogue radio galaxies north of –20° declination have been made at a frequency of 8,000 MHz. Widely differing values of flux density have been measured on different dates for one of these galaxies, PK 0048–09, and it is believed to be varying.

The observations were made between November 1968 and November 1969 with the University of Michigan 85-foot radio telescope using a wide-band (1,000 MHz) tunnel diode radiometer[1] and a dual feed-horn system[2]. The technique was to scan the source in both right ascension and declination. All scans were one degree long; they were started 0·5° off source and continued for two minutes at a rate of 0·5° per minute. Data were integrated with a time constant of two seconds so that each scan consisted of a series of sixty intensity measurements. The low signal-to-noise ratio for PK 0048–09 required several scans to obtain a flux density measurement. Between thirty and fifty two-minute scans were made each time it was observed. The observing procedure, data reduction and calibration will be described in detail in a later article.

Fig. 1 shows the measured 8,000 MHz flux density of PK 0048–09 as a function of time along with the fluxes of three other galaxies in the programme (PK 1345+12, 3C 264, PK 0124+18) which showed no significant changes. Between November 1968 and February 1969 a decline of 17 per cent in the flux density of PK 0048–09 was noted. This was followed by an increase of 83 per cent between February and July. The flux then remained roughly constant until October, when it seems to have declined by almost 20 per cent in a period of about ten days. Since then no significant change has occurred.

The largest of these changes, the 83 per cent rise between February and July, was more than ten times greater than the mean errors (4–6 per cent) associated with the measurements. Many of the mean errors of the measurements of the three comparison sources in Fig. 1 are larger than those on the measurements of PK 0048–09. This is because more scans were taken per measurement on PK 0048–09 in an effort to reduce the uncertainty.

All three measurements of the flux density of the radio galaxy PK 0124+18 were made within three hours of measurements of the flux density of PK 0048–09. If instrumental effects were the cause of the changes in PK 0048–09, one would expect PK 0124+18 to have been similarly affected. Obviously this did not occur. The antenna gain was carefully monitored by observing a standard source immediately before and after observations of a source in the programme, and no change larger than a few per cent was recorded.

Fig. 2 shows the flux densities of five more galaxies in the programme (3C 227, 3C 444, 3C 136·1, 3C 71, PK 1313+07) during the time interval in question. Again, no significant changes are seen. The eight galaxies in Figs. 1 and 2 bracket the range of flux densities over which PK 0048–09 has been observed to vary and are located at declinations both north and south of that source. Variations between measurements made on different dates for all sixty galaxies in the programme are usually smaller than the mean errors of those measurements. It is therefore concluded that the latter are reliable indicators of observational uncertainty and that the changes recorded in the flux density of PK 0048–09 are probably intrinsic to the source.

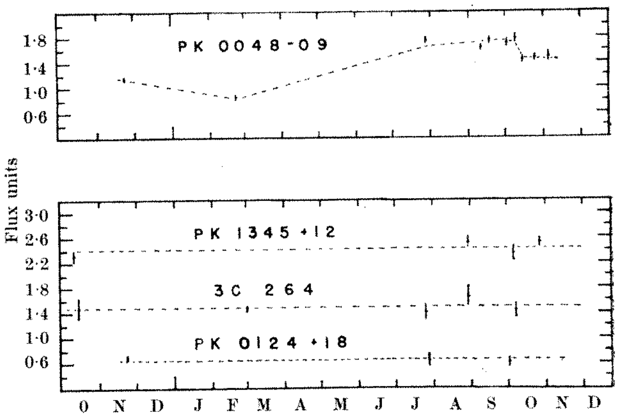

Fig. 1. Time variations in the flux density of PK 0048–09 and lack of similar behaviour in other galaxies. 1 flux unit = 10^{-26} W m^{-2} Hz^{-1}.

The radio spectrum of PK 0048–09 is shown in Fig. 3, where the range of variability recorded at 8,000 MHz is denoted by arrows. The points at 408 MHz, 1,410 MHz and 2,650 MHz have been taken from the Parkes Catalogue[3]. The point at 2695 MHz was measured by Kellermann, Pauliny-Toth and Tyler[4], while that at 5,000 MHz was recorded by Pauliny-Toth and Kellermann[5]. An attempt has been made to adjust all measurements to the same absolute calibration scale. The discrepancy between the flux densities at 2,650 MHz and 2,695 MHz may indicate that the source is also variable at those frequencies; differences of this size between the measurements of different observers are not uncommon, however.

The remarkable feature of the radio spectrum is the apparent lack of a low-frequency component. According to current ideas on the evolution of radio sources, this indicates that the radio source in PK 0048–09 is of recent origin and is considerably younger than those in most radio galaxies. It may be relevant that the extremely rapid radio variable VRO 42.22.01 (BL Lacertae)[6] has a radio spectrum similar to that of PK 0048–09 (ref. 7).

PK 0048–09 was identified as an eighteenth magnitude galaxy of indeterminate type in a small cluster of galaxies by Bolton and Ekers[8]. According to them it is much stronger on blue-sensitive plates than on red-sensitive plates. No optical spectrum has been reported.

Two other radio galaxies, 3C 84 (NGC 1275) and 3C 120, are definitely known to vary and both are classified as Seyfert galaxies. The variations in 3C 120 are not unlike those reported here for PK 0048–09. A decrease of 60 per cent in its 10,630 MHz flux between November

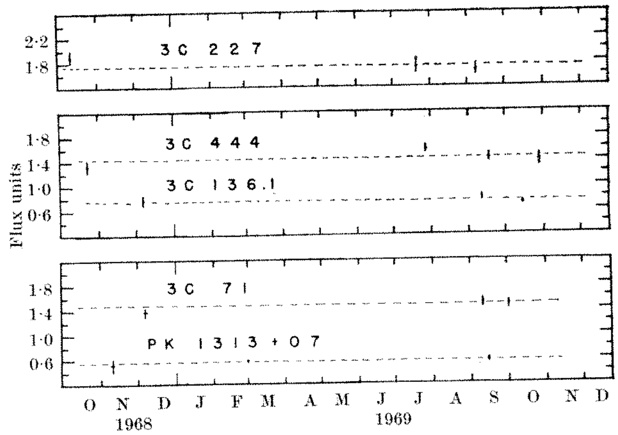

Fig. 2. Lack of significant time variations in the flux densities of five additional galaxies in the programme.

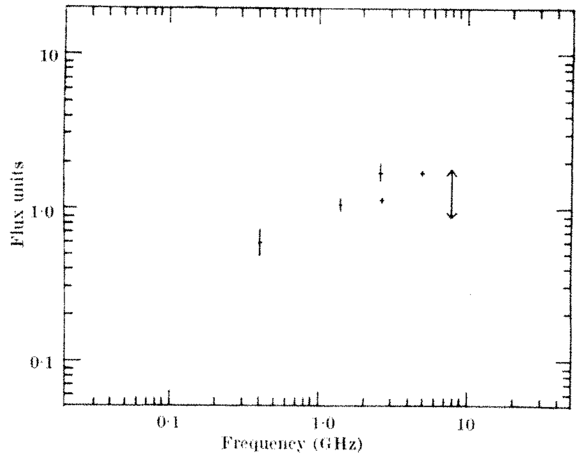

Fig. 3. The radio spectrum of PK 0048–09.

1966 and May 1967 was followed by an increase of 125 per cent between July and October 1967 (ref. 9). A similar outburst was observed at 8,000 MHz at the end of 1967 (ref. 10) and another occurred in the summer of 1968. On the other hand, 3C 84 has behaved more quietly. It showed a linear increase in flux density at 8,000 MHz of 10 per cent per year between August 1961 and January 1966 (ref. 11) and similarly at 10,630 MHz it increased by 7 per cent between July 1966 and April 1967 (ref. 9). McCullough and Waak[12] have reported a linear increase of 19 per cent at 19,300 MHz from 1966 to 1968 with the possibility that several small bursts have been superimposed on this rise not excluded. Most recently, however, an outburst at 90,000 MHz has increased the flux density of 3C 84 by 80 per cent between October and December 1969 (ref. 13). Both galaxies are also optical variables.

I thank Professor F. T. Haddock and Dr H. D. Aller for advice and criticism, and G. E. Latimer, Dr T. V. Seling and K. Holmes for designing and maintaining equipment. This work was supported in part by the US National Science Foundation and I was aided by a NASA traineeship.

Note added in proof. A new outburst has increased the 8,000 MHz flux density of PK 0048–09 from 1·41 ± 0·05 flux units on November 24, 1969, to 2·35 ± 0·08 flux units on January 31, 1970.

An Explanation for the Broad Supernova Bands

SPECTRA of type I supernovae show broad emission bands, none of which has been satisfactorily explained[1]. Seddon[2] has proposed that the structure in the visible spectrum be regarded as broad absorption bands on a more intense continuum. The absorption bands could be produced by clouds of dust surrounding the star. On this viewpoint several supernovae absorption features fall near some of the much narrower unidentified absorption bands arising in the interstellar medium. This article reports an application of this new interstellar band explanation to supernovae spectra interpreted in terms of absorption features. The more intense background used to obtain the supernovae absorption will be discussed after a brief presentation of the proposed absorption band origin.

My explanation for the most intense interstellar bands is that they are due to iron ions in crystals such as garnet silicates (unpublished). Because of the strong electric fields of neighbouring O^{2-} ions in the crystal, the absorption bands due to iron ions are very different from the absorption bands of free iron ions. At low crystal temperatures, bands with widths of about 30 Å can occur, while at room temperature and above, band widths are typically several hundred Å. Garnets are a type of silicate of variable composition indicated by

$$\overset{(8)}{P_3}\overset{(6)}{Q_2}(\overset{(4)}{Si}O_4)_3$$

where P may be Ca^{2+}, Mn^{2+}, Fe^{2+}, Mg^{2+}, and other ions, Q may be Fe^{3+}, Al^{3+}, Cr^{3+}, and other ions, and Si may be replaced by Fe^{3+}. The numbers in parentheses indicate that P is surrounded by eight negative ions, Q by six ions (octahedrally) and Si by four ions (tetrahedrally). Iron ions can occupy all three different positive ion sites giving rise to several different crystal field bands in each site. Energies of these transitions do not vary greatly from one composition of garnet to another because negative ion configurations are the same and distances are comparable. Fig. 1*b* shows the bands due to iron ions in garnets taken from room temperature optical absorption measurements. The solid curves are all taken from data on laboratory grown yttrium iron garnet (YIG) crystals[3], chemical composition $Y_3Fe_2(FeO_4)_3$, whose optical properties have been more extensively studied than any naturally occurring garnets. In YIG, Fe^{3+} ions occupy the octahedral Q sites (6) and the tetrahedral Si sites (4). To complete the sketch of all iron bands in garnets, bands due to Fe^{2+} in the P sites are shown in the dotted curves as taken from the natural almandine garnet spectrum in Fig. 1*c* (ref. 4). It is worth noting that iron impurities occupying the octahedral sites (6) give rise to bands in Fig. 1*c* near the same wavelengths as in YIG. The bands near 4400 Å and 6100 Å are absent in the mineral, however, because iron rarely replaces silicon.

In all garnet crystals there is a rising absorption in the ultraviolet, with shape and position which depend on the exact chemical composition. The background has been subtracted to display the bands of Fig. 1*b*, but such an absorption edge is seen in Fig. 1*c*. If the absorption bands in supernovae spectra are due to surrounding clouds of such dust, the ultraviolet intensity transmitted through the dust should be very low. A suggestion of this effect may be seen in the decrease of the short wavelength intensities as the absorption bands of the supernova increase with time[5]. In the absence of knowledge about the original light spectrum incident on the dust, I have assumed that it follows an infinite temperature Planck distribution. The supernova spectrum has been subtracted from this assumed continuum and plotted in Fig. 1*a*. Data from the supernova in NGC 4496 studied by Bloch, Chalonge and Dufay[5] have been used because of the wide spectral range covered and because the authors have attempted to correct for instrumental errors to present true intensities. It may be noted, however, that the averaged spectrum used by Seddon[2], and the spectra of other type I supernovae[6,7], show similar bands. Only one spectrum has been used rather than an average of all spectra in order to display the largest possible wavelength range. The break in the curves near 6000 Å indicates the addition of longer wavelength data from the

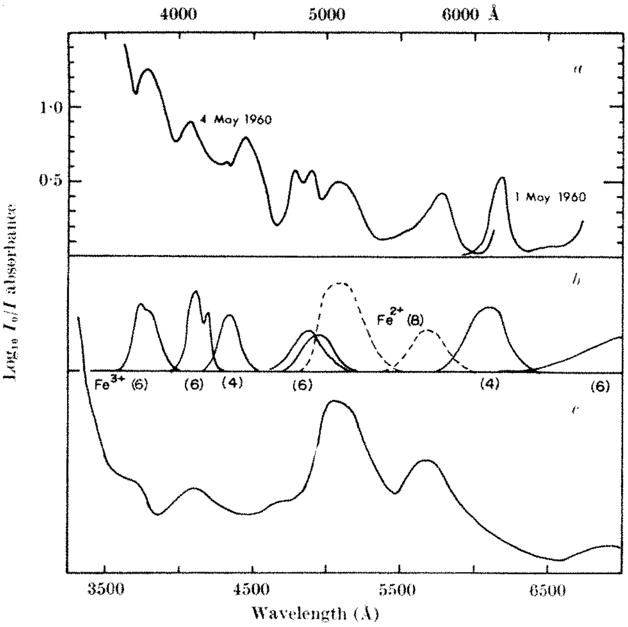

Fig. 1. *a*, Data from the supernova in NGC 4496. *b*, Bands due to iron ions in garnets taken from optical absorption measurements. *c*, Spectrum of almandine garnet $Fe_3Al_2(SiO_4)_3$.

spectrum of May 1 to the spectrum of May 4 in order to further extend the wavelength range. Due to the use of only one spectrum, the band positions are uncertain to perhaps 50 Å and are somewhat uncertain in shape.

Comparison of Fig. 1*a* and Fig. 1*b* shows that seven bands due to iron ions in garnet crystals correlate in wavelength and approximate width within the supposed uncertainty. These bands are centred at wavelengths of about 6100, 5700, 5100, 4900, 4400, 4100 and 3800 Å. The band at 4900 Å in the supernova spectrum even seems to show a two-fold splitting corresponding to the laboratory spectrum, and the increase of the long wavelength limit of the supernova curve corresponds to the edge of the 7000 Å garnet band. One also notices the rising background in the ultraviolet produced by the form of the continuum used. The similarity of this absorption to that in garnets may offer some vindication for use of the high temperature continuum background. In view of the fact that only the bands near 5100 and 5700 Å are due to Fe^{2+} (8), there may be significance in the fact that these two bands seem to grow faster in the later stages of the supernova in NGC 4496 (ref. 5). The two bands also appear comparatively weaker in spectra from supernovae in NGC 2713 (ref. 6) and NGC 3389 (ref. 7). A very rough estimate of the amount of garnet dust necessary to produce the observed bands can be obtained by using the absorption coefficients of almandine. The estimated quantity of dust in a unit cross-section in the line of sight, if compacted into a solid mass, would be equivalent to a thickness of 0·01 to 0·1 cm.

If the present interpretation is correct, several important facts concerning supernovae are implied: (1) The widths of the features in the supernovae spectra are chiefly due to inherent broadness of the optical absorption bands in the solids. The large widths should not then be associated with large velocities. (2) The measured blue and ultraviolet intensities which reach us may bear little resemblance to the initial intensities. (3) The supernova dust cloud which gives rise to the broad absorption bands, when cooled down to the low temperature of interstellar dust, could give rise to a number of the much narrower bands observed to arise in the interstellar medium.

Scattering of X-rays from Pulsar NP 0532 by Interstellar Grains

SLYSH[1] recently considered the scattering of soft X-rays from the Crab Nebula, and suggested that although all the observed X-rays from the Crab Nebula could have originated as pulsed X-rays from the pulsar NP 0532 at the centre, only ~10 per cent unscattered by interstellar grains are recorded as pulsed X-rays in the 1–10 keV region[2–4]. The remaining 90 per cent are scattered, appearing as a diffuse source about 2′ wide[5,6] in which the pulses are smeared out. In this report we show that the optical depth for scattering by interstellar grains is small in the 1–10 keV region, and that the pulsed component is reduced by ~20 per cent at the most. Consequently, the observed spectrum of the pulsed component in the 1–100 keV region[2–4,7,8] should closely correspond to the spectrum of the pulsar at the source, which would not have been the case from the analysis of Slysh. The optical depth for scattering is quite insensitive to the exact model of interstellar grains.

We have assumed that interstellar grains are single smooth spheres, that single scattering holds, and that the incident and scattered radiations have the same wavelength. The optical depth due to extinction (scattering and absorption) by the grains along the line of sight is defined by

$$\tau(\lambda) = n_g R \pi a^2 Q_{\mathrm{ext}}(\rho) \tag{1}$$

where n_g and a are the number density and radius of the grains, R the distance of the object and Q_{ext} is the extinction efficiency (suffix x is used later to indicate X-ray quantities). ρ is an important physical variable defined by

$$\rho = 2x(m-1) \tag{2}$$

where

$$x = 2\pi a/\lambda \tag{3}$$

and $m = m' - m''$ is the complex refractive index of the grain. Re{ρ} represents the additional phase difference introduced by the grain for the wave passing across its diameter. For X-rays, m is typically close to but less than 1.

$$m_{\mathrm{x}} - 1 = -\frac{N_e r_e \lambda_{\mathrm{x}}^2}{2\pi} - i\frac{\mu\lambda_{\mathrm{x}}}{4\pi} \tag{4}$$

where r_e is the classical electron radius ($2{\cdot}818 \times 10^{-13}$ cm), μ is the linear attenuation coefficient of the grain material, λ_{x} is the wavelength of the X-radiation, and N_e is the number density of both bound and free electrons in the grain

$$N_e = N_0 \left\langle s\,\frac{Z}{M} \right\rangle \tag{5}$$

Here s is the density of the grain material (g cm^{-3}), N_0 is Avogadro's number, M is the gram molecular weight and Z is the number of electrons per molecule. The factor $\left\langle s\,\frac{Z}{M} \right\rangle$ should be taken as a weighted mean over the molecular species constituting the grain. For typical values of $a \approx 0{\cdot}1$–1 μm, $s \approx 1$, and $\lambda_{\mathrm{x}} \approx 1$–$10$ Å, we find

$$0 > m_{\mathrm{x}} - 1 \gg -1,\quad x \gg 1,\quad 0{\cdot}02 < \rho_{\mathrm{x}} < 2$$

Because x can be as large as 10^4 it is not practicable to use the rigorous Mie theory[9] of scattering by spheres. We may, however, take advantage of the fact that

$m_x \approx 1$ and m''/m' is very small ($\sim 3 \times 10^{-2}$–3×10^{-3}), that is, absorption is negligible. Taking only the real part of ρ_x

$$\rho_x = 0{\cdot}34 a \lambda_x \left\langle s \frac{Z}{M} \right\rangle \tag{6}$$

Depending on the values of m_x, x and ρ_x, appropriate approximations can be used to calculate Q_{ext} (ref. 9). With $0 > m_x - 1 \gg -1$ and $x \gg 1$, Rayleigh–Gans scattering can be used for $\rho < 1$ and the anomalous diffraction approximation for $\rho \gtrsim 1$. In the latter case

$$Q_x = 2 - \frac{4}{\rho_x} \sin \rho_x + \frac{4}{\rho_x^2}(1 - \cos \rho_x) \tag{7}$$

For very soft X-rays $\rho_x \gg 1$ and Q_x approaches 2·0, the asymptotic limit. For hard X-rays $\rho_x < 1$ and

$$Q_x \approx \frac{1}{2} |\rho_x|^2 - \frac{8x}{3} Im(m-1)$$

Dielectric grains (dirty ice) of radius $a = 0{\cdot}25$ µm, density $s = 1{\cdot}05$ and $m = 1{\cdot}33 - i\ 0{\cdot}05$ give a good fit to the observed optical and near-infrared extinction in the region 0·33 to 2·13 µm, as shown in Fig. 1, based on Mie theory calculations. In the visual region $\lambda = 0{\cdot}54$ µm, $\rho = 1{\cdot}92$ and $Q_{ext} = 1{\cdot}78$. From equation (7) it can be seen that the same extinction occurs for $\rho_x = 2{\cdot}15$. Then, putting $\left\langle s \frac{Z}{M} \right\rangle = 0{\cdot}55$ for dielectric grains we obtain $\lambda_x = 43{\cdot}5$ Å. Similarly in the infrared, $\lambda = 1$ µm, $\rho = 1{\cdot}04$ and $Q_{ext} = 0{\cdot}58$. The same extinction occurs in the X-ray region for $\lambda_x = 22{\cdot}5$ Å. It is thus seen that the optical depth in the visual and infrared is also reflected in the X-ray region as a consequence of the refractive index as defined in equation (4). It may be noted that whereas in the optical region $\rho \propto a/\lambda$, in the X-ray region $\rho_x \propto a \lambda_x$. It is not obvious from this, however, if similar wavelength dependence would occur for Q_{ext} and Q_x.

In the direction of the Crab Nebula, the extinction in the visual is 1·08 magnitudes kpc^{-1} (ref. 12). This corresponds to an optical depth of 1·0 kpc^{-1}. Taking a distance of $R = 2$ kpc for the Crab Nebula[13], we obtain $\tau(0{\cdot}54\ \mu m) = 2{\cdot}0$. In Fig. 2, we have shown the optical depth for scattering of X-rays from the Crab Nebula as a function of wavelength (curve 1) by setting $\tau(43{\cdot}5\ \text{Å}) = 2{\cdot}0$. It should be noted that it is not necessary to know the values of $N_g = n_g R$ to calculate τ_x. But substituting for τ and Q_{ext} at 0·54 µm in equation (1) we deduce the column density of grains as $N_g = 5{\cdot}7 \times 10^8$ grains cm^{-2}. For $R = 2$ kpc, $n_g = 9{\cdot}3 \times 10^{-14}$ grains cm^{-3}. Calculations show that the extinction in the visual region for pure ice ($m'' = 0$) differs from that of dirty ice only by ~ 1 per cent.

Ice grains, pure or dirty, do not adequately account for the observed extinction in the ultraviolet and infrared.

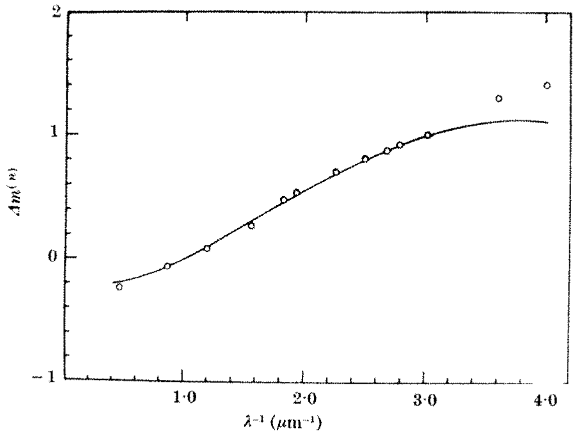

Fig. 1. Theoretical normalized extinction curve in the visual and near-infrared, for dielectric spheres of radius $a = 0{\cdot}25$ µm and refractive index $m = 1{\cdot}33 - i\ 0{\cdot}05$. The circles are experimental observations of Boggess and Borgman[10] and Stecher[11]. $\Delta m^{(n)} = \dfrac{\Delta m(\lambda^{-1}) - \Delta m(1)}{\Delta m(3) - \Delta m(1)}$

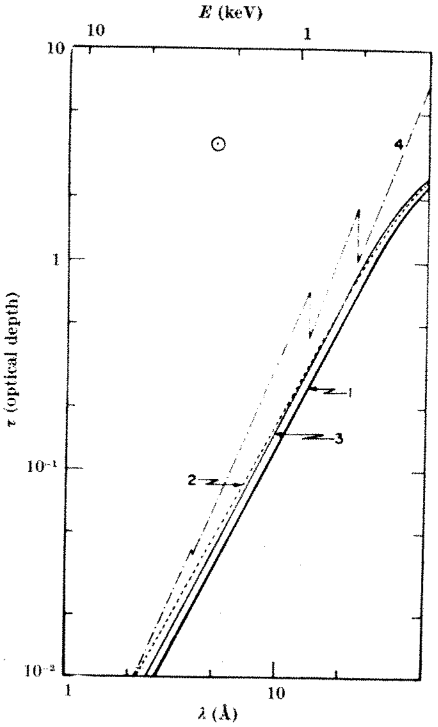

Fig. 2. Optical depth against wavelength of X-rays in the direction of Crab Nebula. Curves 1, 2, 3 are for scattering by interstellar grains. (1) Dirty-ice grains of uniform size, $a = 0{\cdot}25$ µm and $m = 1{\cdot}33 - i\ 0{\cdot}05$; (2) same as 1 but with a size distribution function (see equation 8); (3) composite grains with graphite core of radius 0·054 µm, and ice mantle of radius 0·16 µm. Curve 4 is the optical depth for photoelectric absorption by interstellar gas. The circle is the optical depth due to scattering given by Slysh[1] at 5 Å.

Composite grains with graphite cores of radius 0·054 µm and ice mantles of radius 0·16 µm have been proposed for explaining the ultraviolet and infrared observations[14,15]. This model of grains also successfully accounts for the observed results on polarization, albedo (the fraction that is scattered) and back-scattering[14]. For graphite core–ice mantle grains, Q_{ext} ($\lambda = 0{\cdot}54$ µm) $= 1{\cdot}26$ (ref. 15). The same extinction occurs in the X-ray region at $\lambda_x = 37{\cdot}5$ Å. Curve 3 in Fig. 2 shows the optical depths against λ_x for graphite–ice grains. It is similar to the curve for dirty ice.

So far we have assumed all the grains to be of the same size. We have calculated the optical depth in the X-ray region for ice grains using a size distribution

$$n(a)\text{d}a = n(0)\text{e}^{-5(a/a_0)^3}\text{d}a \tag{8}$$

This functional form suggested by Greenberg[16] is a very good representation of the original Oort–Van de Hulst distribution derived physically[17]. Following Greenberg[16] we have chosen $a_0 = 0{\cdot}5$ µm as the best fit for the optical observations of extinction. The corresponding optical depth in X-rays is shown as curve 2 in Fig. 2. To draw this curve we have chosen n_g such that the total mass of the grains is the same as for the case of the uniform size model. The distribution function slightly alters the shape of the curve. Comparing curves 1, 2 and 3 we note that the optical depth is insensitive to the model of the grains. Also shown is the optical depth obtained by Slysh[1] which is too large by a factor of ~ 80 at 5 Å.

The optical depth for photoelectric absorption in the interstellar gas is also shown (curve 4) using the cross-sections given by Bell and Kingston[18], and assuming a column density of $1{\cdot}6 \times 10^{21}$ H atoms cm^{-2} (ref. 19 and unpublished work of Grader *et al.*). At $\lambda_x = 20$ Å the optical depth for absorption is 1, and at all wavelengths the interstellar gas absorption dominates over scattering by interstellar grains.

Table 1 shows the rocket and balloon results on F_{obs}, the fraction of pulsed X-rays from the pulsar NP 0532. In the last column we have given F_s, the pulsed fraction

Table 1. ROCKET AND BALLOON RESULTS

Authors	Energy interval E_1, E_2 (keV)	Wavelength interval λ_1, λ_2 (Å)	F_{obs} (%)	F_s (%)
Fritz *et al.*[2]	0·8– 4	3 –15	$5·0 \pm 0·6$*	6 ± 1
Bradt *et al.*[3]	1·5– 8	1·5 –8	$8·4 \pm 0·3$*	$9·0 \pm 0·5$

* Errors were estimated by us from the data.

at the source, after correcting for scattering by the interstellar grains. The pulsed component observed in hard X-rays (> 20 keV) is unaffected by grains, and in soft X-rays the correction is 10–20 per cent. It is therefore clear that the observed spectrum of the pulsar in the 1–100 keV region should correspond closely to the spectrum at the source. The absorption by interstellar gas depletes the steady as well as the pulsed components by the same factor, so that F_{obs} is independent of photoelectric absorption. It should be emphasized that the conclusions remain unchanged even if the optical depth is altered by a factor two either way. Such a large uncertainty in optical depth is unlikely, however, because of the constraints placed by experimental observations of optical extinction on grain models.

In conclusion, the spectrum of the pulsed X-rays from NP 0532 (in the 1–100 keV region) is affected only very slightly by scattering by interstellar grains. The major part of the X-ray flux—80 to 95 per cent depending on the energy—arises as unpulsed X-rays from the pulsar source and/or the nebula, although the contribution from the former is likely to be quite small. It is worth noting that optical observations of NP 0532 (ref. 20) show that the unpulsed radiation from the pulsar itself is very small.

We thank Professor B. V. Sreekantan and Dr M. V. Krishna Apparao for comments.

Pulsars and the Universal X-ray Background

IT is now established that there is a universal X-ray background with an energy flux of about 10^{-7} erg cm^{-2} sr^{-1} s^{-1} (M. Oda, at the thirty-seventh IAU symposium, Rome, 1969). One possibility is that the background is a superposition of X-ray emission by all the galaxies in the universe, but the value obtained by taking the average X-ray emission per galaxy as that estimated for our galaxy is not enough[1]. Silk[2] has taken the evolution of the universe into account using observations on radio sources as a guide to raise the intensity to the required level. The second explanation is the Compton scattering of the universal microwave background photons by intergalactic electrons[3]. This seems to be inadequate using earlier estimates of the intensity of intergalactic electrons, and an appeal to cosmological evolution did not help[4]. Recently, however, Brecher and Morrison[5] using shorter lifetimes for escape of electrons from galaxies, and also the observations on radio sources, find the Compton process capable of explaining the X-ray background. Both explanations involve important assumptions, however. Silk estimates the average galactic emission by assuming that the galaxy contains a hundred sources like the strongest observed source Sco X–1. Brecher and Morrison assume that the lifetime of electrons in all galaxies is less than a million years and that the electrons escape into intergalactic space without being trapped in galactic haloes.

In this report, I suggest that the X-ray background arises as a superposition of sources, but that the sources are nascent pulsars in various galaxies. I use as a guide the pulsar NP 0532 in the Crab nebula, the strongest pulsar observed so far. The X-ray energy output[6] from NP 0532 is about 10^{36} ergs s^{-1}; the optical output[6] is about 10^{34} ergs s^{-1} and the radio radiation[7] is a few times 10^{31} ergs s^{-1}. The total energy dissipation is estimated[8] to be $2–4 \times 10^{37}$ ergs s^{-1}. Thus the X-ray emission of the pulsar is 2–5 per cent of the total energy dissipation. A newborn pulsar is estimated to have a rotational energy content[8] of 10^{52} ergs. The rate of energy dissipation and its half-life can be estimated using certain assumptions, but it turns out that this is not necessary for the present work.

The X-ray background intensity I from the superposition of galaxies can be written as

$$I = \frac{1}{4\pi}\,\frac{\rho\,.\,L\,.\,S\,.\,\tau}{T} \text{ ergs cm}^{-2}\text{ sr}^{-1}\text{ s}^{-1}$$

where ρ is the density of galaxies, L is the dimension of the universe, T is the period for the birth of a pulsar (supposed to occur in a supernova explosion), S is the rate of X-ray emission of the pulsar and τ is the time for which the pulsar emits X-rays at that average rate. It is sufficient to know the product $S\tau$ and not S and τ separately. The product $S\tau$, which is the total energy emitted by the pulsar in X-rays, is taken to be about one per cent of the total energy, taking NP 0532 as a guide. In fact when the pulsar is born, magnetic fields associated with the supernova remnant are higher and it is likely that intensities are higher. Thus $S\tau$ is greater than 10^{50} ergs. I use $\rho \simeq 3 \times 10^{-75}$ galaxies per cm^3, $L = 10^{28}$ cm and $T = 100$ yr. Then:

$$I = \frac{1}{4\pi}\,\frac{3 \times 10^{-75}\,.\,10^{28}\,.\,10^{50}}{3 \times 10^{9}}$$

$$\simeq 10^{-7} \text{ ergs cm}^{-2}\text{ sr}^{-1}\text{ s}^{-1}$$

Thus it seems the universal background can arise as a superposition of radiation from pulsars in various galaxies. It may be argued that every supernova explosion may not be associated with a pulsar and the average time T for the birth of a pulsar might be larger than 100 yr. Even in such a case the product $S\tau$ plausibly can be taken higher by a factor of ten than the value which I have used. Effects due to the evolution of the universe, which I have not dealt with here, should also enhance the intensity of the background[2].

It is important that the superposition of the radio radiation from these pulsars should not be larger than the observed extragalactic radio radiation. This is possible if the pulsar radio radiation is less than the X-radiation by a factor of 10^4. This is true for NP 0532 and is even more likely to hold in the earlier life of a pulsar when the magnetic fields are higher.

The X-ray energy spectrum due to the superposition cannot be predicted—it would involve assumptions on the nature of the energy spectrum of pulsars during their early life. But as the radiation escapes from the pulsars into intergalactic space, absorptive effects caused by gas within the galaxies should leave an impression on the spectrum.

I thank my colleagues at the Tata Institute of Fundamental Research for criticism and discussion.

Secondary Periodicities in Pulsars

PERIODIC intensity fluctuations in pulsars, first noted by Conklin *et al.*[1] in CP 1919, have now been reported by a number of observers[2-9]. The present data support the earlier results. They also reveal a very pronounced modulation for CP 0834 which cannot be explained readily by current theories and give an upper limit for the stability of the secondary periodicity in the case of CP 1919.

This report describes measurements of five pulsars using the 4-acre, 81·5 MHz phased array at the Mullard Radio Astronomy Observatory. The aerial is used as a transit instrument and allows approximately two minutes' observation of each source per day. Successive pulse amplitudes were used to obtain the autocorrelation function of pulse amplitude in the range 0 to 30 pulse periods. The power spectrum was obtained by Fourier transformation of the observed autocorrelation function.

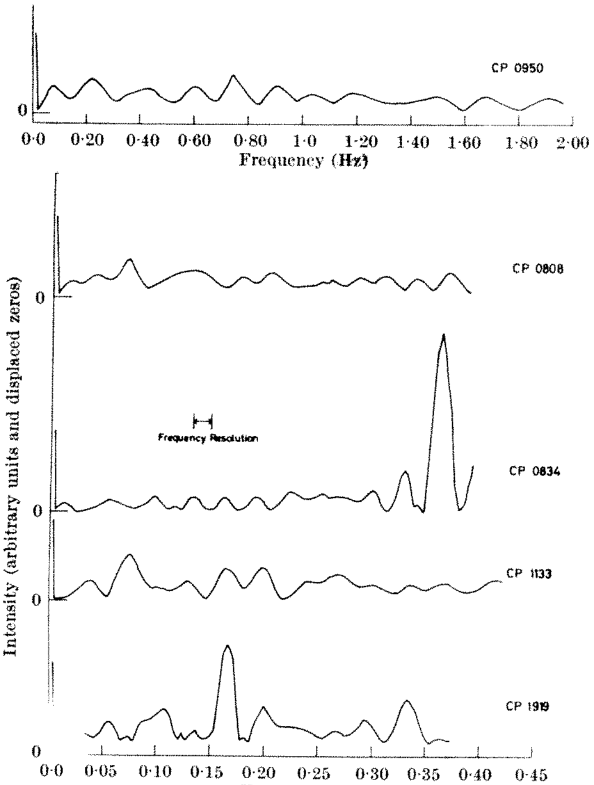

Fig. 1. Power spectra of the pulse-to-pulse intensity variations for five pulsars. Intensity scale has arbitrary units and displaced zeros.

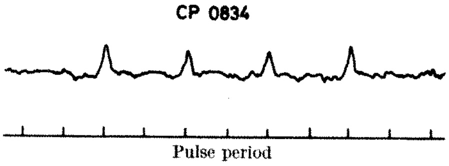

Fig. 2. Record of CP 0834 showing alternate pulses only.

Table 1. SUMMARY OF THE POWER SPECTRA DATA FOR FIVE PULSARS

Pulsar	Frequency of second periodicity (Hz)	Percentage modulation
CP 0808	0·069	$M \sim 5\%$
CP 0834	0·363	$33\% \leq M \leq 100\%$
CP 0950	—	—
CP 1133	0·075	$M \sim 5$–10%
CP 1919	0·167	$25\% \leq M \leq 50\%$

Fig. 1 shows the derived power spectra for five pulsars, and the significant features are summarized in Table 1. For the pulsar CP 0950 no significant feature has been found. In the case of CP 0808, however, a possible feature near 0·07 Hz coincides with a more marked feature noted by Taylor *et al.*[5]. A similar feature for CP 1133 at ~0·075 Hz may also be significant. The pulsars CP 0834 and CP 1919 both show prominent spectral components, corresponding to modulation periods of 2·16 times and 4·39 times the pulse period respectively. The spectrum of CP 1919 shows a clear feature at 0·167 ± 0·008 Hz which is only partially obscured by the effects of the large random pulse-to-pulse variations found in this source. Taylor *et al.*[5] have suggested that their failure to observe this feature is due to the smallness of their data sample of 1,344 pulses. In our data, at a somewhat lower frequency, the feature could sometimes be observed in samples of only 100 pulses, however. It is therefore possible that this modulation is not a constant feature of the source. The results for CP 0834 are particularly interesting because of the very strong modulation effect observed. At 81·5 MHz the percentage modulation (defined as $[(I_{\max}-I_{\min})/(I_{\max}+I_{\min})\times 100$ per cent$]$) is rarely found to be less than 33 per cent and can approach 100 per cent. The very pronounced character of the amplitude variations at this frequency is consistent with the frequency dependence reported by Taylor *et al.*[5], who found little modulation for frequencies above about 200 MHz. A section of record with 100 per cent modulation (that is, every second pulse missing) is shown in Fig. 2.

It is important to investigate the constancy of the observed secondary periodicities. For both CP 0834 and CP 1919 the spectral features are unresolved, implying a Q value greater than 100. In order to look for long-term changes, a power spectrum analysis of CP 1919 has been carried out using data obtained in December 1967. No detectable difference exists between the two sets of data, implying an upper limit of 5 per cent for the change in period over the time interval of 1·4 yr. This result, together with the measurements of other observers[3,5], seems to conflict with the change of period reported by Slee[4] for this source, which implied a variation in period of the order of 2·5 per cent per month.

The origin of the secondary periodicities is uncertain. For CP 1919 Drake and Craft[2] have reported sub-pulse structure of ~15 ms period which, being incommensurate with the main pulse period, will produce a drifting pattern with respect to the long main pulses 35 ms. The observed peak in the power spectrum can then be explained in terms of aliasing. For the case of CP 0834, however, where the modulation reaches 100 per cent, such an explanation seems unlikely because, in order to obtain such a large modulation, the sub-pulse period would have to be of the same order as the basic pulsar period. A phase scatter similar to that noted by Drake and Craft[2] in the sub-pulses of CP 1919 and CP 2015 would also be inconsistent with the observed modulation. Similarly, the model of Vila[10] which explains the sub-pulse in terms of a rotation and the primary pulsar periodicity as due to precession is also inappropriate in a case where the two periods are comparable in value.

For CP 0834, at least, some mechanism apart from sub-pulse structure seems to be necessary.

I thank Drs P. F. Scott and A. Hewish for discussions.

Pulsar Wobble and Neutron Starquakes

Two types of non-secular changes in pulsar frequency f have been reported. One is a sudden small frequency jump Δf in both NP 0532 (the Crab pulsar)[1,2] and PSR 0833 (the Vela pulsar)[3,4]. The other is a slow, small amplitude "wobble" of frequency ν in the Crab pulsar frequency[5]. A number of explanations for the jumps have been put forward, based on the model of a pulsar as a rotating neutron star: (1) the near passage of a planet in an orbit of high eccentricity (unpublished work of Michel); (2) a fluid instability caused by the crust of the neutron star rotating more slowly than its core[6]; (3) a sudden relaxation of strains which have built up in the stellar crust (starquake)[7,8]. Suggested mechanisms for the wobble include: (a) induced motion by yet another planet[5]; (b) free precession of a non-spherical star (unpublished work of Chiuderi and Occhionero); (c) normal mode vibrations of quantized vortex lines within the rotating superfluid core[9].

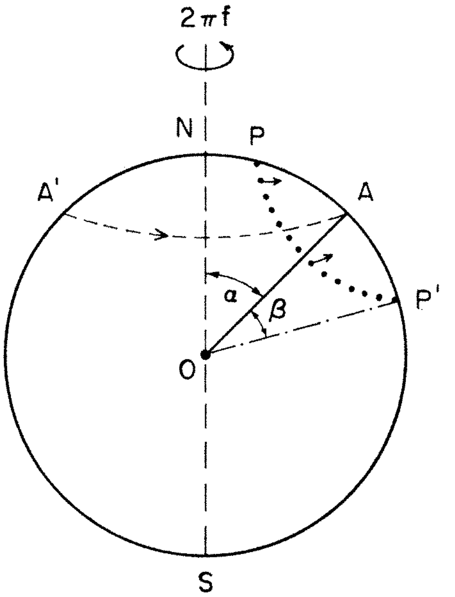

Fig. 1. Reference figure for motion of points on the surface of a precessing oblate spheroid.

The various models for the frequency jumps have different consequences for the subsequent behaviour of the wobble frequency. If explanations (3) and (b) hold (free precession and starquake frequency jumps), there should be a considerable and predictable post-jump decrease in the Crab wobble frequency. Such a model, together with the similarity between the Crab pulsar wobble frequency (Rome pulsar conference) $\nu = 1{\cdot}6 \times 10^{-7}$ Hz, and its residual jump after a few weeks $\Delta f_p = 4{\cdot}3 \times 10^{-8}$ Hz, supports the notion of a relatively weak crust strength in the Crab which relaxes every few years.

For simplicity I consider a rapidly spinning, axially symmetric, slightly oblate spheroid whose paraxial moment of inertia I exceeds its perpendicular moment of inertia by δI. It has a Poinsot precessional motion when its spin angular momentum is not exactly along a principal axis of inertia. The motion of characteristic points on the surface of such a spheroid is sketched in Fig. 1. The fixed angular momentum direction is $\overline{\mathrm{ON}}$; the line $\overline{\mathrm{OA}}$ is the axis of symmetry of the rotating spheroid. The instantaneous spin direction deviates from OA by such a small angle ($\sim \delta I/I$) that it is ignored in the figure. The point A moves along the line of constant latitude (relative to ON) AA′ at constant angular frequency f. Any other point P in addition rotates with precessional frequency ν_p about the OA axis with

$$\nu_p = \frac{\delta I}{I} f \cos \alpha \tag{1}$$

It therefore moves along constant latitude lines, but the latitude adiabatically varies up and down. As the point A disappears over the horizon, the point P on various revolutions has moved from P to P′ and then back to P over the horizon. In the absence of a more definitive understanding of the pulsar signal it is not clear how to associate such geometrical motions with the period of the pulsar clock. I assume that it is related to the time some special point on the neutron star surface comes over the horizon or passes any other fixed longitude determined by the fixed axis $\overline{\mathrm{ON}}$ and the direction to the observer. For this motion, the pulsar clock phase φ is

$$\varphi = 2\pi\nu_p t + \tilde{\varphi} \tag{2}$$

with the wobble in phase, $\tilde{\varphi}$, determined by

$$\cos \tilde{\varphi} = \frac{(\cos 2\pi\nu_p t) \sin \alpha}{[1 - (\cos \alpha \cos \beta + \sin \alpha \sin \beta \sin 2\pi\nu_p t)^2]^{\frac{1}{2}}} \tag{3}$$

The wobble is not sinusoidal except in the two limiting cases where the point P lies near the pole A or near the equator. For $\beta \ll 1$, $\beta < \alpha$

$$\tilde{\varphi} \sim \frac{\beta}{\sin \alpha} \cos 2\pi\nu_p t \tag{4}$$

For P on the spheroid equator $\beta = \pi/2$. Then when $\alpha \ll 1$

$$\tilde{\varphi} \sim \nu t + \frac{\alpha^2}{4} \sin 4\pi\nu_p t \tag{5}$$

In these limits the wobble frequency therefore can be ν_p or $2\nu_p$. The reported wobble phase amplitude $\sim 0{\cdot}06$. From equation (1) the reported 72 day wobble period implies

$$\frac{\delta I}{I} \cos \alpha \sim 2{\cdot}6 \times 10^{-9} \text{ or } 5{\cdot}3 \times 10^{-9} \tag{6}$$

The frequency jump in the Crab pulsar was initially (September 28 ± 1, 1969) $2{\cdot}6 \times 10^{-7}$ Hz. After about a week there had been a relaxation to a "permanent" $\Delta f = 4{\cdot}3 \times 10^{-8}$ Hz. In the starquake interpretation of such events, the initial jump was associated with a sudden relaxation in shape of the slightly over-oblate crust toward the oblateness appropriate to its present rotation. The interval of a week was the characteristic relaxation time for the crust to communicate its changed angular speed to the deep stellar interior[10]. Then the permanent decrease in stellar moment of inertia was

$$\frac{\Delta I}{I} = -1{\cdot}4\times10^{-9} \tag{7}$$

Because the crust–core relaxation time of about a week is so much less than the precession period, the I and δI of equation (6) presumably also refer to the entire star and not just the deformed crust. From equations (1), (4), (5), (6) and (7) it follows that after the starquake the wobble period would be expected to increase from 72 ± 3 days to either 95 or 170 days (as long as α remains small or does not change greatly). For a non-axially symmetric star δI and ΔI would be the geometric mean of the perpendicular moments of inertia, but there would be no qualitative change in interpretation.

For a rapidly spinning elastic or fluid spheroid, only residual deformation not directly caused by its present rotation contributes to the δI in equation (1) (refs. 11 and 12). The relatively large centrifugal oblateness of the rotating neutron star ($\sim10^{-4}$ for the Crab) is neglected because it adjusts to any change in the rotation axis. The much smaller fixed residual oblateness from crust rigidity or perhaps the magnetic field (private communication from J. Ostriker), which would remain if $\nu\to0$, gives δI. The long wobble period in the Crab therefore implies a shape which has almost entirely relaxed to the hydrodynamic one even before the small quake. This is qualitatively different from the state of the Vela crust. The Vela frequency jump $\Delta\nu/\nu\sim2\times10^{-6}$ implied a crust shear strain $\sim10^{-2}$, of order of the maximum strain which crust matter could sustain[7]. The Crab crust, on the other hand, should be highly faulted so that it relaxes only after a strain $\sim10^{-5}$. Such a small strain and another small starquake should build up from stresses associated with the slowing down of the Crab in a very few years (private communication from D. Pines and G. Baym)

$$(\sim10^{-5}(GMR^{-2})(4\pi^2\nu\dot{\nu}R)^{-1})$$

I thank Drs C. Chiuderi and F. Occhionero for interesting conversations. This research was supported in part by the US National Science Foundation.

Search for High Energy Gamma Rays from Four Pulsars

IT has been suggested[1,2] that high energy cosmic rays originate in pulsars. If this is true, it is conceivable that the pulsars might also be emitting ultra high energy, pulsed gamma rays with the same periodicities as observed at radio frequencies. These gamma rays might be the result of either the decay of π^0-mesons or the bremsstrahlung of electrons in the regions surrounding the pulsars. There is no precise theory yet on this aspect. There have already been several searches for high energy gamma rays from pulsars[3-5].

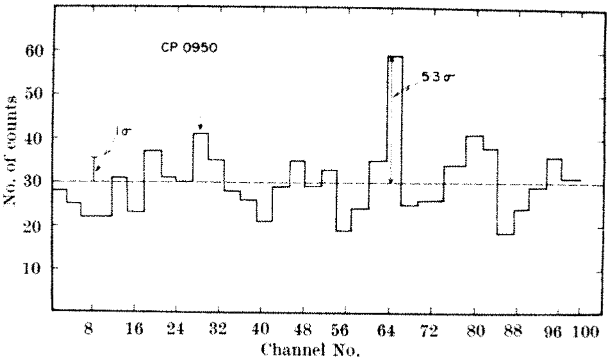

Fig. 1. Phase histogram obtained for CP 0950. The pulsar period is divided into 100 phase channels which are grouped in threes in the figure. The position of the interpulse as observed by Rickett and Lyne[7] at 408 MHz is shown by the arrow approximately at the 29th channel. The average of the histogram is shown by the dashed line.

During the latter part of April 1969 we tried to detect the possible emission of high energy pulsed gamma rays ($\gtrsim10^{13}$ eV) from four pulsars: CP 0950, CP 1133, AP 1541 and PSR 1642. Detectable Čerenkov light flashes are produced in the atmosphere by the relativistic electrons of cascade showers induced by gamma rays and charged cosmic rays of high energy ($\gtrsim10^{12}$ eV). The latter constitute the main background of noise limiting the minimum measurable gamma ray flux. The method in our experiment, as in the others, is based on looking for these nanosecond duration Čerenkov light signals in excess of the background from the direction of pulsar under investigation. If pulsars emit gamma rays in a pulsed mode with the same periodicity and similar pulse widths as in the case of the radio signals, time averaging by superposition of the gamma ray signals over a large number of time periods can reveal such a gamma ray flux even if it is much weaker than the background.

The Čerenkov light is detected by two large searchlight mirrors (90 cm diameter and 41 cm focal length) and focused onto two fast photomultipliers (56 AVP) placed at their foci. The mirrors track each pulsar for about an hour when it is close to meridian transit. Whenever a coincidence occurs within the resolving time of 5 ns between the two photomultipliers, the time as shown by a crystal controlled digital clock is recorded to a precision of 5·1 ms. The short term drift (typically over a few hours) of the crystal oscillator is found to be less than one part in 10^6. The full field of view of each mirror is 3° and the ratio of genuine Čerenkov light signals (which are mostly due to showers induced by cosmic rays) to chance coincidences is about 1 : 2. From the background Čerenkov signal rate, the known aperture of the field of view and the approximate area of collection of high energy gamma rays of 3×10^4 m^2 (see ref. 6, for example), the threshold energy of detection in our experiment is estimated to be $\approx10^{13}$ eV. Observations were made on clear nights during the period April 16–28, 1969, at Mukurthi located at an altitude of 7,200 feet above sea-level in the Nilgiri Hills in South India.

Time averaged phase histograms were made for each pulsar, with the recorded Čerenkov coincidence times for

* The threshold energies are to be trusted only to within a factor of 3.

the corresponding geocentric period of the epoch, using a computer. A calibration procedure and measured value of the clock drift permitted us to establish that the clock was accurate within ± 50 parts in 10^6. The phase histograms were therefore made for a scan of the clock calibration extending over this range of uncertainty. The scan resolution used of 2 parts in 10^6 was determined by the duration of the run and an assumed minimum pulse width of about 1 per cent of the corresponding pulsar period for the pulsed gamma ray emission.

Of the four pulsars, only CP 0950 showed a significant peak in one of the channels, of 5·3 standard deviations above the average (Fig. 1). Fig. 1 also shows the position where Rickett and Lyne[7] found the interpulse at a frequency of 408 MHz. They estimate that the energy in the interpulse is about 1·8 per cent of that in the main pulse[7].

A χ^2 test on the histogram, excluding the channel in which the peak appeared, shows that $P(\chi^2) = 0{\cdot}38$ for the assumption that the distribution is Poissonian. The probability of statistical fluctuations accounting for the peak observed in Fig. 1 is deduced to be $2{\cdot}5 \times 10^{-3}$. This value was arrived at as follows. (i) The Poisson probability of obtaining ≥ 59 counts when the expected average is 30 is $1{\cdot}88 \times 10^{-6}$. (ii) The number of ways of grouping into three adjacent bins, when the total number of bins is 100, is = 100. (iii) The number of trial clock periods is 50, and the number of adjacent trial periods in which the same peak has appeared with appropriate phase shift is 4.

The expectation value is therefore

$$1{\cdot}88 \times 10^{-6} \times 100 \times \frac{50}{4} \sim 2{\cdot}5 \times 10^{-3}$$

We also made a total of ten attempts on the other pulsars which showed no significant peaks. Depending on the caution one wishes to exercise, one might say that the statistical chance of observing a peak which is $\geq 5{\cdot}3$ standard deviations above the average is $2{\cdot}5 \times 10^{-3}$ for that particular run on CP 0950 or $2{\cdot}5 \times 10^{-3} \times 11 \sim 3 \times 10^{-2}$ for the whole experiment. A second observation on CP 0950 would have established unambiguously whether it is steadily pulsating in gamma rays or not. This was not feasible because the experiments were started late in April. The number of clear nights were few and when the atmospheric conditions were good the Moon interfered with the observations on CP 0950. Further observations are feasible on this pulsar only after December 1969.

In the case of the other pulsars, CP 1133, AP 1541 and PSR 1642, at least two observations were made on each and no significant peaks ($\geq 5\sigma$) were observed. Only upper limits could therefore be deduced for their gamma ray fluxes. Our results along with those of others[3-5] are listed in Table 1. The upper limits given by us are such that, if the true gamma ray fluxes were higher than those given, we would have seen them as five standard deviations or higher from the average. The threshold energies quoted can be trusted only to a factor of ~3. This uncertainty is due to assumptions of the lateral and angular spread, time distribution and atmospheric absorption and so on of Čerenkov light.

It is unlikely that CP 1133, AP 1541 and PSR 1642 are emitters of pulsed gamma rays resulting in intensities higher than the limits given by us. CP 0950 seems to be a good candidate for further observations. It may be significant that CP 0950 is also probably the nearest pulsar, considering that it has the lowest dispersion measure[8] ($\int N_e ds = 2{\cdot}94$ electrons cm^{-3} pc).

Dynamic Relaxation of Planetary Systems and Bode's Law

BODE's law, which states that the semi-major axis r_i of the ith planet from the Sun is given by

$$r_i = r_1 a^{(i-1)} \tag{1}$$

where a is a constant, is obeyed by the inner satellites of Jupiter, Saturn and Uranus as well as the planets[1]. Because the initial conditions in these satellite systems are not likely to have been the same as in the planetary system, this suggests to me that Bode's law may have resulted from a process of dynamical relaxation. That an epoch characterized by strong dynamical encounters occurred before the planets relaxed into stable orbits is also suggested by the surprisingly large differences between the inclinations of their angular momentum vectors of rotation and those of orbital revolution.

To test this hypothesis eleven planetary systems each with a central star of 1 $M_\odot$ but with widely different planetary mass functions were evolved from random initial orbits on an IBM 360/67 computer by numerically integrating the equations of motion. The integrations were done in two dimensions to save computer time. They were performed in double precision using a fourth-order Adams–Moulton routine with the length of the time steps being controlled by the truncation errors. Special precautions were taken to reduce these errors during close encounters. The median cumulative error, ΔE, in the energy E_0 of a system was $\Delta E/E_0 \sim 10^{-5}$.

Despite large differences in planetary mass functions and initial conditions the various systems tended towards stationary states having a number of common characteristics, the principal one being a tendency for the periods of adjacent orbits to be small integer fractions of each other, that is, they show the commensurabilities of the mean motions of classical celestial mechanics (see ref. 2). This

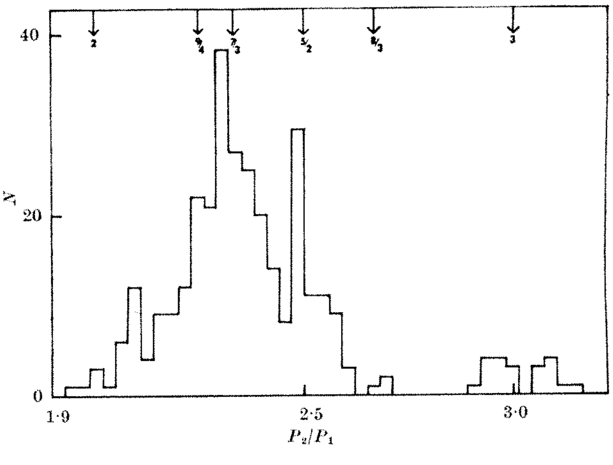

Fig. 1. Frequency of the ratio of the periods of planets 2 and 4 in system 5. This was evaluated at intervals of ten years starting 1,000 yr after the beginning of the planetary evolution.

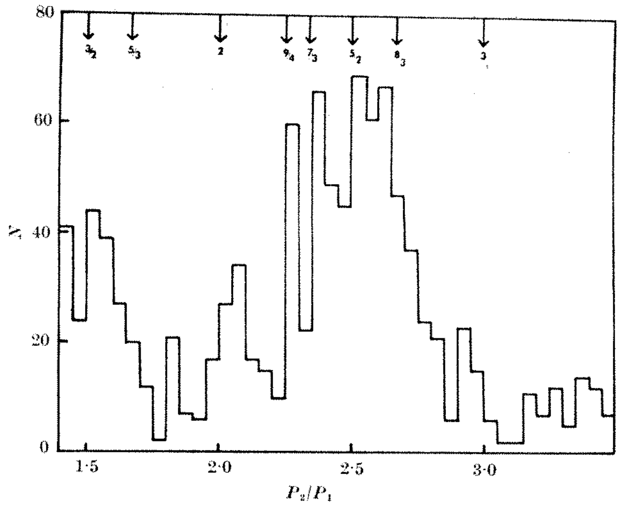

Fig. 2. Frequency of the ratio of the periods of the two outermost planets in system 11 except when the ratio is less than 1·4, in which case the third outermost planet is used in place of the second. The ratio was evaluated at intervals of ten years starting 1,000 yr after the beginning of the planetary evolution.

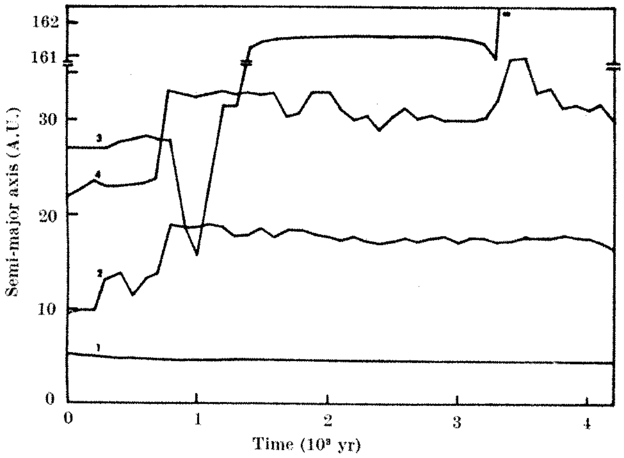

Fig. 3. Time variation of the semi-major axes of the planets in system 5.

is illustrated by Figs. 1 and 2, which give the frequency of period ratios of planets in systems 5 and 11, the two systems which were evolved for the longest periods of time. Figs. 3 and 4 give the time variations of the semi-major axes of the planets in these two systems while Fig. 5 shows these for system 9, the only one in which two planets were in stationary orbits from the beginning of the integrations. These two planets were accidentally placed into nearly commensurate orbits with a period ratio of (13/6). The tendency towards commensurate orbits is also evident in Figs. 1 and 2 despite the two systems having at best reached only quasi-stationary states.

A quantitative test of the correlation between the observed frequency pattern of the period ratios, R_i, shown in Figs. 1 and 2 and the commensurate points is difficult to construct because any given R_i is, in general, not independent of the R_is which proceeded it. If the distribution of R_is tends to be Gaussian around the commensurabilities and if the commensurabilities are equally probable the function

$$F(\Delta)=\sum_{i=1}^{N}\sum_{j=1}^{8}\exp\{-[R_i-(C_j+\Delta)]^2/\sigma\} \qquad (2)$$

where the C_js are the commensurabilities 3/2, 5/3, 2, . . . 3 will have a maximum near $\Delta=0$. In Fig. 6 we have plotted this function for the R_is of system 5 with $\sigma=0{\cdot}025$. This shows a maximum near $\Delta=-0{\cdot}01$, which is less than 0·05 of the average spacing between commensurabilities. This suggests a high correlation between the frequency pattern of the R_is and the commensurabilities.

The three systems which have been discussed cover a wide spectrum of initial conditions and planetary mass functions. In system 5 each of the four planets has ten times the mass of one of the Jovian planets while in system 11 each of the six planets has a mass of $5\times10^{-4}\,M_\odot$. The initial semi-major axes and eccentricities of the planetary orbits in these two systems were chosen at random, although, due to an early misjudgment about conditions in the solar nebula, the initial semi-major axes in system 11 were only allowed to lie in a narrow range between 6 and 8 A.U. In system 9 the masses of the planets are $8\times10^{-4}\,M_\odot$, $3\times10^{-4}\,M_\odot$ and $1\times10^{-7}\,M_\odot$. As such widely different systems could evolve towards stationary states characterized by commensurate orbits, it seems likely that nearly all planetary systems will evolve towards these stationary states. The initial conditions and planetary mass functions seem only to determine the time necessary to reach such a state.

If the dynamical evolution of the semi-major axes of the planets in a system can be approximated by a succession of random walks for which the length of each step is directly proportional to the mass of the perturbing planet, the fact that system 5, which has planets ten times as massive as the Jovian planets, reached a quasi-stationary state in about 2×10^3 yr suggests that the Jovian planets reached such a state in about 2×10^5 yr. Considering the large uncertainty in this calculation, a reasonable estimate of the time necessary for the Jovian planets to evolve to their present orbits after their formation is 10^5–10^6 yr.

Recent investigations[3–6] have shown that commensurate orbits are more frequent in the solar system, particularly among the Jovian planets and among their satellite

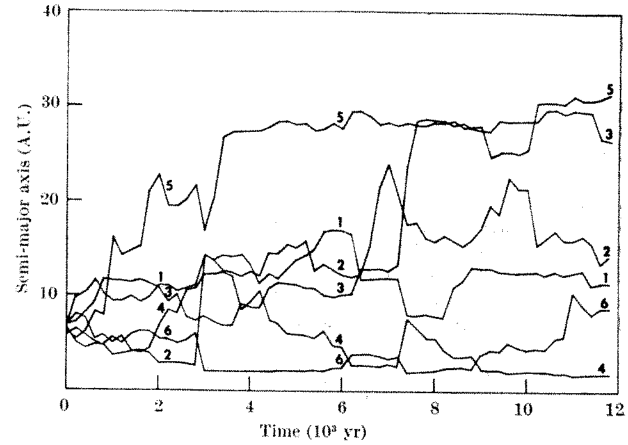

Fig. 4. Time variation of the semi-major axes of the planets in system 11.

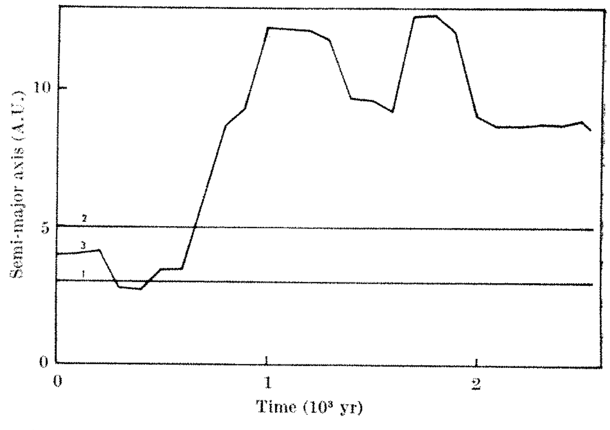

Fig. 5. Time variation of the semi-major axes of the planets in system 9.

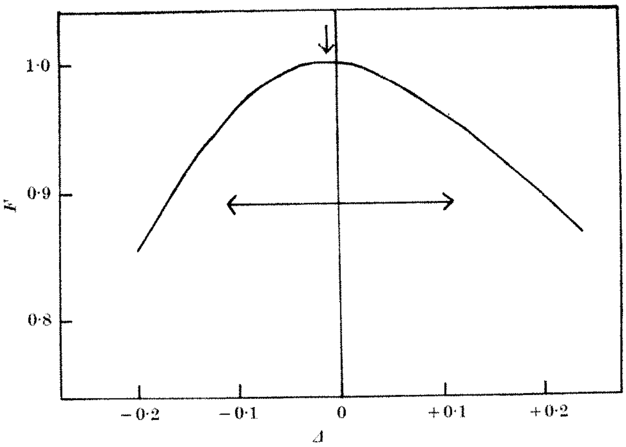

Fig. 6. Correlation between the frequency pattern of the period ratios of system 11 shown in Fig. 2 and the commensurate points. The arrow indicates the position of the peak of the curve, and the horizontal bar shows the average spacing between commensurabilities.

systems, than is expected from chance alone. For those commensurate pairs of orbits which have been studied in detail it has been found that the commensurability condition leads to resonant perturbations of large amplitude, but these cause only periodic changes in the orbital elements[7]. It thus seems likely that commensurate orbits are the final signatures of a system of strongly interacting planets with commensurability being the stablest possible arrangement of their semi-major axes.

Bode's law results from the fact that some commensurabilities are more favoured than others. We see in Figs. 1 and 2 that most commensurabilities lie in a narrow range between (9/4) and (8/3); this is true for the other computer simulated systems as well. Because of this small spread in the period ratios, the period of the ith planet from the Sun is given closely by the relation

$$P_i = P_1 A^{(i-1)} \tag{3}$$

where A is constant, but this is just Bode's law as it can be trivially converted to equation (1) by Kepler's third law. Pluto is usually cited as being the most flagrant violator of Bode's law. This results from the approximate character of the law. The orbit of Pluto is actually highly commensurate with the orbit of Neptune, the period ratio being nearly (3/2). We see in Fig. 2 that the second largest clumping of commensurate points is near (3/2), but these commensurabilities are considerably less frequent than those in the range (9/4)–(8/3). The smaller commensurabilities are much more frequent in the satellite systems than in the solar planetary system and in the computer simulated planetary systems. The reason for this will be discussed in a later paper.

The implications of these results on theories of the origin of planetary and satellite systems as well as a more detailed report on the analysis of the numerical experiments will also be given in a later paper.

I thank Professor F. T. Haddock and Dr R. L. Sears for helpful discussions.

Lunar Continental Migration and Maria Spreading

Contemporary ideas about the broad features of continental migration and ocean floor spreading are largely independent of whether or not there is any sea present. This report considers the possibility that the lunar maria were formed by internal geological processes similar to those which formed the ocean floors of the Earth.

Evidence that the maria are younger than elsewhere comes from the density of cratering[1]. But if the rate of bombardment has remained more or less constant and the maria, though "new", are still quite old, why are they not more heavily cratered ? I believe we have no alternative but to abandon the uniform bombardment rate and accept that the rate of cratering diminished rapidly during the first 10^9 yr of the existence of the Moon. The mean density of cratering allows us to place the maria in an "age" sequence. For example, Mare Nubium should be older than Mare Crisium. We are thus led to the view that some of the maria surfaces are newer than others.

In order to understand the role of maria spreading I have constructed a simple laboratory model. This is a layer of hot viscous fluid, which can be cooled from above. A layer of aluminium powder of thickness about 0·1 mm is spread on the upper surface to represent a patch of crustal material. Fig. 1 shows the ensuing distribution of crustal material, which should be compared with the view of the Moon in Fig. 2.

The vigour of the motion, in a sufficiently viscous material, is determined by the Rayleigh number $A = \gamma g \Delta T R^3/\kappa\nu$, where γ is the coefficient of cubical expansion, g the acceleration of gravity, ΔT the temperature drop across the layer, R the depth of the layer, κ the thermal diffusivity, and ν the kinematic viscosity of the fluid (refs. 2 and 3). If $A \gg 10^3$, after a short interval of time (of order $A^{-2/3}$), convective motion is vigorous and extends throughout the layer. Close inspection of the flow reveals a remarkable situation[3] in which small-scale eddying motions develop near the cooled upper surface in a thin layer, called the thermal sublayer, of thickness $\delta \sim A^{-1/3}$ (Fig. 3).

As they grow in amplitude, the rising hotter fluid, seen from above, takes the form of upwelling blobs, while at the margin between these blobs narrow sheets of colder fluid plunge downwards. These sheets stir the deeper interior to the overall appearance of a motion made up of large eddies extending right across the layer. Once the blob has expended its thermal energy it rapidly dies away. But other sublayer eddies are continuously being formed to create an ever changing pattern of rapid small-scale motions in the sublayer and slower larger motions at depth. I want to emphasize that this structure is quite different from convection at low Rayleigh numbers ($A \sim 10^3$) where a regular structure of convective cells more or less fixed in space occurs.

The role of a surface layer, simulating old crust, is partially to inhibit the motion in the sublayer beneath it by lowering the cooling rate. If the surface layer is sufficiently thick the outgoing horizontal viscous stress during the upwelling phase of blob production may not persist for sufficient time to rupture the surface layer. Once the surface layer has been ruptured, however, there is a tendency for the crust immediately surrounding the mare to be stretched by a surface flow predominantly outward so that new blobs can more readily rupture the mare surroundings.

The model reveals an important aspect of the process of production of new mare. All but the smallest mare are produced not by the action of a single buoyant blob but by many. As each blob approaches the surface of the lithosphere the outgoing horizontal viscous stresses push outward the old crust. The net effect of the mutual action of many blobs is to expand progressively a mare by sweeping away old crust at the margin. Each blob rising near a mare margin thereby produces a "bay" in the old crust.

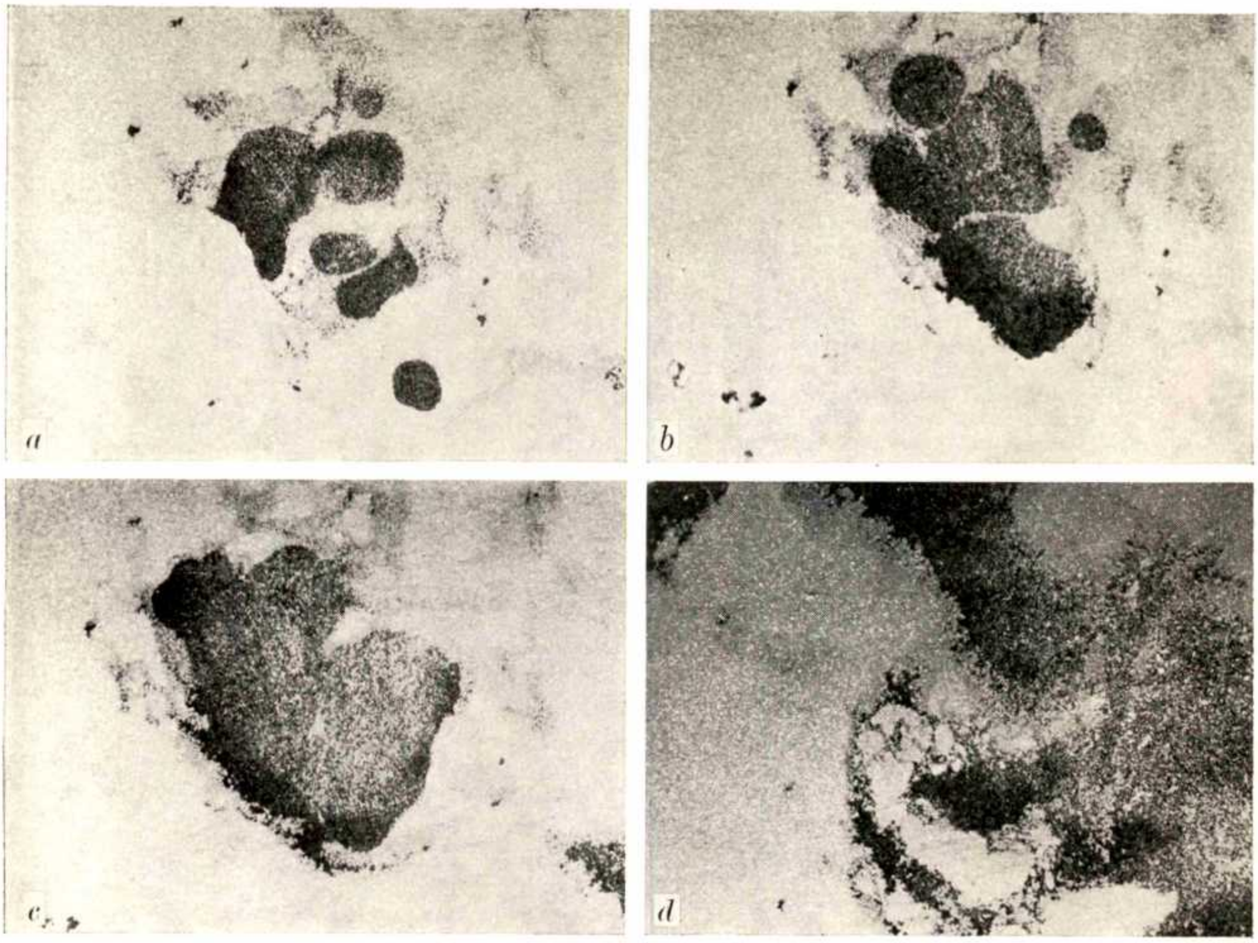

Fig. 1. Laboratory simulation of mare formation. Photographs of the upper surface of a layer of vigorously convecting viscous fluid cooled from above which has a thin surface layer of white powder. Photographs taken at times from the onset of cooling equivalent to, in units of 10^9 yr: *a*, 0·3; *b*, 0·4; *c*, 0·5; *d*, 1·0. In this particular simulation *d* shows an extreme stage, the complete disruption of the surface layer into two distinct parts.

To demonstrate that blobs are also rising continuously beneath the entire area of the mare, Fig. 4 is a photograph of a large mare on the surface of which I have sprinkled some extra aluminium powder. The blob structure is revealed by the horizontal displacement of this material to the regions between rising blobs. Here I want to emphasize that the size of the buoyant elements is reflected not in the size of the mare (which is determined by the persistence of upwelling) but in the size of the embayments at the margin of the mare. The embayments have widths of about 5°, and taking the width as about twice the depth of the sublayer in which the blobs develop, we have $\delta/R \approx 1/40$. This requires a Rayleigh number of order 10^7.

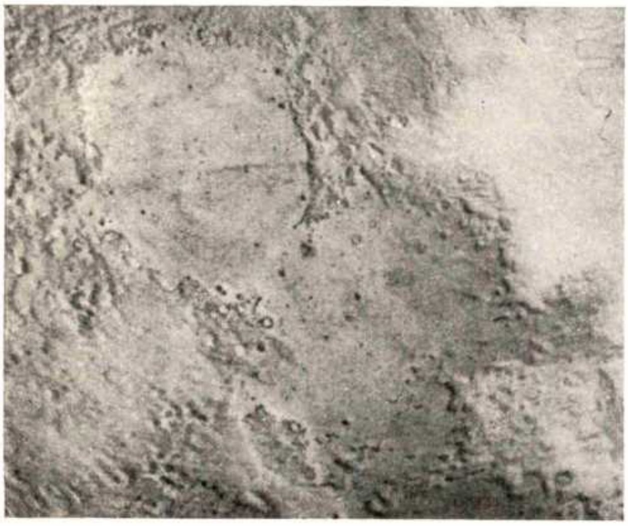

Fig. 2. A view of part of the lunar surface centred on Mare Tranquillitatis—an attempt to emphasize the distinction between mare and continent by printing simultaneously a positive and negative photograph with a small relative displacement.

Certain lunar structures provide some supporting evidence. Domes occur almost exclusively in the maria and may be analogous to the volcanic domes on terrestrial ocean floors. This type of volcanism does not occur on continental areas. Rilles, ridges and wrinkle ridges are evidence of vigorous displacements in the mantle beneath the maria. They can be identified with similar ridge systems on the ocean floors of the Earth and are analogous to the structures shown within the mare of Fig. 4. Mountain chains outside the heavily cratered areas near the south pole take the form of isolated or connected chains usually marginal to the maria. I suggest that these systems are analogous to the so-called island–arc structures on Earth. Where mantle convection has been locally persistent, fragments of continental type material have been swept together and possibly augmented by discharge from the mantle itself. This process is seen in the model, for example, the strip of crustal material stretching from the right across the middle of the mare of Fig. 1*b*.

In broad terms the maria occupy a single connected area outside which continental material extends continuously from the southern portion of the front face across the rear face except for isolated maria such as Mare Muscoviense, At the margin of a mare the predominant tendency is not only a progressive growth of the mare by embayment but an outward surface stress. The overall effect of this stress is to push continental material away from the mare. This is a version of continental drift produced by "mare floor spreading". Hence the surface area which is predominantly mare will expand and tend to push all the continental material together.

The occasionally more vigorous blob may penetrate the continental material (Mare Muscoviense) and if the supply of internal energy is not yet depleted this new mare will expand, possibly to the point of breaking up the continental mass once more. On Earth, one of the puzzling features of what is known about continental migration is that apparently an original Gondwanaland began to break up about 10^8 yr ago, with the implication that nothing much had happened to Gondwanaland before that time. To my mind it is difficult to accept that continental disruption and migration have only occurred in the recent past. But there then remains the question of how a Gondwanaland was formed at all. I would suggest that the discussion of the distribution of the lunar mare can be applied to the Earth and that Gondwanaland was simply one of a sequence of continental aggregations of which there have been many.

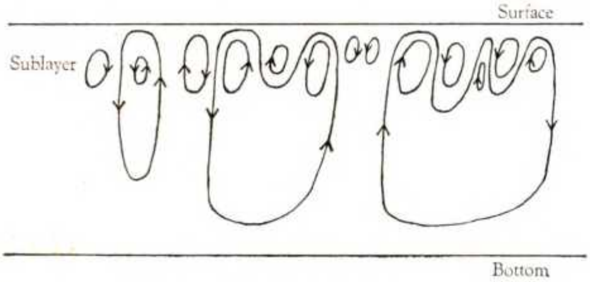

Fig. 3. Schema of the motions in a fluid layer vigorously cooling from above.

The relative rates on the Moon and the Earth at which the processes of continental migration and ocean floor spreading occur can be estimated if we assume that the dominant process is free convection. The ratio of cooling times[4] is

$$\sigma = \tau_{\text{Moon}}/\tau_{\text{Earth}} = (R_{\text{Moon}}/R_{\text{Earth}})\ \ (g_{\text{Earth}}/g_{\text{Moon}})^{1/3} \doteq 0{\cdot}5$$

In other words, lunar processes run down about twice as fast as those in the Earth. If the age of the Sea of Tranquillity is about $3{\cdot}5 \times 10^9$ yr and assuming a solar system age of about 5×10^9 yr we have a crude estimate of the rate ratio $\sigma \approx 1{\cdot}5/5 \approx 0{\cdot}3$.

This report has emphasized the role of mare spreading, with continental migration playing a neutral and secondary part. Previously[5] I have suggested that on the Earth, at present, migration through continental self-propulsion could play a primary part. Taken together with computed thermal histories[4] these two ideas suggest the following. The early stages of the cooling of all bodies of planetary size is the same, provided the initial temperatures and the rock types are similar. Vigorous convection is confined largely to a thin sublayer near the surface and the interior of the body is little affected. The lunar evidence suggests that mare production arising from vigorous penetrative convection is the dominant process at this stage. Gradually the internal energy of the body becomes depleted and if the body is sufficiently small, as seems to be the case with the Moon, convective processes rapidly lose their vigour and the mare structure is "frozen". On the other hand, with a somewhat larger body, as seems to be the case with the Earth, the less vigorous processes responsible for continental self-propulsion progressively become relatively more important as the dominance of penetrative convection diminishes. There is already rather good evidence for the dominance of penetrative convective processes in the early stages of the Earth from studies of the extensive areas of dome-like structures[6] in shield areas of Archaean age (3×10^9 yr BP).

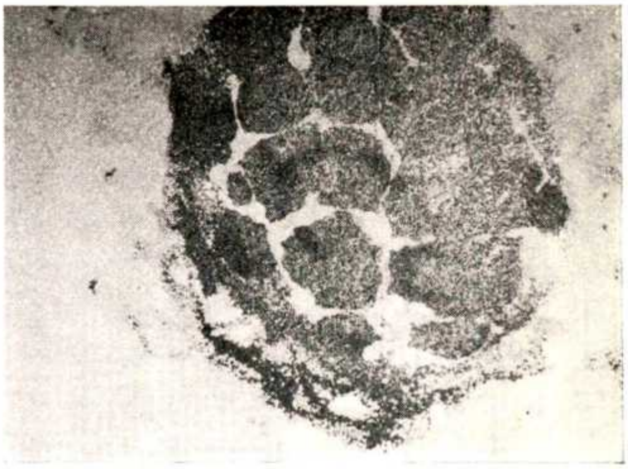

Fig. 4. Demonstration of the convective structure within the mare area, at an equivalent time of $0{\cdot}7 \times 10^9$ yr. Some extra powder was sprinkled on the surface just before the photograph was taken.

Symmetry of Crustal Earthquakes above Benioff Zones

INTERMEDIATE and deep earthquakes have received much attention since the establishment of the World Wide Standard Seismographic Network (WWSSN) seismograph stations and the introduction of the concepts of the "new global tectonics". The WWSSN is not suitable for studying the distribution of shallow earthquakes and the morphology of such earthquakes can best be defined with local networks. The excellence of the New Zealand local network and its position with respect to the seismicity of the Hikurangi active margin[1,2] allow shallow (and deeper) earthquakes to be located with considerable accuracy.

Fig. 1 shows the positions of seismograph stations in the northern half of New Zealand together with the epicentres of well determined shallow earthquakes (in which Pg or Sg is recognized) between 37° S and 34° S for the period January 1, 1963, to April 30, 1966. Most earthquakes occur within the seismograph network. The axis of the negative isostatic gravity anomalies which characterize the Hikurangi margin of New Zealand[3] is also shown in Fig. 1.

Fig. 2 gives the depths of all well determined[2] earthquakes for the same period and region. Crustal earthquakes are restricted to one of two depths: 12 km or 33 km. All shocks in which P^* or S^* phases are identified (but not Pg or Sg phases) are restricted to 33 km depth; because focal depth is an adjusted parameter in the

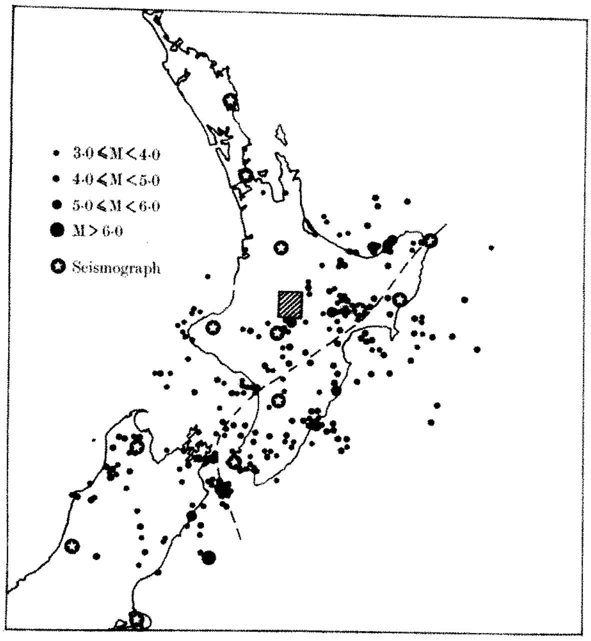

Fig. 1. New Zealand Seismograph Stations, shallow earthquakes from January 1, 1963, to April 30, 1966, between latitudes 37° and 43° S and axis of negative isostatic gravity anomalies (dashed line). Shaded area indicates many epicentres of Taupo earthquake swarm, 1964–5.

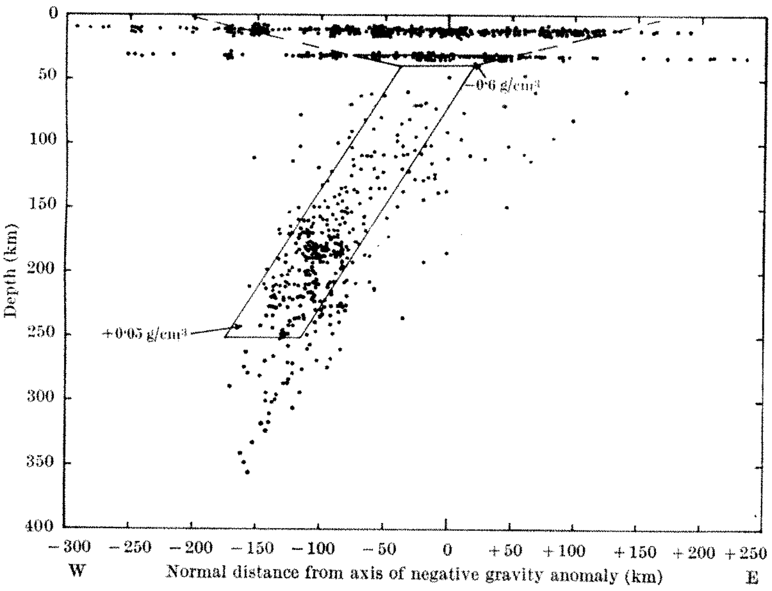

Fig. 2. Section of seismicity across Hikurangi Margin normalized to axis of negative gravity anomalies. Crustal downwarp model which fits gravity anomalies is superimposed on section. The Benioff zone is taken to have a density contrast of $+0\cdot05$ g/cm^3 with the mantle and the crust a density contrast of $-0\cdot6$ g/cm^3.

determination of the hypocentres, those shocks which do not have identified P^* or S^* phases but which have adjusted focal depths of less than 33 km are restricted to 33 km depth. Shocks below the crust are plotted at their computed depths.

The section has been produced by taking the normal distance of all epicentres from the axis of the negative gravity anomaly shown in Fig. 1. One of the models developed to explain the gravity anomalies of the Hikurangi Margin is superimposed on the section. These models have in common a high density region coincident with the Benioff zone to produce the positive anomaly[4], but low density regions can be disposed in several ways to produce the negative anomaly. The model in Fig. 1 is the "crustal downwarp" analogue in which the depth of the base of the crust is depressed by 8 km[1].

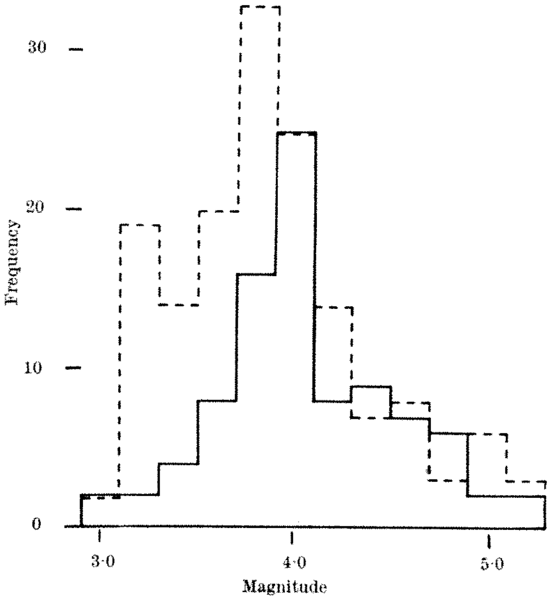

Fig. 3. Frequency histogram of magnitudes east of the gravity anomaly axis (full line) and west of the axis (dashed line). Shocks of Taupo earthquake swarm not included.

Crustal seismicity is roughly symmetrical about the negative gravity anomaly axis. More accurately, the axis of crustal seismicity coincides with the centre of the crustal downwarp or low density zone or, equally, with the centre of the upper surface of the high density zone. Moreover, the arms of the crustal downwarp envelop most of the crustal earthquakes, the spread of the 12 km earthquakes being greater than that of the 33 km earthquakes. It must also be borne in mind that 12 km and 33 km are maximum depths for these earthquakes.

Fig. 3 shows a histogram of magnitude frequencies of shallow shocks east and west of the negative gravity anomaly axis. Above magnitude $M=4\cdot0$ there is no discernible difference between the two sides. A much greater number of shocks of $M<4\cdot0$ occurs on the western side of the gravity axis, but this only indicates population distribution because the New Zealand Seismological Reports "contain *all* shocks of magnitude 4·0 and above . . . together with those shocks of lower magnitude . . . that have been reported felt".

The crustal seismicity of the Hikurangi margin is therefore essentially symmetrical, in contrast to the mantle seismicity. Such symmetry is perhaps unexpected if the cause of the earthquakes is sought in terms of overthrusting of lithospheric plates[5]. Rather, crustal earthquakes may be caused by what is effectively a gravitational loading of the crust.

Molecular Oxygen as an Electron Trap in the Thermoluminescence of Saturated Hydrocarbons

MOLECULAR oxygen participates in organic thermoluminescence both as an electron trap and as a luminescence quencher[1–4]. Although the mechanisms of luminescence quenching have been discussed[5], the trapping process is only poorly understood. This communication reports new results which throw further light on the problem in saturated hydrocarbon matrices.

It was shown by Charlesby and Partridge[1–4] that when molecular oxygen is present in polyethylene, the thermoluminescence glow curve produced by warming samples previously subjected to low temperature gamma radiolysis exhibited an additional glow peak which disappeared when molecular oxygen was removed. This suggested that the peak originated in electron trapping on the oxygen molecules. The results presented here cover not only a wide range of both low and high density polyethylenes but also a series of saturated hydrocarbons having between five and twenty main chain carbon atoms.

The measurements were made using a technique which has already been described in an earlier report[6]. The essential features are a controlled slow rate of warming of 3 K per minute and a careful measurement of the sample temperature. Polyethylene samples, in the form of thin sheets 1/16 inch thick, were found to contain sufficient luminescent impurity introduced during the manufacturing process to provide an adequate number of luminescence centres. On the other hand, the paraffin hydrocarbons, obtained from Koch Light Laboratories, were purified in the laboratory using the method of Potts[7] and trace quantities of anthracene were added to provide the necessary luminescence centres.

Table 1. TEMPERATURES OF GLOW MAXIMA IN THE THERMOLUMINESCENCE GLOW CURVES OF THE LOW MOLECULAR WEIGHT *n*-ALKANES DOPED WITH ANTHRACENE

Sample	Molecular formula	Peak temperatures (K)
n-pentane	C_5H_{12}	120, 138
n-hexane	C_6H_{14}	102, 113, 160
n-heptane	C_7H_{16}	90, 108, 144, 180
n-octane	C_8H_{18}	94, 111, 186*, 215
n-nonane	C_9H_{20}	91, 108, 130, 170, 196, 208
n-decane	$C_{10}H_{22}$	93, 110, 135, 175*, 209
n-undecane	$C_{11}H_{24}$	91, 140, 190
n-dodecane	$C_{12}H_{26}$	98, 109, 163*, 215, 260
n-tridecane	$C_{13}H_{28}$	87, 92, 125, 135, 172
n-tetradecane	$C_{14}H_{30}$	90, 108, 160*, 176, 203, 269
n-pentadecane	$C_{15}H_{32}$	94, 190, 218, 233
n-hexadecane	$C_{16}H_{34}$	96, 102, 155*, 267
n-octadecane	$C_{18}H_{38}$	97, 105, 154*, 252
n-eicosane	$C_{20}H_{42}$	98, 107, 145*, 160, 204

Oxygen peaks are denoted by an asterisk.

All samples of polyethylene showed the oxygen glow peak at 145 ± 4 K. This was found to be independent of polymer molecular weight, degree of branching and consequently degree of crystallinity. The glow curves of the low molecular weight paraffins showed a number of glow peaks and the peak temperatures are summarized in Table 1. The oxygen concentration in these samples was reduced by bubbling the samples with oxygen free nitrogen gas for prolonged periods before irradiation. While not completely eliminating molecular oxygen, such treatment does reduce the oxygen concentration by displacement and so reduces the intensity of any glow peak caused by electron trapping on molecular oxygen. The attenuated peaks are indicated in Table 1 by an asterisk.

From Table 1 two features are immediately apparent. No oxygen peak is observed in any of the paraffins having an odd number of main chain carbon atoms. Also, the temperature at which the oxygen peak occurs in the even paraffins decreases with increasing molecular weight. This distinction between the even and odd paraffins is reflected in a number of the other physical properties of these compounds; for example, melting temperature[8] and mechanical relaxation mechanisms[9]. This effect is thought to originate in the different crystalline structures of the even and odd paraffins; the even paraffins have triclinic crystal symmetry while the odd paraffins are orthorhombic[10].

If the differences between the thermoluminescence properties of the even and odd paraffins are in fact due to the different crystalline structures, then it is expected that the temperatures of the thermoluminescence glow maxima of the oxygen peaks might follow the same type of molecular weight dependence as the other properties which behave in a similar manner. Broadhurst[8], for example, has examined the melting characteristics of these compounds and has shown that the melting temperature, T, follows a dependence on the number of main chain carbon atoms, n, of the form

$$T = T_0 \cdot \frac{n+a}{n+b}$$

where T_0, a and b are constants. Similarly Sinnott[11] has shown that the temperatures of occurrence of the mechanical relaxations in single crystals of polyethylene can be regarded as the extrapolation to infinite chain length of the relaxation temperatures observed in the low molecular weight paraffins observed by Illers[9] and obey a law of the same form as the equation above. Using such a law, the results for the thermoluminescence glow peak temperatures of the oxygen peak are plotted in Fig. 1 together with a theoretical plot of the equation with $T_0 = 145$, $a = -4{\cdot}66$ and $b = -5{\cdot}46$. The agreement is good, suggesting that this form explains the observed variation in the oxygen peak temperatures.

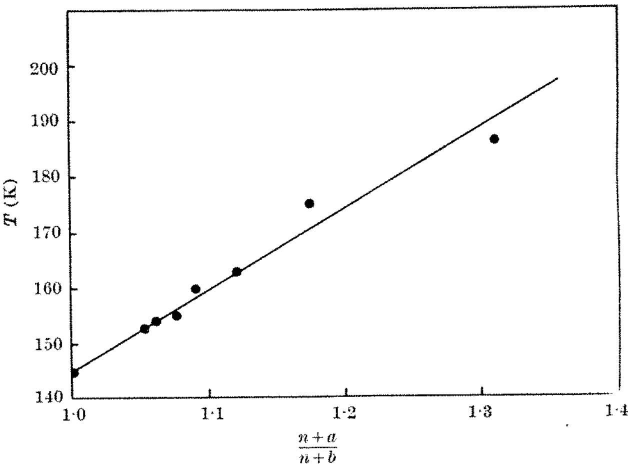

Fig. 1. Plot of oxygen peak temperature as a function of $(n+a)/(n+b)$, where n is the number of main chain carbon atoms, $a = -4{\cdot}66$ and $b = -5{\cdot}46$. Polyethylene is represented by putting $n = \infty$.

To find the physical meaning of this law it is necessary to consider the way in which molecular oxygen acts as an electron trap. The simplest form of such trapping which has been proposed[2] is the direct attachment of an electron to the oxygen molecule to form the negative ion, O_2^-. It is expected that the temperature of liberation of the attached electron will depend on the electron affinity of molecular oxygen. Vedeneyev[12] quotes a value of 0·87 ± 0·13 eV for the electron affinity by comparing several sets of data. When the approximation of Curie[13] is used for the untrapping of electrons from traps of fixed depth, this suggests that the molecular oxygen glow peak ought to occur in the temperature range 370 K to 500 K, which is considerably higher than any of the experimentally observed values. The experimental values therefore imply that the trap depth of the molecular oxygen traps in saturated hydrocarbon matrices is reduced from the electron affinity of oxygen to the observed value by an interaction between the matrix and the oxygen molecules. If such an interaction were dependent on molecular weight, then the variation would be expected to be greater at low molecular weights as the relative change produced by the addition of an extra main chain carbon is proportionally greater in the low molecular weight range. This is indeed observed.

Because of the similarity of the interaction with the variation in crystalline structure, it is clear that at some chain length the properties of the even and odd paraffins must converge. In terms of crystallinity this occurs at about twenty carbon atoms[8]. To test whether the oxygen peak also appears in the odd paraffins of similar chain length, a sample of highly purified $C_{35}H_{72}$ was tested and a weak oxygen peak was found at about 152 K. This showed that oxygen trapping does occur in odd paraffins and that the above law is obeyed when the crystal structures of the even and odd paraffins are similar. These results are therefore consistent with the view that electron trapping occurs on molecular oxygen by the formation of the negative ion O_2^- and that the trap depth is given by the electron affinity of molecular oxygen reduced by a factor determined by the matrix–oxygen interaction energy, which is dependent on molecular weight.

The exact nature of the interaction forces is, however, more difficult to ascertain, but some qualitative deductions can still be made. The oxygen may interact with either the $—CH_2—$ groups or the $—CH_3$ end groups. If the interaction is with the latter, then as the chain length increases the proportion of end groups relative to the remainder of the chain will decrease and the interaction will decrease. In fact the reverse is observed, indicating an interaction with the $—CH_2—$ groups.

Of the possible interaction forces available, only van der Waals and hydrogen bond forces are of the correct order of magnitude. Muller[14] has considered the van der Waals forces existing in the n-alkane chains; it has been found that such forces have an interaction energy of the order of 0·1 eV, which is somewhat below the value required to give the observed reduction in the oxygen trapping energy. Furthermore, such forces fall off according to an inverse sixth power law, which implies that the interaction energy would vary with molecular weight only to an appreciable extent in the very low molecular weight range. The results indicate, however, that although the depression of the trapping energy is proportionally less in the middle range of chain lengths it is easily measurable. Hydrogen bonding forces, on the other hand, which are caused by electrostatic polarization[15], fall off according to an inverse square law, and this coupled with the fact that such forces can be greater than the van der Waals forces suggests the origin of the observed interactions. Further work is at present being carried out with a view to ascertaining the exact nature of these interaction forces.

Electron Channelling Patterns from Small (10 μm) Selected Areas in the Scanning Electron Microscope

THE generation of electron channelling patterns in the scanning electron microscope (SEM) (refs. 1, 2) presents a unique method for obtaining crystallographic information from bulk crystals while viewing directly in the SEM. A technique for generating patterns from small selected areas has been described[3] and developed[4] to give electron channelling patterns from regions 50 to 100 μm in diameter. In this double deflexion rocking beam method the double deflexion scan system in the 'Stereoscan' SEM was modified by attenuating the current in the lower scanning coils so that the scanning crossover point, which normally occurs approximately in the plane of the final aperture (Fig. 1*a*), was lowered into the specimen chamber (Fig. 1*b*). A specimen could then be brought into coincidence with the lowered crossover point, and the variations in direction of incidence necessary to generate patterns occurred about a fixed point on the specimen surface.

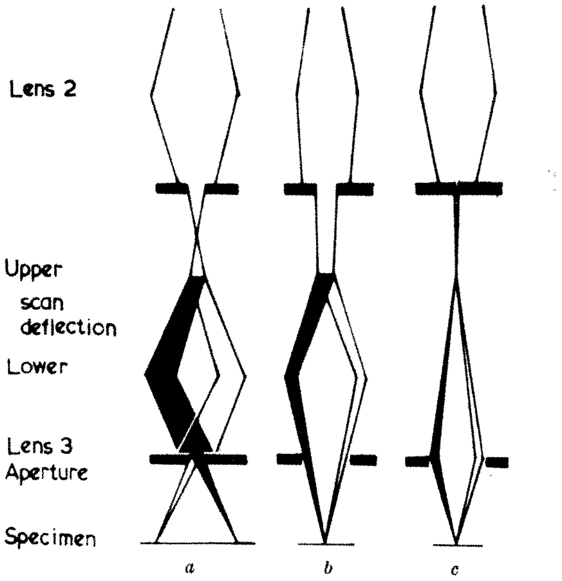

Fig. 1. Schematic beam diagrams of (*a*) standard scanning; (*b*) double deflexion rocking beam technique (method 1); and (*c*) deflexion focusing rocking beam technique (method 2).

A detailed analysis of the factors limiting the size of the selected area (to be published separately) showed that the double deflexion system behaved very much as a lens, possessing defects analogous to spherical aberration and astigmatism. These enlarge the crossover from a "point" the size of the probe to a "circle of confusion" of much larger diameter. By appropriately trimming the deflexion coils, the "astigmatism" type of defect can be reduced to negligible proportions; the "spherical aberration" type of defect can be reduced by superimposing a small correction signal on the main scan currents activating the coils.

By making these corrections, the circle of confusion was reduced to about 10 μm in diameter. Further reductions should be possible with better corrections. To illustrate the present state of development of the double deflexion technique, an electron channelling pattern was generated from a twin ~10 μm wide in an annealed copper polycrystal. The micrograph and pattern are shown in Fig. 2. Grain contrast in the micrograph is a direct result of the electron channelling mechanism, each grain essentially showing part of an electron channelling pattern.

Another method for obtaining a rocking beam has been developed, and can also be used to generate channelling patterns from selected areas 10 μm in diameter. Instead of using both upper and lower deflexions of the scanning system, a single deflexion is used in conjunction with the final lens. This lens "focuses" the scan and brings the beam back to a point on the optic axis of the SEM. We call this technique the deflexion focusing method, and it is illustrated schematically in Fig. 1*c*. Here the divergence of the beam, which must be kept low to display channelling patterns[3], is defined by means of an aperture replacing an existing splash aperture.

The deflexion focusing method gives similar results to the fully corrected double deflexion method: patterns can be obtained from grains 10 μm wide. The principal factor determining the size of the circle of confusion is the spherical aberration of the final lens. This could be overcome by means of correction waveforms applied to an auxiliary set of beam deflexion coils, and it should be possible to reduce the diameter of the selected area to 2–3 μm.

The operation of either method is very simple: the sample is examined under standard scan (corresponding to Fig. 1*a*) and the area of interest is brought to a predetermined spot on the screen. Switching to rocking beam (corresponding to Fig. 1*b* or *c*) causes a channelling pattern from the area of interest to appear on the screen.

The patterns are limited in angular width to about 10° by the dictates of microscope geometry. This is sufficient for a unique identification of the crystal orientation, which can either be performed analytically[5] or more easily by comparison with a map of channelling patterns of all possible orientations. The crystallographic orientation (relative to the optic axis of the SEM) of any grain, subgrain, precipitate, particle and so on, down to 10 μm in diameter on the surface of a solid specimen, can thus be determined to an accuracy of better than 10^{-2} radian.

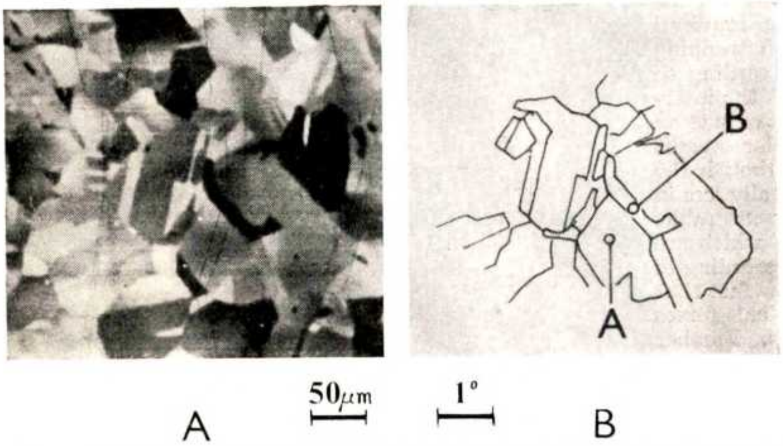

Fig. 2. Electron channelling pattern from a small twin in an annealed copper polycrystalline specimen using method 1. (Beam current was ~10^{-7} A, divergence ~5×10^{-3} radians, and diameter ~5 μm.

We thank Dr G. R. Booker and Mr D. C. Joy for valuable discussions.

Migration of a Neutrally Buoyant Particle in Poiseuille Flow: a Possible Explanation

MANY theoretical and experimental investigations have been made into particle migration in laminar tube flow. Segré and Silberberg[1,2] noted that all the particles in a neutrally buoyant suspension of rigid spheres flowing down a vertical tube congregate in about 0·6 of the tube radius, and Maude and Yearn[3] reported precise experimental evidence for another high concentration zone near to the tube wall, which they term the "wall peak". Rubinow and Keller[4] explained the occurrence of high concentration zones by deriving the transverse force on a spinning sphere. It was subsequently shown by Saffman[5] that the lift force on a freely rotating particle caused by rotation is insignificant, and the radial velocity of the particle is given by

$$\frac{V_r}{U_0} = -6\cdot1\left(\frac{a}{R}\right) Re_{\mathrm{T}}^{\frac{1}{2}} \left(\frac{r}{R}\right)^{\frac{1}{2}}\left(\frac{\Delta V_z}{U_0}\right) \quad (1)$$

where U_0 is the maximum fluid velocity, a the particle radius, R the tube radius, Re_{T} the Reynolds number $(=U_0R/\nu$, ν is the kinematic viscosity), r the radial position of the particle and ΔV_z the axial relative velocity. If the particle lags behind the fluid, $\Delta V_z>0$ and the radial migration is towards the tube axis. The relative velocity ΔV_z cannot directly be applied for this purpose, but Repetti and Leonard[6] have introduced the effective fluid velocity caused by the presence of the particle, and they explained the Segré–Silberberg effect, using the axial particle velocity obtained experimentally by Goldsmith and Mason[7].

This communication provides a possible expression for the relative velocity, ΔV_z, and explains the occurrence of the high concentration zone in Poiseuille flow of a neutrally buoyant suspension. It is assumed that the particle tends to minimize disturbances in the flow tube caused by its own presence.

According to Vand[8], the velocity gradient G of the fluid is disturbed by interaction between a sphere and a rigid wall, and the effective velocity gradient G' at the centre of the sphere becomes

$$G' = G(1 - \varphi) \qquad (2)$$

where

$$\varphi \doteqdot \frac{5}{16}\left(\frac{a}{R-r}\right)^3 - \frac{1}{8}\left(\frac{a}{R-r}\right)^5$$

and Goldsmith and Mason[7] have observed that the rate of rotation of single spheres is approximately $G'/2$ in place of $G/2$. Because the gradient G' acts on the particle rotation, we postulate that the remainder $(G - G')$ acts on the migration, and the particle should move with a velocity frame

$$V_z = U + \int (G - G')\mathrm{d}r + C \qquad (3)$$

where

$$U = U_0\left[1 - \left(\frac{r}{R}\right)^2\right]$$

$$G - G' = G\varphi = -\frac{2U_0 r}{R^2}\varphi$$

U is the fluid velocity and C the constant of integration. To minimize the disturbance for the parabolic velocity profile of the fluid, the following relation is assumed for the velocity frame

$$\int_0^R V_z\,\mathrm{d}r \left(= \int_0^{R-a} V_z\,\mathrm{d}r + V_z \Big|_{r=R-a} \times a \right) = \int_0^R U\mathrm{d}r \qquad (4)$$

The velocity frame, V_z, can be obtained from equations (3) and (4), but, to avoid duplication, it is not shown here.

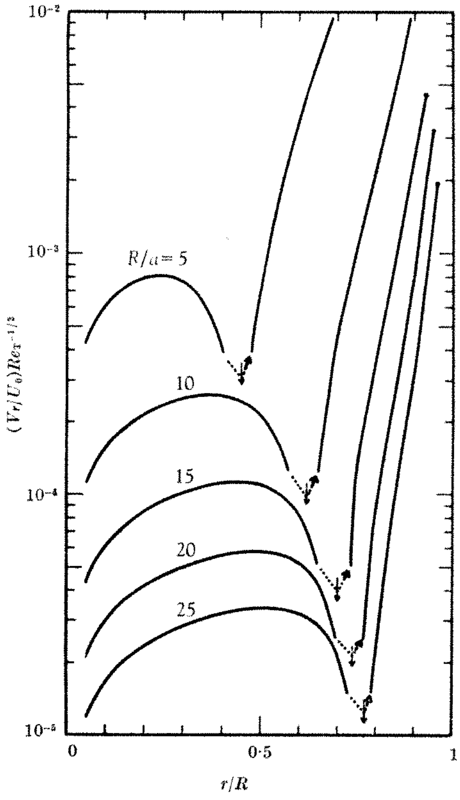

Fig. 1. Radial velocity of a neutrally buoyant particle. The right-hand side of the broken arrows is the negative velocity region and the left-hand side (convex curves) is positive.

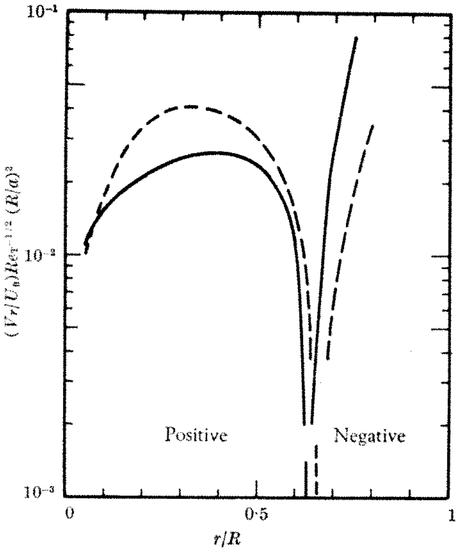

Fig. 2. Comparison of the calculated result (full curve) with the data line of Jeffrey and Pearson (broken curve). $R/a = 11{\cdot}1$.

In the absence of particle and wall interactions, a freely suspended particle lags behind the fluid by $(2/3)U_0(a/R)^2$. This slip velocity is caused by the particle being unable to accommodate itself perfectly to the curvature of the Poiseuille field[9-11]. Accordingly, the fluid velocity effectively acting on the particle is

$$U_{\text{eff}} = U - \frac{2}{3}U_0\left(\frac{a}{R}\right)^2 \qquad (5)$$

The effective relative velocity therefore becomes

$$\frac{\Delta V_z}{U_0} = \frac{U_{\text{eff}} - V_z}{U_0} = -\frac{5P^3}{8}\left(\frac{1}{1-r/R}\right)^3 + \frac{5P^5}{16}\left(\frac{1}{1-r/R}\right)^2$$
$$+ \frac{P^5}{12}\left(\frac{1}{1-r/R}\right)^3 - \frac{P^5}{16}\left(\frac{1}{1-r/R}\right)^4 - \frac{5P^2}{24} \qquad (6)$$
$$+ \frac{7P^3}{48} - \frac{5P^3}{8}\ln P + \frac{P^5}{48}$$

where $P = a/R$.

The particle entering a mouth of the flow tube congregates at a radial point where $\Delta V_z = 0$ (see Table 1). The results calculated from equation (6) agree well with the experiments of Segré and Silberberg[1,2] ($R/a \doteqdot 6 \sim 15$), Oliver[12] ($R/a \doteqdot 4$), and Jeffrey and Pearson[13] ($R/a \doteqdot 11 \sim 22$). The stable point shifts towards the tube wall as R/a increases. The radial particle velocity can be derived by substituting equation (6) into (1), as shown in Fig. 1. The radial velocity becomes zero at the tube axis and at a point listed in Table 1. The tube axis is the unstable equilibrium point at which no particle congregates. Despite including conditions to which Saffman's equation does not apply, Fig. 2 agrees well with the radial velocity calculated from equation (1), and the data line of Jeffrey and Pearson[13]. Although equation (6) includes the above assumption, it explains the migratory phenomena of the particle fairly well.

Table 1. STABLE POINT WHERE $\Delta V_z = 0$

R/a	4	5	10	15	20	22	25
r/R	0·40	0·45	0·62	0·70	0·74	0·75	0·77

For small particle and/or low Reynolds number, the particle migration becomes slow, and they will not congregate at a point in a tube of finite length. When the

Reynolds number is large and the particle is small, it is probable that only particles placed near the tube wall migrate prominently. For example, in the experiment of Maude and Yearn[3], in which $Re_T \doteqdot 600$ and $R/a \doteqdot 20$, the negative maximum velocity is fifty-five times as large as the positive one (see Fig. 1). Even if the outward migration is insignificant, it is therefore probable that the particle placed near the tube wall migrates inwardly by a short distance, and the prominent migration ceases in a short time. This will cause the "wall peak".

The above analysis gives the relative velocity effectively acting on a neutrally buoyant particle in Poiseuille flow and, applying it to Saffman's equation[5], the radial particle velocity can be calculated. The result explains the occurrence of the high concentration zone fairly well and the wall peak seems to be a phenomenon similar to the Segré–Silberberg effect.

I thank Mr Hikaru Nagashima for help with the early stage of this work.

BIOLOGICAL SCIENCES

Virus of the 1918 Influenza Pandemic

THE results of tissue culture neutralization of influenza viruses with sera obtained from ten persons from a remote Pacific island (Fais in the Western Caroline Group) have been described[1]. The persons concerned were alive in the decade before a devastating epidemic of influenza on the island in 1924, believed to have been a residual wave of 1918-type influenza. The ten sera contained no neutralizing antibody to strains of the influenza A1, A2 and equine virus, but did neutralize both human influenza AO viruses (PR8, WS and BH) and swine virus. This suggested that Fais has escaped influenza in the past twenty-five years. Because the titre of antibodies was quantitatively greater against the PR8 and BH—though not WS—than against swine virus, the authors conclude that 1918 influenza was more likely to have been caused by a virus related to the influenza AO group than to the swine virus.

In 1936, sera were examined in London for influenza antibodies in islanders from St Helena and also from Tuitula and Apia in Samoa, who were alive in 1918. Both areas were selected because historical[2] and local records confirmed that no epidemic of influenza occurred there in the 1918–19 period. The findings relating to the St Helena islanders were published[3] but not those from the Pacific. The Samoan sera were obtained by the late Sir Patrick Laidlaw from Dr P. J. Monaghan of the Western Samoan Administration, and from this information it was suggested that Pacific islanders who escaped through quarantine in the 1918 epidemic did become infected from 1920 onwards as pointed out by Brown *et al.*[1].

Sera were examined by inoculating mice intranasally with dilutions of serum and mouse lung filtrates from mice infected with either the WS or the Shope (1931) swine influenza virus. Hyperimmune horse sera prepared from each of the viruses and of similar homologous potency were included in the test. The results of the lung tests from the groups of mice are expressed in terms of the neutralization titre of each standard horse serum. Table 1 presents the distribution of antibody titres obtained with both viruses. More than half the sera possessed antibodies to swine virus, but eight of the fourteen sera did not neutralize the WS virus. In the table, S/5 represents a titre one-fifth that of the standard antiserum, and is the most potent serum that was found.

It is clear that the antibody titres against swine influenza virus were greater than those against the WS virus. The results are comparable with those of the sera obtained from St Helena islanders in 1935. Of the twenty-three islanders from St Helena aged 35 to 74 and bled in 1935, however, twenty-two were again sampled in 1936 by Dr P. B. Wilkinson of the island's health department. In the interval, a considerable epidemic of influenza occurred on the island. Table 2 shows the results of mouse lung neutralization tests with the two sets of sera using the WS and swine viruses expressed, as before, in terms of the homologous standard.

Table 1. MOUSE LUNG NEUTRALIZATION TESTS WITH FOURTEEN SAMOAN SERA COLLECTED IN 1936

	Number of sera with titres in each range					
Viruses	S/5	S/10	S/25	S/50	S/125	< S/125
WS	—	1	1	—	4	8
Shope	3	1	4	2	1	3

Table 2. ST HELENA SERA IN 1935 AND 1936 MOUSE LUNG NEUTRALIZATION TESTS

		Number of sera with titres in each range							
Virus	Collection date	> S/5	S/5	S/10	S/25	S/50	S/125	< S/125	Totals
WS	1935	—	—	1	—	4	6	12	23
	1936	2	—	10	3	3	4	—	23
Shope	1935	—	1	—	5	6	10	1	23
	1936	2	5	8	1	5	1	—	22

It is clear that the 1936 epidemic of influenza enhanced the antibodies to both viruses and the final titres against swine virus were at least as high or higher than the titres against WS virus. This suggested that the swine virus antibodies in the Samoan and the original St Helena sera resulted from some previous infection with a virus related to swine virus, and were not merely heterologous.

The results obtained in 1936 with both the sera from Samoa and St Helena showed that the distribution of anti-swine virus antibodies found in remote island groups said to have escaped the 1918 influenza were surprisingly similar to those obtained at the same time from persons living in London or in the United States and who were alive in 1918[4,5]. The fact that anti-swine virus antibodies were present in adult islanders in substantial amount and were boosted by influenza of the AO variety suggested that they were antibodies resulting from some previous infection, possibly of the 1918–20 epoch. The absence of an epidemic of influenza during the great pandemic does not rule out the possibility of subsequent infection during the 1920s with re-circulating virus of the same serological type as the 1918 influenza. Brown *et al.*[1] prefer the explanation that anti-swine virus antibodies in Fais islanders are heterologous antibodies arising from antigens of the type A viruses related to those of swine virus, but the evidence from the anti-swine virus antibodies in the European and American sera is against this interpretation.

In 1935, it was found[4] that children under ten born in London after 1925 had no demonstrable neutralizing antibodies to swine virus. Low titres were found in those aged ten to fourteen and higher titres were found in most of those older than twenty. Similar results were obtained by Shope[5] and Francis and Magill[6] with American sera and in Australia by Burnet and Lush[7]. Using pooled sera that had been collected in 1953 and 1954 from Sheffield and Ann Arbor, Michigan, and tested by the haemagglutination method, Davenport *et al.*[8] found that persons under thirty years of age had no swine virus antibodies, but peak titres were present in sera from persons aged thirty-five to forty-five. Masurel and Mulder[9] similarly tested individual sera from persons of different ages collected in 1957 and 1958. Though low titres of swine antibodies were found in sera from 10 to 40 per cent of children and young adults, high titres were found in most sera from those aged thirty and over and there was a peak in persons aged forty to fifty. In 1964, Schild and Stuart-Harris[10], using individual sera collected in 1961–2, found very low titres of H1 antibody to swine virus in sera from persons less than thirty, and peak titres in the fifty to sixty age group. This evidence strongly favours a cohort of persons aged between twenty and thirty in 1935 and forty to fifty in 1955 who continue to possess high titres of anti-swine antibodies. It does not favour a slowly rising percentage of persons in any one year with swine antibodies resulting from repeated infections with the various human influenza viruses. This does not preclude the fact that heterologous antibodies appear after infection with any one strain of influenza virus. The evidence suggests that, in the case of influenza viruses, childhood infection orients the antibody response to subsequent infection by later viruses as first suggested by Francis *et al.*[11].

The data published by Philip and Lackman[12] using sera from Alaskan villagers where influenza either did or did not occur in 1918 also strongly confirm the hypothesis that the presence of anti-swine antibodies in human sera results from exposure to an influenza virus closely related to the swine influenza virus which was circulating in the 1918 and early 1920 period. The view[1] that the 1918 influenza virus was one of the human AO type is inadequate to explain the accumulated evidence for the presence of swine virus antibodies in human sera.

Comparison of the Fates of Ag–B Locus Compatible Homografts of Skin and Hearts in Inbred Rats

TISSUES and organs are not all equally vulnerable to transplantation immunity. Renal homografts sometimes succeed in conditions in which homografts of skin would have failed[1] and there is suggestive evidence that liver grafts may be less exacting in their genetical requirements than those of kidney, especially in pigs[2]. A few reports during the early days of human cardiac transplantation prompted speculation that this organ might be superior to kidney with regard to its capacity to override histoincompatibility barriers. It was suggested that: (1) because the heart is essentially a muscular pump, without complex metabolic functions, it might be less vulnerable to immunological insult than kidney; and (2) being composed chiefly of muscle and devoid of epithelial components, hearts might be "less antigenic" than organs with large amounts of epithelial tissue such as kidneys.

In the light of the recent results of clinical cardiac grafting, the status of the human heart as a possible partially privileged organ has become difficult to uphold. That there is probably nothing immunologically unique about the cardiac transplant had previously been suggested by Shumway and Lower's finding that the functional survival time of cardiac homografts in non-immunosuppressed dogs is only 7 days[3], and that auxiliary rat heart grafts[4] across the major, Ag–B, histocompatibility locus in this species are rejected as promptly as homografts of skin, liver[5] and pancreas[6].

It is, however, generally agreed that the most favourable situation for revealing the existence of possible differential histocompatibility requirements is that which obtains when donor and recipient are compatible at the major locus for the species concerned. White and Hildeman[7] and Mahabier *et al.*[8] have reported that kidney homografts may enjoy prolonged (if not permanent) survival in inbred rats where Ag–B compatibility exists—for example, with the Fischer→Lewis combination—even though skin homografts are rejected promptly. By contrast, Freeman and Steinmuller[9] have recently reported that Lewis rats reject Fischer heart homografts with essentially the same vigour as skin. Freeman and Steinmuller's data are in agreement with our own previously reported findings[10] in regard to Fischer hearts in Lewis hosts. These authors interpret their study as indicative that the heart (unlike the kidney) is as susceptible to rejection as skin where minor histoincompatibilities exist. We present evidence here which challenges this generalization. We have recently found that when Fischer rats are used as the recipients, Lewis heart homografts display striking prolongation of survival as compared with those of skin.

The subjects of the work to be described were adult rats, weighing 250–450 g, of the inbred Lewis and Fischer strains, obtained from Microbiological Associates, Inc., Walkersville, Maryland. These two strains of rats are known to have similar alleles at the Ag–B locus, though they differ with respect to antigens determined by at least four other H-loci (our unpublished results).

To determine the survival times of skin homografts, animals of similar sex from these strains were paired off at random and two trimmed grafts of belly skin, 1·5–2·0 cm in diameter, were exchanged between them. Following primary inspection on the sixth day after the operation, the grafts were scored daily to determine their survival times, according to our standard procedures.

The auxiliary hearts were transplanted by the technique of Ono *et al.*[11]. The donor pulmonary artery was anastomosed to the recipient's inferior vena cava and the donor aorta to the recipient's abdominal aorta. The donor pulmonary veins and venae cavae were ligated. Thus the direction of blood flow was from recipient aorta into donor aorta and thence into the coronary arteries. After perfusing the myocardium, blood returned to the right side of the heart and was pumped into the host inferior vena cava. Ischaemia times were 60–90 min. Within 1–2 min of revascularization the hearts began to beat spontaneously and vigorously. The beating hearts could be easily palpated through the anterior abdominal wall in the unanaesthetized animals and this proved to be the most convenient means of assessing function daily. Electrocardiograms and surgical exploration were carried

Table 1.

Donor–host strain combination	Type of graft	No. of hosts studied	Skin graft survival times (days)	Functional survival times of hearts (days)	Absolute survival times of hearts (days)
Fischer→Lewis	Skin	10	7, 2 × 8, 9, 4 × 10, 2 × 11 (MST: 10·0 ± 0·8; *S.D.* 1·15)		
Fischer→Lewis	Heart	12		2 × 7, 4 × 8, 5 × 9, 11 (MST: 9·0 ± 0·5; *S.D.* 1·08)	2 × 8, 6 × 9, 10, 13, 15, 22
Fischer→Lewis (presensitized)	Heart	4		2 × 4, 7, 8	
Lewis→Fischer	Skin	10	9, 3 × 12, 13, 3 × 14, 16, 18 (MST: 13·8 ± 1·5; *S.D.* 1·18)		
Lewis→Fischer	Heart	10		7, 9, 12, 14, 16, 23, 24, 25, 26, 27 (MST: 18·6 ± 6·0; *S.D.* 1·66)	8, 11, 13*, 15, 18, 27, 50*, 61*, 88*, 100*
Lewis→Lewis	Heart	6		6 × 100	

* In the L→F heart homografts absolute survival time was shortened in these instances by removing the heart (for histology) while it was still beating weakly.

out when doubt existed as to the status of the transplanted hearts.

The results of preliminary skin graft exchanges between animals of the same inbred strain confirmed their isohistogenic status, and the survival of all of six Lewis→Lewis heart grafts for 100 days afforded evidence that the operative technique used was adequate to meet the metabolic and physiological requirements of this organ.

The experiments carried out and their results are summarized in Table 1. Fischer skin grafts on Lewis hosts were rejected more rapidly than skin transplanted in the opposite direction, the median survival times (MSTs) of the two series of skin grafts being 10·0 ± 0·8 days and 13·8 ± 1·5 days respectively.

The first indication of incipient rejection of a cardiac homograft was a decline in the forcefulness of what had previously been a palpable, strong, regular beat. Within the next 24–48 h there was usually either total cessation of heart beat or the beat became so feeble that it was no longer detectable with certainty by palpation.

In either case the animal's abdomen was explored surgically at this time. When direct observation of the heart confirmed either the complete absence of pulsatory activity or only very weak activity, this was scored as the "functional end point", for the organ's activity had fallen below the level needed to support the circulation and sustain life had it been transplanted orthotopically rather than as an accessory. In most instances the heart was removed at this time for histological study, because it clearly no longer had haemodynamic significance.

With the Fischer→Lewis combination when observation of cardiac homografts was continued beyond their "functional" end points, contractile activity of the myocardium and electrical activity on the EKG ceased completely within a few days. The "functional" and absolute survival times of the transplanted hearts were indistinguishable from the survival times of skin grafts.

The fate of the Lewis→Fischer heart transplants, however, proved to be more interesting from the immunological point of view. Four out of ten such hearts continued to beat weakly long after the functional end point was reached, and in fact displayed electrocardiographic activity and rhythmic myocardial contractility even at the time of their eventual removal for histological study, 50–100 days after grafting. Hearts removed at either the functional end point or after all signs of contractility had ceased showed typical mononuclear cell infiltration of the myocardium, though this tissue usually appeared to have a high degree of survival. With this combination, both "functional" and absolute survival times of heart transplants proved to be significantly longer than skin graft survival time.

It is interesting to note that Fischer hearts, transplanted to Lewis hosts specifically presensitized by bilateral grafting with Fischer skin, continued to beat vigorously for 4–8 days, a surprisingly long time in view of the fact that the vascular supply in these organ grafts was immediately restored surgically and did not require 2–3 days for regeneration as with skin grafts.

The findings with the Fischer→Lewis combination lend no support to the thesis that hearts are less vulnerable to transplantation immunity than skin. Lewis hearts in Fischer rats did, however, enjoy a slightly but significantly longer "functional" survival time than skin grafts, and the total survival time (with weak beats) of the Lewis hearts in Fischer hosts was in some cases 50–100 days. This finding is similar to that of White and Hildeman's with Fischer kidneys in Lewis hosts. As in the case of our heart transplants, White and Hildeman's kidney homografts, though enjoying prolonged survival, did not continue to function normally, as evidenced by the uraemia developing in their hosts. It is possible that the immunosuppressive effects of the uraemia may have helped in further prolonging graft survival.

The asymmetry in MSTs of exchanged skin grafts suggests that the histoincompatibility barrier confronting Fischer grafts in Lewis rats is a more formidable one than in the reverse direction, though both MSTs depend on antigens determined by minor loci. The heart homograft results reported here are also in keeping with this thesis. We do not know of any study in which kidneys have been transplanted from Lewis to Fischer rats, but in the opposite direction kidneys enjoy prolonged survival while hearts and skin do not. We are currently engaged in comparing the survival of skin and hearts taken from [(Fischer × Lewis) F_1 × Lewis] R_2 backcross donors transplanted to Lewis recipients, each donor giving its heart to one host and a skin graft to another. This allows the fates of these two types of graft to be compared over a wide range of histoincompatibility. In all such experiments so far (more than twenty pairs), the heart has survived longer than the skin and in many instances by more than 100 days.

We conclude from these findings that heart transplants across a histoincompatibility barrier other than Ag-B are less vulnerable to rejection than skin grafts, but it seems likely that they are more susceptible than kidney grafts.

We thank Mr George Sawchuck for technical assistance. The work was supported in part by a US Public Health Service grant. C. F. B. is a Markle scholar in academic medicine.

Radioimmune Assay for Histocompatibility Antigens

A MAJOR obstacle in histocompatibility testing has been the need for whole cells as the final target for antiserum action, for example, haemagglutination, complement fixation or complement-dependent cytotoxicity. Catt and Tregear[1] have reported that antibody adsorbed irreversibly onto polystyrene test tubes can specifically bind isotope-labelled antigen in nanogram amounts. We have applied a modification of their test to the assay of mouse transplantation antigens.

All operations were carried out at room temperature. One ml. of a dilution of serum in 0·05 M carbonate buffer, *p*H 9·6, was added to polystyrene (12 × 75 mm) test tubes (Falcon Plastics) and incubated for 1 h in an upright position. The antiserum was removed by suction and the tubes were rinsed twice with saline. 0·4 ml. of a solution of bovine serum albumin (25 mg/ml.) in 0·15 M saline, 0·01 M phosphate buffer at *p*H 7·2 was added to the tubes. The tubes were rotated in a tissue culture roller drum at 20 r.p.m. for 30 min. The solution was removed by suction and 0·25 ml. of a solution of the same composition, containing ^{125}I-labelled antigen, was added. Incubation was continued in the roller drum for another 3 h. After the tubes were rinsed three times with saline, the amount of ^{125}I bound to the empty tubes was determined in an automatic gamma counter. All assays were performed in triplicate. The presence of 25 mg bovine serum albumin minimized the non-specific adsorption of ^{125}I-labelled proteins onto the plastic.

The antiserum used was developed in C57Bl/10 SnJ mice inoculated with the DBA/2 lymphoblast L-5178Y microsomal lipoprotein fraction (MLP), which has been shown to be a potent source of transplantation antigens, both H2 and non-H2[2,3].

The MLP was labelled according to the method of Hunter and Greenwood[4]. A fresh, dialysed MLP preparation (20 µl. containing 50 µg protein) was iodinated with 2 mCi of carrier-free ^{125}I (Amersham Searle). The MLP being insoluble, the unused ^{125}I was removed by dialysis (4 × 100 ml.) over a 2 day period in the cold.

The extent of specific binding of labelled antigen by various dilutions of the antiserum is shown in Table 1. Even at a 1 : 25,000 dilution, a significant amount of radioactive antigen was specifically bound. This serum gave a 1 : 160 titre when assayed by conventional complement-induced lysis of DBA/2 lymphocytes, using trypan blue as an indicator.

Table 2 shows the results of absorption studies performed with this serum. Incubation of the serum with spleen MLP from the strain isogeneic to the serum donor (C57Bl/10) had no effect on the titre in either the radioimmune assay or in the conventional haemagglutination titration. The MLP of congenic resistant-strain spleens, B10.D2, reduced the bulk of the antigen-binding capacity in both tests (approximately 85 per cent in each case). Because the H2D antigen is present in this MLP[5], the antibody removed was more than likely H2 antibody. A second absorption with B10.D2 MLP did not reduce the titre any further. The antigen-combining activity was reduced by absorbing the resulting serum with DBA/2 MLP, a source of non-H2, as well as H2D antigens[6]. It therefore seems that the method will be effective for detecting non-H2 antigens, as well as antibodies directed against these antigens. The final product after these absorptions still had a residual antigen-binding capacity. The nature of this antibody is being investigated further. Further applications of the test will be published elsewhere[7].

Table 1. BINDING OF ^{125}I-LABELLED L-5178Y MLP TO ANTIBODY-COATED TUBES

Antiserum	Antiserum dilution	Antigen bound per tube (c.p.m.)	Specific binding (c.p.m.)	Specific binding (ng protein)
C57Bl/10 anti L-5178Y	1 : 1,000	6,654 ± 108	5,276	0·67
	1 : 5,000	4,485 ± 135	3,107	0·40
	1 : 6,250	3,830 ± 473	2,452	0·31
	1 : 25,000	1,966 ± 369*	588	0·08
	1 : 125,000	1,183 ± 146	− 195	—
Foetal calf	1 : 50	1,575 ± 647	197	
	1 : 250	1,468 ± 210	90	
Control		1,378 ± 302†		

The antiserum-coated tubes were exposed to 0·25 ml. of a solution described in the text containing 78,420 c.p.m. (10 ng of MLP protein) for 3 h.

* Significant at the 0·02 per cent level.

† The control tubes were treated with alkaline buffer for 1 h, then treated as described in the text.

Table 2. ABSORPTION EXPERIMENTS WITH THE ANTI-L-5178Y SERUM

Treatment	Specific binding (c.p.m.)* 1 : 250	1 : 1,000	1 : 5,000	Ha titre†
Untreated		2,943	1,752	320
(*a*) Absorbed with 1 mg C57Bl/10 MLP		2,852	1,843	320
(*b*) Absorbed (*a*) with 1 mg B10.D2 MLP		370	− 43	40
(*c*) Absorbed (*b*) with 1 mg B10.D2 MLP	1,221	702	—	—
(*d*) Absorbed (*c*) 2 × 1 mg DBA/2 MLP	767	− 207	—	—

* Absorptions were carried out sequentially with the serum used in Table 1. One ml. of the serum was incubated in step (*a*) 1 h at 37° C, then overnight at 4° C on a roller drum (1 r.p.m.). The suspension was centrifuged 30 min at 100,000*g*. The supernatant fluid was titred and subjected to step (*b*) in the same conditions as for step (*a*). Steps (*c*) and (*d*) were then carried out in succession and the values obtained entered in the table. The values in the table are the specific binding found at the dilution indicated, relative to the original serum. Non-specific absorption with the antigen preparation used was 3,465 ± 307 c.p.m. per tube.

† This titration was performed by Dr J. Palm, using DBA/2 red cells, according to a procedure previously used[3]. The values in the table are the reciprocal of the dilution that was the end-point in the titration.

We thank Dr Joy Palm for carrying out the cytotoxicity and haemagglutinating antibody titrations, and Misses R. Crocamo and B. Van Dyke for technical assistance. This work was supported by Public Health Service research grants from the US National Cancer Institute, and a training grant from the US National Institute of General Medical Sciences.

Simple Method of Subtyping Human G-Myeloma Proteins based on Sensitivity to Pepsin Digestion

HUMAN immunoglobulin G comprises four subclasses called IgG 1, IgG 2, IgG 3 and IgG 4. G-myeloma proteins result from the proliferation of a single clone of plasma cells and belong to only one of the four possible subclasses. At the present time such myeloma proteins represent the only readily available source of subclass specific protein and are increasingly in demand for both immunological investigations and protein sequence analysis. Subtyping of G-myeloma proteins may be achieved by immunological procedures using subclass specific antisera[1,2], by Gm typing[3] or by chemical typing[4]. Early work with G-myeloma proteins of the four subclasses revealed striking differences in sensitivity to papain[5,6] and these observations have recently been extended by other groups[7,8] to provide a basis for subtyping. In a recent investigation of the Gm markers associated with the pFc′ fragments of different IgG subclasses[9], differences were observed between the subclasses in their sensitivity to pepsin digestion and seemed to provide a further tool for subtyping myeloma proteins.

G-myeloma proteins were isolated by two-step procedures involving 'Pevikon'-block electrophoresis and DEAE-cellulose chromatography. One ml. solutions of the proteins (1·5 per cent) were prepared in 0·1 M acetate buffer *p*H 4·5 and digestion was performed at 37° C with twice recrystallized pepsin (Worthington) using an enzyme : substrate ratio of 1 : 100. Aliquots (100 µl.) of the digest mixtures were removed at 0 h, 2 h, 6 h, 10 h and 24 h. Solid Tris salt was immediately added to give a final *p*H of 8·0 and samples were stored at −20° C until required for analysis.

The digestion of the proteins was then studied as a function of time using acid urea starch gel electrophoresis at *p*H 3·0 according to the method of Edelman and Poulik[10]. A marker of pFc′ fragment (prepared from pooled human IgG) (ref. 11) was included with each analysis.

Fig. 1*a–e* shows representative photographs of the course of digestion in the following myeloma proteins: IgG 1 Gm(f), IgG 2 Gm(n–), IgG 3 Gm(g), IgG 3 Gm(b) and IgG 4 Gm(−). The starch gel patterns of the pepsin digested IgG 1 protein (Fig. 1*a*) closely resembled the patterns previously observed with pooled IgG undergoing similar digestion[12]. Thus the pFc′ fragment was present in all samples (except at 0 h) and the appearance of the fragment was paralleled by a steady increase in the F(ab′)$_2$ fragment and a decrease in the amount of intact IgG. The maximum intensity of the pFc′ band was seen after 10–24 h digestion.

The pepsin digestion of an IgG 2 protein is shown in Fig. 1*b*. In this case the pFc′ fragment was visible at 2, 6 and 10 h but not at 24 h. The maximum intensity of the pFc′ band was evident at 6 h. Another point of difference between the IgG 1 and IgG 2 classes was the absence of residual intact IgG in the 24 h aliquot from the IgG 2 protein.

The digestion of an IgG 3 Gm(g) protein is shown in Fig. 1*c* and differs strikingly from the patterns for IgG 1 and IgG 2 proteins. The pFc′ fragment was present in the 2 h aliquot as shown by a heavily stained band but was only weakly present at 6 h and absent at 10 h and 24 h. Also striking is the absence of intact IgG at 2 h. An essentially similar pattern is seen in the digestion of an IgG 3 Gm(b) protein (Fig. 1*d*). The pFc′ band at 2 h was, however, very much weaker than in the IgG 3 Gm(g) protein. The IgG band was not detectable at 2 h.

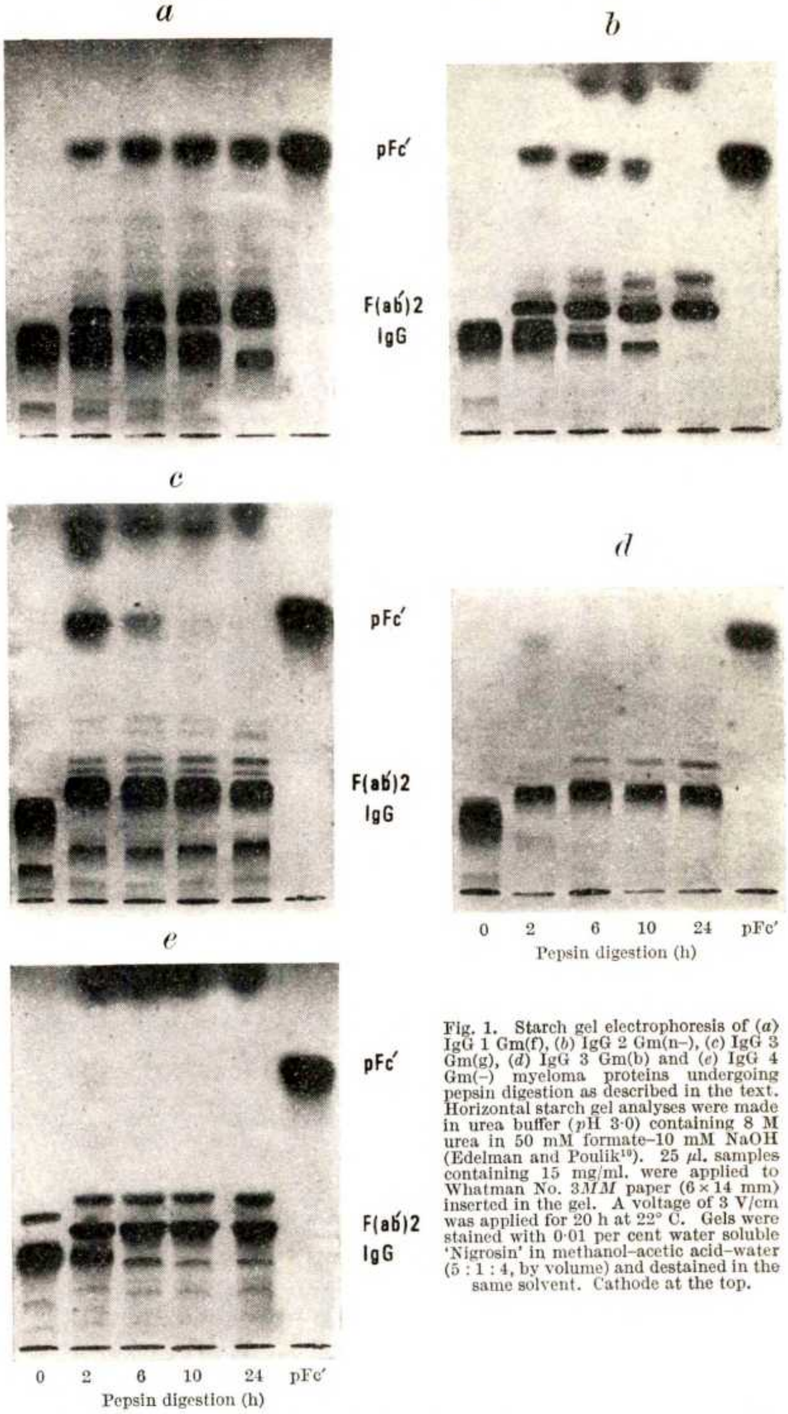

Fig. 1. Starch gel electrophoresis of (*a*) IgG 1 Gm(f), (*b*) IgG 2 Gm(n–), (*c*) IgG 3 Gm(g), (*d*) IgG 3 Gm(b) and (*e*) IgG 4 Gm(–) myeloma proteins undergoing pepsin digestion as described in the text. Horizontal starch gel analyses were made in urea buffer (*p*H 3·0) containing 8 M urea in 50 mM formate–10 mM NaOH (Edelman and Poulik[10]). 25 µl. samples containing 15 mg/ml. were applied to Whatman No. 3*MM* paper (6 × 14 mm) inserted in the gel. A voltage of 3 V/cm was applied for 20 h at 22° C. Gels were stained with 0·01 per cent water soluble 'Nigrosin' in methanol–acetic acid–water (5 : 1 : 4, by volume) and destained in the same solvent. Cathode at the top.

Finally, Fig. 1*e* shows that pepsin digestion of the IgG 4 protein produced starch gel patterns somewhat similar to those of IgG 3 Gm(b). There were, however, two differences. First, no pFc′ band was seen at any stage and second, there was residual undigested IgG at 2 h.

The results of starch gel analyses of nineteen G-myeloma proteins (Table 1) suggest that the patterns illustrated in Fig. 1 are representative of each subclass and furthermore that the human IgG subclasses fall into two groups in their sensitivities to pepsin digestion. In the conditions used the IgG 1 and IgG 2 proteins are relatively resistant to the enzyme because both the release of pFc′ fragment and the disappearance of intact IgG are slow processes; these two subclasses are distinguishable by the time of maximum production of pFc′ fragment—6 h for IgG 2 proteins and 10–24 h for IgG 1 proteins.

The IgG 3 and IgG 4 subclasses are highly sensitive to pepsin. In the case of the IgG 3 proteins, pFc′ fragment is seen at 2 h but only weakly (if at all) at 6 h. Intact monomeric IgG was not detectable after 2 h digestion in any IgG 3 protein studied. The difference between IgG 3 Gm(b) and Gm(g) proteins may indicate different conformational structures in the region where pepsin cleaves off the pFc′ fragment (near residue 332 of the γ-chain). A similar explanation may also apply to the IgG 4 proteins

Table 1. PEPSIN HYDROLYSIS OF G-MYELOMA PROTEINS

Class and designation of protein		Presence of pFc′ fragment 2 h	6 h	10 h	24 h	Presence of undigested IgG 2 h	6 h	10 h	24 h

	Sta	(W +)†	–	–	–	+ +	W +	–	–
	Ger	–	–	–	–	+	–	–	–

W + = weakly stained band. Tr = trace amount, less than W +.
* Aggregated IgG. † "pFc′-like" band on anodic side of normal pFc′ mobility range.

which were characterized by the absence of a pFc′ fragment (Joh and Ger proteins) or the presence of a faint, anodically migrating, "pFc′-like" fragment. The different mobility of this IgG 4 "pFc′-like" band and the presence of residual IgG at 2 h distinguishes this subclass from the IgG 3 Gm(b) proteins.

A correlation between heavy chain subclasses and papain sensitivity of IgG myeloma proteins was suggested by earlier investigations[5,6] and has been confirmed by Jefferis *et al.*[7] and Gergely *et al.*[8]. The latter group investigated the papain susceptibilities of fifty G-myeloma proteins. IgG 2 and IgG 4 proteins were resistant to papain, whereas IgG 3 proteins were sensitive. The IgG 1 class was heterogeneous in that three out of seventeen specimens were papain resistant. This heterogeneity was not related to Gm type. In our investigation of nineteen myeloma proteins no heterogeneity was evident within the subclasses except in the case of the IgG 3 proteins where it was, apparently, related to Gm type.

Finally, because pFc′ fragment is not widely available we have investigated other possible markers for use in the starch gel electrophoretic analysis. Trypsin (see Fig. 2) was found to migrate on the anodic side of the pFc′ region but can nevertheless usefully serve as an indicator for the fragment in subtyping experiments.

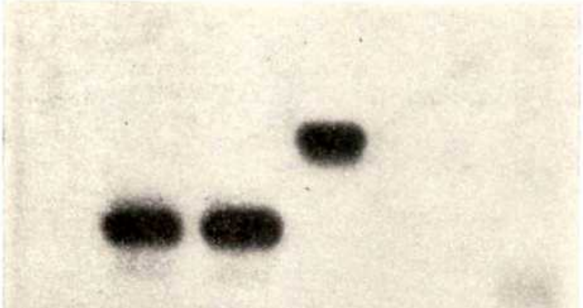

Fig. 2. Acid urea starch gel electrophoresis (*p*H 3·0) of 1 per cent solutions of bovine serum albumin (BSA); trypsin; BSA + trypsin; pFc′ fragment; IgG and reduced IgG. If trypsin is arbitrarily given an R_F value of 1·00, the pFc′ fragment has an R_F value in the range 1·19–1·26 (average 1·23). Cathode at the top.

Rheumatoid Anti Gm Factors with Specificity for the pFc′ Subfragment of Human Immunoglobulin G

THE rheumatoid factors are anti-γ-globulin antibodies directed against heavy chain determinants in the Fc region of immunoglobulin G (IgG). Although quantitative differences seem to exist, each of the four subclasses of IgG is able to interact with suitable preparations of rheumatoid factor[1,2]. In addition, Gm genetic markers are involved in certain rheumatoid factor reactions and the delineations of several new Gm markers have been performed with anti Gm antibodies from patients with rheumatoid arthritis, for example, Gm(a), (x), (b) and (g)[3].

It is now more common, however, to use anti Gm antibodies from normal individuals or heteroantisera for Gm typing[3].

The pFc′ subfragments of IgG1 molecules have recently been shown to possess Gm(a) and "non a" serological activities[4,5]. The pFc′ fragment is a dimeric subunit of molecular weight 26,000 from the C-terminal end of the heavy (γ) chains. A related but smaller fragment, termed Fc′ fragment (molecular weight 21,000), is located between amino-acid residues 14 and 105 (numbered from the C-terminal end)[6] and seems to lack both Gm(a) and "non a" serological activities[4]. We have now investigated the reactivity of the Fc′ and pFc′ fragments with rheumatoid factors of known anti Gm activity. The specificity and sensitivity of rheumatoid anti Gm sera seem to differ from those originating from normal individuals and heteroantisera[3,7,8]. The former are inhibited by concentrated solutions or aggregated material of γ-globulin, negative for a particular Gm marker. By contrast, anti Gm antibodies from normal sera and heteroantisera are not inhibited. Nevertheless, we found that the rheumatoid anti Gm reagents exhibited the same reactivity for the pFc′ and Fc′ subfragments as other anti Gm systems but were less sensitive.

The pFc′ and Fc′ fragments were prepared from pooled IgG (Kabi, Stockholm) as previously described[4]. In addition pFc′ fragments were prepared from myeloma proteins of each of the three subclasses IgG1, IgG2 and IgG3 (ref. 9). The anti Gm reagents were obtained from patients with typical rheumatoid arthritis. Two reagents were used to test each of the following specificities: anti Gm(a) (3051 and 3070), anti Gm(x) (M.S. and Wi) and anti Gm(b) (3167 and 3510). Only one anti Gm(g) reagent (3978) was available. Appropriate controls included the testing of all intact proteins and fragments with anti Gm reagents obtained from normal sera or by heteroimmunization.

Table 1. INHIBITION OF VARIOUS RHEUMATOID FACTORS WITH pFc′ AND Fc FRAGMENTS

Class and designation of protein	Protein or fragment tested	Lowest concentration (mg/ml.) of protein or fragment giving inhibition				
		Anti Gm(a)	Anti Gm(x)	Anti Gm(g)	Anti Gm(b)	Rheumatoid factor without anti Gm activity
Pooled IgG	IgG	0·06	0·06	0·12	0·12	0·03
	pFc′ fragment	0·06	0·06	> 1·00	> 1·00	> 1·00
	Fc′ fragment	> 1·00	> 1·00	> 1·00	> 1·00	> 1·00
IgG1 Gm(a)	IgG	0·06	—	> 1·00	> 1·00	0·06
	pFc′ fragment	0·06–0·12	—	> 1·00	> 1·00	> 0·5
Gm(f)	IgG	> 1·00	—	> 1·00	> 1·00	0·03
	pFc′ fragment	> 1·00	—	> 1·00	> 1·00	> 0·5
IgG2 Gm(n –)	IgG	> 1·00	—	> 1·00	> 1·00	0·06
	pFc′ fragment	> 1·00	—	> 1·00	> 1·00	> 0·5
IgG3 Gm(b)	IgG	> 1·00	—	> 1·00	0·06	> 0·5
	pFc′ fragment	> 1·00	—	> 1·00	> 1·00	> 0·5
Gm(g)	IgG	0·5	—	0·06	> 1·00	> 0·5
	pFc′ fragment	0·5	—	> 1·00	> 1·00	> 0·5

All anti Gm reagents were used in dilutions corresponding to 2 or 4 agglutinating units with red cells coated by anti Rh[3]. —, Not tested.

Table 1 shows the results of haemagglutination–inhibition tests with rheumatoid anti Gm sera. Inhibition was achieved in the rheumatoid anti Gm(a) system with pooled IgG and with pFc′ fragment prepared from it. Similar results were obtained with an isolated Gm(a) myeloma protein and its pFc′ fragment. Anti Gm(x) exhibited the same pattern of reactivity with pooled IgG and its fragments but was not tested with isolated myeloma proteins or their fragments. No inhibition of the anti Gm(a) system was obtained with IgG1 Gm(f), IgG2 or IgG3 myeloma proteins and fragments except for a faint activity with the IgG3 Gm(g) protein which probably arose from contamination. Inhibiting activity for rheumatoid anti Gm(g) and anti Gm(b) was found only in the intact IgG3 Gm(g) and IgG3 Gm(b) myeloma proteins, respectively. With these antisera no inhibition was obtained with either pFc′ fragment from pooled IgG or pFc′ fragments from isolated Gm(g) or Gm(b) myeloma proteins. Similarly, a general rheumatoid factor without specificity for Gm antigens was not inhibited by any of the pFc′ fragments. In every case the reactivities observed with the rheumatoid anti Gm antibodies corresponded to those of anti Gm reagents from normal individuals or heteroantisera. The sensitivity was, however, less in the rheumatoid systems and a four to eight-fold difference was seen between the endpoints of inhibition using the two types of reagents.

Because heat-aggregated γ-globulin shows a very strong affinity for rheumatoid factor, additional experiments were performed with pFc′ fragments (at 10 mg/ml.) from pooled IgG heated to 63° C for 15 min. No increase in inhibitory activity was observed with these pFc′ fragments or with pFc′ fragments of isolated myeloma proteins treated similarly at a concentration of 1 mg/ml. It is, however, possible that the treatment did not give an aggregation comparable with that of whole γ-globulin, and further study on this point is needed.

The observation that rheumatoid factors with anti Gm(a) and anti Gm(x) activities interact with structural regions of the pFc′ fragment is in agreement with recent studies which used inhibition of precipitation techniques to show reactivity of rheumatoid factor with both the pFc′ and Fc′ fragments[10]. Because anti Gm(a) activity is frequently detected in rheumatoid sera, the Gm(a) site is probably easily exposed and strongly antigenic in the rheumatoid process. The strong antigenicity of the Gm(a) site in heteroimmunization (see ref. 3) supports this view.

In IgG1 Gm(a–) molecules the site which corresponds to the Gm(a) structure has recently been defined and called "non a"[5]. No rheumatoid factor has yet been reported to be reactive with this "non a" site but preliminary evidence points to the existence of such antibodies in rheumatoid sera[5]. The "non a" structure is also present in IgG2 and IgG3 molecules of all genetic types. Accordingly, rheumatoid factors with anti "non a" activity would be autospecific and inhibited by IgG Gm(a–) proteins as well as by all IgG2 and IgG3 proteins and human sera.

Our study indicates that rheumatoid factors are directed against at least two distinct molecular regions in the Fc fragment of IgG molecules. One is the Gm(a) site within the pFc′ fragment. The other sites for rheumatoid factor reaction are probably located outside the pFc′ fragment. The rheumatoid anti Gm(g) and anti Gm(b) antibodies are probably directed against structures in the N-terminal half of the Fc region, but they may require the interacting presence of both the C and N terminal halves. This was also the case with a general rheumatoid factor lacking anti Gm specificity. In this system, too, which may be similar to the one described by Allen and Kunkel[11], no inhibition was obtained with any pFc′ fragment.

It is of interest that rheumatoid anti Gm(b) has a specificity similar to (b^1) (ref. 12) and that the Gm(b^1) site has now been shown to be absent from the pFc′ fragment[9]. In addition, the recent identification of "non g" which is probably antithetic to the Gm(g) structure[5] makes it likely that the Gm(b^1) and Gm(g) sites are located in different regions of the Fc fragment. Considered together, these observations indicate the presence of multiple structural regions on the IgG molecule for reactivity with rheumatoid factors.

Origin of Small Lymphocytes following Blastogenesis induced by Short-term PHA Stimulation

WE have reported that short-term (24 h) exposure of human lymphocyte cultures to phytohaemagglutinin (PHA) results in the conversion of 90 per cent or more of the small lymphocytes to "blastlike" forms. Subsequently, the cultures revert to cells which resemble the original unstimulated small lymphocytes, both morphologically and metabolically, but remain fully reactive to renewed PHA stimulation[1]. In this report, we offer evidence that, in the 24 h PHA-stimulated cultures, most lymphocytes become blastoid but do not divide; instead, they return to their original form by 9 or 10 days after stimulation.

Lymphocyte cultures were prepared in replicate and subjected to 24 h stimulation with Difco 'PHA-P' as previously described[2]. Viable cell count was followed with erythrosin[3]. During the first 6 days, accurate cell counts could not be made in the stimulated cultures due to heavy clumping induced by PHA. Rough counts, however, indicated that the total cell numbers fluctuated from the initial count by less than 30 per cent. By the seventh day and thereafter, the clumps had become looser and could be dispersed by mechanical action. Daughter cell production was determined by incorporation of [^{3}H-*methyl*]-thymidine into cellular DNA, followed by isolation and measurement of this label in the acid insoluble fraction[1]. Daughter cell formation was measured daily by 24 h pulse label, that is, each day two vials were labelled and then collected after 24 h. Cumulative daughter cell production was determined by continuous label. For this purpose, additional vials were exposed to ^{3}H-thymidine and the label was maintained in the cultures throughout the experiment. Again two vials were taken daily. When continuous label was used, fresh ^{3}H-thymidine was included in the daily media changes. ^{3}H-Thymidine was not toxic to either the stimulated or the unstimulated lymphocytes at the isotope concentration used (0·01 μCi/ml.). In addition, daughter cell production was determined by autoradiography, using the same label and Eastman Kodak film emulsion 'NTB2' (ref. 4).

Data from a representative experiment showing daughter cell formation, as measured by DNA synthesis, are presented in Table 1. PHA-stimulated and control cultures were simultaneously tested. Column *A* lists daily DNA synthesis (daughter cell formation) during days 3 to 11 after PHA stimulation. This reaches a maximum at day 4, then drops to levels found in control cultures (column *D*) by day 9–10. Column *B* lists the total DNA synthesis occurring during the test period. This is determined by successive addition of the daily increments of DNA synthesis listed in column *A*. Column *C* gives the actual cumulative DNA synthesis in such cultures as determined by continuous ^{3}H-thymidine labelling. The higher values in column *B* as compared with column *C*, beginning at day 5, indicate that many of the daughter cells do not survive long. By day 11 the cumulative counts, based on continuous label, approach the level of unstimulated cells, indicating that most of the daughter cells have died.

Table 1. DAUGHTER CELL FORMATION IN HUMAN LYMPHOCYTE CULTURES

	PHA-stimulated cells			Unstimulated cells
Column	*A*	*B*	*C*	*D*
Day after stimulation	Daily DNA synthesis (c.p.m.)	Total DNA synthesis (c.p.m.)	Cumulative DNA synthesis (c.p.m.)	Cumulative DNA synthesis (c.p.m.)
3	109	—	—	8
4	450	659	670	28
5	405	1,064	720	33
6	330	1,394	560	20
7	180	1,574	390	41
8	107	1,681	260	20
9	49	1,730	100	21
10	50	1,780	70	14
11	22	1,813	40	11

Cell formation was measured by DNA synthesis in c.p.m. A tracer dose of ^{3}H-thymidine (specific activity 6·7 Ci/mmole) at a final concentration 0·01 μCi/ml. was used as a marker. Background (25 c.p.m.) has been subtracted.

Table 2 presents data on daughter cell formation as determined by autoradiographic measurements. Column *A* shows the percentage of daughter cells formed daily during days 3 to 11 after PHA stimulation, based on counts of a thousand cells. Column *B* lists the total percentage of daughter cells formed in such cultures during the test period. This is determined by successive addition of the percentages of daughter cells formed daily as listed in column *A*. Column *C* gives the actual cumulative percentage of daughter cells in such cultures as determined by continuous ^{3}H-thymidine label. Daughter cells accumulate for a few days as seen by equivalent values in columns *B* and *C* for days 4 and 5. As the rate of DNA synthesis declines, day 6, the values in column *B* begin to exceed those in column *C*, indicating the disappearance of daughter cells. By day 10, only 6 per cent of the cells were labelled, yet the number of viable cells remained at 57 per cent of the initial number. This indicates that most of the cells present at that time represent lymphocytes which have not divided. Because these cells were blasts on day 7, as shown in column *F*, they must have reverted to their original form.

The mechanism of PHA action is still unclear. There is evidence that PHA attaches to the cell, and subsequently

Table 2. AUTORADIOGRAPHIC MEASUREMENTS

10	0	—	6	0·9	Small	0
11	0	—	7	0·9	Small	0

Measurements were made of daughter cell formation in human lymphocyte cultures. ^{3}H-Thymidine (specific activity 6·7 Ci/mmole) was used as a marker. Column *E* describes type of cell: small, medium, large or blast-type lymphocyte.

appears in the cytoplasm[5-7]. If this, indeed, is the case, then reversion of blastogenesis may depend on release or inactivation of this mitogen, thus permitting reactivation of the receptor mechanism in the lymphocytes. Although the reverted cells behave metabolically and appear microscopically much like small lymphocytes, it still remains to be shown whether other aspects of the reversion are also complete, for example, enzymatic pattern.

The ability of the lymphocytes in culture to undergo repeatedly reversible transformation in metabolic activity and morphology, as well as mitosis, further increases the scope of activities demonstrated for these cells. Thus short-term lymphocyte stimulation with PHA provides a system for studying (1) the control mechanism of differentiation and dedifferentiation and (2) the mechanisms leading to blastogenesis and mitosis.

We thank Dr John Ifft for his suggestions regarding the autoradiographic studies and Michael Klein for his assistance. This work was supported by US Public Health Service grants.

Cell Movement and Cell Spreading: a Passive or an Active Process?

Wolpert, Macpherson and Todd[1] have recently described some experiments on the effects of temperature on the spreading and rounding up of cultured cells. They believe their findings invalidate the "passive" theory of tissue cell movement which I have previously put forward[2]. In this theory, the advancement of the cell margin during spreading or locomotion is considered to be passive in the sense that it is analogous to the spreading of a liquid on a suitably wettable surface. It is helpful to express the theory in terms of surface (interfacial) tensions because it places adequate emphasis on the part played by the medium and the substrate.

The challenge offered by Wolpert and co-authors is based on two experiments. In the first experiment the failure of cells to spread on a (glass ?) Petri dish at 2° C, whereas they do spread at 37° C, is held to refute the idea of passive spread because passive spreading "ought not to be significantly affected by lowered temperature". It is well known that the surface tensions of pure liquids are relatively unaffected by temperature changes (the surface tension of water, for example, changes by only 7 per cent in this temperature range), but if surface-active impurities are present or if the system is intrinsically more complex, profound changes of surface tension in response to changing temperature may occur. A chief cause of such temperature dependence is the adsorption of molecules at an interface. Adsorption of very small amounts of material can cause spectacular changes in surface tension. Not only is the process of adsorption itself temperature dependent, but other temperature sensitive factors such as solubility, the formation of complexes or coacervates, or the rates of biochemical change could affect the number of molecules available for adsorption. The more complex the system and the more heterogeneous its molecular population, the more opportunities there are for such factors to operate.

The surface properties of a cell are primarily dependent on the molecular species at the cell surface. The synthesis and breakdown of these molecules (and in some cases their transport) are largely determined by metabolic processes. To claim that the wetting properties of a cell should not be significantly affected by changes of temperature is to assume that the molecular population at the cell surface will not be significantly altered whether the cell metabolism is working optimally at 37° C or virtually switched off at 2° C.

In the second experiment, cells which had already spread at 37° C were found to display no tendency to round up when the temperature was lowered to 2° C. If a cell remains permanently rounded up at 2° C, one would certainly expect—on purely thermodynamic grounds—that a spread cell would tend towards this condition if cooled to the same temperature. The factors which oppose such a tendency should not be neglected, however. One of these is hysteresis of wetting—the familiar tendency of liquids to remain spread over areas of surface which have already been wetted. Wetting hysteresis is particularly marked in complex situations involving heterogeneous molecular populations. It may also be greatly enhanced by adsorption hysteresis. Molecules already adsorbed at an interface (particularly polymeric molecules such as proteins) do not necessarily desorb in conditions which discourage adsorption.

In addition, the resistance of the cell to deformation may be increased at low temperatures. Increased stiffness could slow down the process of rounding up so that it may not be discernible in 24 h. Wolpert and co-authors believe they have eliminated this possibility by showing that cells at 2° C will round up relatively quickly if trypsinized and detached from the surface. There is no reason, however, to expect the rate of rounding up of attached cells to be the same as that for detached and trypsinized cells at the same temperature. In terms of surface thermodynamics the detached cells do not share any common factors with the spread cells; nor has the possibility that trypsin may affect the rigidity of the cell membrane been excluded.

None of the foregoing arguments is crucial to my case, however, because I am unable to confirm the reported finding that spread cells show "no sign of rounding up" at 2° C. My experiments differ from those reported only in the use of oil-sealed culture chambers[3] in order to allow adequate microscopy for quantitative experiments. After 24 h, planimetric measurements of photographs revealed a reduction in average area per cell of 39·8 per cent in the case of L cells, 38·7 per cent for HeLa cells, 23·9 per cent for monkey kidney cells, 59·7 per cent for hamster ovary cells, and 28·8 per cent for human lung cells. At least thirty randomly selected cells were measured in each case and sampling errors were eliminated by measuring the same cells before and after the temperature change. Although these measured differences are considerable, it is entirely possible that they could be overlooked when Petri dishes are examined visually without the aid of objective measurements.

My colleagues at the Dyestuffs Division of this company, P. K. Davies and H. R. Harper, have carried out an experiment with a simple aqueous surface-active agent system which imitates very neatly the behaviour reported for cells. They found that droplets of a dilute aqueous suspension of tetradecyl sodium sulphate did not spread on paraffin wax at 2° C but did so at 37° C. Moreover, no retraction of the spread droplets was observed when the system was cooled to 2° C. In this case the behaviour of the droplets is clearly related to changes in solubility of the surface-active molecules with temperature.

The experiment nevertheless illustrates the potential importance of surface-active molecules in more complex systems where their availability may be related to more subtle factors such as those already discussed.

In arguing their case, Wolpert *et al.* have used the classical principles of surface thermodynamics appropriate to pure liquids in ideal conditions. These principles cannot be applied uncritically to systems in which there are opportunities for molecular rearrangement or chemical change. Consequently they cannot be used to refute the theory of passive spread as a component of tissue cell locomotion in culture.

While rejecting the idea of passive spread, Wolpert and co-authors make it clear they would prefer to implicate pseudopod activity in cell spreading and locomotion, remarking that cell spreading is "always associated with the appearance of pseudopods about 0·1 μm thick". These structures cannot be seen in the living cell and it is begging the question to give them a title with functional implications before their significance (if any) for cell locomotion has been established.

Bonding of Small Molecules to DNA following Ionizing Radiation

IONIZATION is known to cause the scission of DNA molecules in bacterial cells[1-3]. The effects of ultraviolet radiation, by contrast, include the formation of pyrimidine dimers, covalent links between DNA molecules, crosslinks between DNA and protein molecules, and covalent bonding of amino-acids and free purine and pyrimidine bases[4-11]. We now report that ionizing radiation of DNA in defined solution or in chromatin can also bring about the formation of covalent links between the DNA molecules and a variety of small molecules.

We have used both purified commercial calf thymus DNA (Calbiochem) and DNA purified from *Tetrahymena pyriformis*[12]. To demonstrate the formation of stable bonds after irradiation, DNA solutions containing labelled small molecules were irradiated in 2–3 mm depths using the electron beam of a Varian Associates 6 meV linear accelerator (Fig. 1). After irradiation, triplicate 50 μl. samples were placed on disks of Whatman 3*MM* filter paper, washed in cold 5 per cent trichloroacetic acid, and dehydrated for liquid scintillation counting[13]. Identical non-irradiated control samples were taken at the same time intervals. To determine the chromatographic properties of the irradiation products some DNA samples were irradiated directly with one million rads in the presence of a mixture of ^{14}C-labelled amino-acids. Following enzymatic hydrolysis with deoxyribonuclease and venom phosphodiesterase the nucleotides were concentrated and chromatographed[14] as described in the caption to Fig. 2. Chromatographic migration of individual nucleotides (adenylic acid, cytidylic acid, guanylic acid and thymidylic acid) was determined for comparison. In each experiment a non-irradiated control solution was also hydrolysed. The irradiated and non-irradiated samples were processed simultaneously and then chromatographed on the same sheet to monitor transfer of non-bound radioactive label as closely as possible.

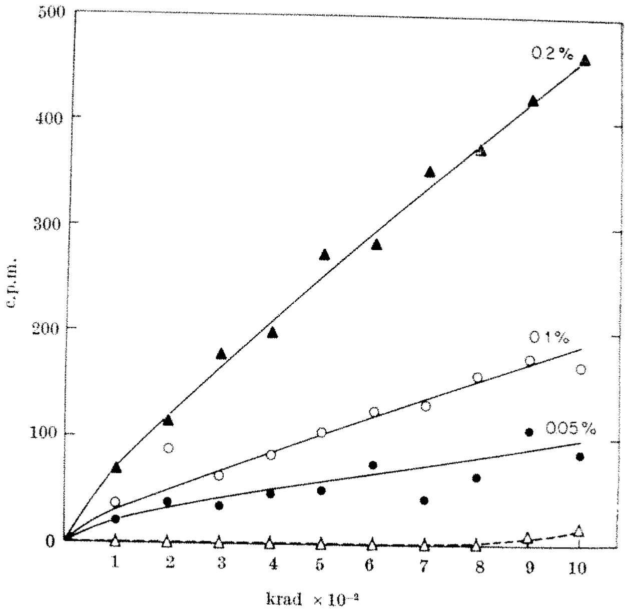

Fig. 1. Formation of acid-insoluble material following ionizing irradiation. Calf thymus DNA (0·05, 0·1, 0·2 per cent in 0·01 M, *p*H 7·4 Tris buffer) containing 20 μCi/ml. ^{3}H-leucine and 1 mg/ml. chloromycetin were irradiated with varying amounts of high-energy electrons using the electron beam of a 6 meV Varian Associates linear accelerator. Following each irradiation increment of 100 krads triplicate 50 μl. samples were removed and deposited on 2·5 cm disks of Whatman 3*MM* filter paper. Each disk was dropped wet into ice-cold 5 per cent trichloroacetic acid and processed for liquid scintillation counting[13]. Each solution was matched with a non-irradiated control which was sampled at the same time and identically processed. The formation of acid-insoluble label in each of the irradiated solutions (▲) and one of the non-irradiated (△) controls (0·1 per cent DNA) is shown. Abscissa: delivered dose in krads × 10^{-2}; ordinate: average c.p.m. for each set of triplicate samples. Specific activity of the ^{3}H-leucine: 1 mCi/0·026 mg. Counting efficiency 3·15 per cent.

One example of covalent bonding induced by ionizing radiation is seen in Fig. 1. In this case tritiated leucine and several concentrations of DNA were irradiated with progressive amounts of 6 meV electrons. The conversion of label from acid solubility to acid insolubility is proportional to the DNA concentration and to the amount of absorbed radiation. In each experiment some trichloroacetic acid insoluble label was found towards the end of the experimental period in the non-irradiated controls. Adding chloromycetin to the solution reduced this value substantially, but never to zero. We attribute this uptake to contamination of the sample with microorganisms (because of sampling time the experimental period is about 45 min). In other experiments we have found that a variety of small molecules are also bound following ionizing irradiation (including thyroxine, glyceraldehyde and other amino-acids). Similar results were obtained when DNA was replaced by RNA or albumin. No significant acid-insoluble products are formed by irradiation of a labelled amino-acid solution in the absence of a high molecular weight carrier molecule.

If the irradiated DNA is hydrolysed and chromatographed the label is found to be distributed over the entire chromatogram with a considerable amount remaining near the origin (Fig. 2). Examination of the chromatograph under ultraviolet light reveals only the expected four nucleotides. The radiation products therefore probably exist in minute amounts and may include a wide variety of compounds. Label is not localized on the chromatograph even if single amino-acids are used as the labelled source.

In another series of experiments we found that label can be bound to DNA existing as native chromatin. To show this we isolated nuclei from logarithmic stage *T. pyriformis* and purified them so as to be free of cytoplasmic contamination[12]. Because these nuclei incorporate many labelled materials spontaneously we used ^{14}C-labelled D-phenylalanine. This optical isomer is not normally incorporated by the cell or isolated nuclei.

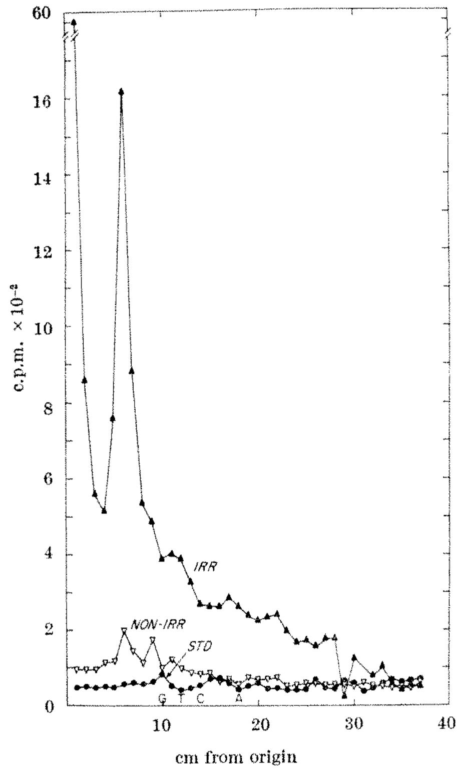

Fig. 2. Chromatography of labelled DNA products. A 0·1 per cent solution of calf thymus DNA (in 0·01 M Tris buffer, *p*H 7·6, 0·005 M $MgCl_2$) containing 10 μCi of a uniformly labelled ^{14}C-amino-acid mixture (New England Nuclear specific activity 0·1 mCi/0·067 mg) was irradiated (1×10^6 rads, electron beam, 6 meV linear accelerator) in a shallow (2–3 mm) solution. Following irradiation the DNA solution was precipitated and washed three times using ice-cold 5 per cent trichloroacetic acid. The pellet was then dissolved in 0·2 ml. of 0·01 M Tris buffer, *p*H 7·6 (containing 0·005 M $MgCl_2$), and digested by adding 0·2 ml. of a solution containing 1 mg/ml. each deoxyribonuclease and bovine serum albumin (in 0·001 M NaCl). The mixture was incubated for 150 min at 37° C. The *p*H was then raised to 8·6 using 0·1 M NaOH. Snake venom phosphodiesterase (0·02 ml. of a 1,000 unit/ml. solution in 1·0 M NaCl) was added, and the solution was again digested for 150 min at 37°. The hydrolysate was evaporated to dryness and resuspended in 50 μl. of distilled water. The entire solution was spotted on chromatographic filter paper and chromatographed for 17 h using an isobutyric acid–ammonium hydroxide solvent system[14]. After being dried, the chromatogram was cut into 1·0 cm transverse strips and each strip was counted in a Beckman *CPM*-200 liquid scintillation counter at an efficiency of 60·7 per cent. Shown are the radiochromatograms obtained from an irradiated DNA solution (▲), a non-irradiated DNA solution (▽), and a control strip containing the four DNA nucleotides (●). No differences in the ultraviolet patterns could be found when the three strips were examined before cutting.

Again we found label associated with material which was acid insoluble following irradiation and which could be concentrated using standard DNA purification procedures.

These experiments strongly suggest that small amounts of amino-acids and carbohydrates can become covalently linked to nucleic acids following ionizing radiation. The reactions may be similar to those linking DNA and protein following ultraviolet irradiation. Our data suggest that they are chemically quite non-specific. So far no material tested has failed to become linked although the doses required for binding vary. Because highly purified DNA and DNA in intact nucleoprotein will both accept such small molecules it seems reasonable to assume that similar reactions occur following ionizing irradiation *in vivo*. Amino-acids and peptides linked to DNA are known to occur in the absence of irradiation[15–17]; the relationship between such naturally occurring materials and the irradiation products described here is unknown. If reactions such as we have found do occur *in vivo* it is obvious that the multiplicity of products must be large. Accordingly, the chance of observing individual products in acid hydrolysates of DNA irradiated *in vivo* is probably small because the concentrations within the cell would not be expected to reach those used in these experiments. It is interesting to speculate on whether the relatively large production of pyrimidine dimers found following ultraviolet irradiation is the result of a high probability of such reactions occurring or of the ease with which the products can be identified. Because of the possible genetic implications it seems important to determine whether lesions such as we have shown here can be repaired in the same fashion as pyrimidine dimer excision. For example, products resistant to repair excision might effectively act as mutagens.

In vitro Synthesis of Hb Hammersmith (CD1 Phe→Ser)

RED cells of patients heterozygous for Hb A and the unstable haemoglobin, Hb Köln (FG5 Val→Met)[1] contain only 10–15 per cent of the abnormal haemoglobin. This was found to arise from defective synthesis of the abnormal β Köln chain[2–4], and not from its removal from cells by Heinz body formation. The techniques used in these studies might, however, have caused denaturation of Hb Köln and produced falsely low values for the proportion of Hb Köln synthesized. The relative rates of synthesis of Hb A and Hb Hammersmith (CD1 Phe→Ser)[5], another unstable haemoglobin, have now been studied, using identical techniques, to test the validity of the Hb Köln experiments and to compare the synthesis of Hb Hammersmith with that of Hb Köln.

The subject studied was a female, 40 per cent of whose haemoglobin was Hb Hammersmith. Whole blood was washed three times with isotonic saline and the red cells were incubated at 37° C with 500 μCi of ^3H-leucine according to the method of Lingrel and Borsook[6]. Samples of cells were removed at known times and after washing and lysis, a stroma-free lysate was prepared. Free ^3H-leucine was removed from the lysate by passage down a column of 'Sephadex *G* 25'. The two haemoglobins were then separated on a column of 'Sephadex *CM* 50' as previously described[4]. The whole of each fraction was collected and its protein concentration measured at $A_{280\,nm}$ (phenylalanine does not absorb at this wavelength). The lysates were concentrated by ultrafiltration for 10 h at 4° C and globin was prepared by acid-acetone precipitation at −20° C. The specific activity of the whole globin from each lysate was measured by liquid scintillation counting and the total counts incorporated into globin A and globin Hammersmith were determined. The α and β chains of each globin were then separated according to the method of Clegg, Naughton and Weatherall[7], the specific activity of the chains were measured and the total radioactivity incorporated into each chain was calculated.

Table 1. INCORPORATION OF ^{3}H-LEUCINE INTO HB A AND HB HAMMERSMITH

Time (min)	Total ^{3}H-leucine incorporated HbA	Total ^{3}H-leucine incorporated Hb Hammersmith	Proportion of total counts in Hb Hammersmith (per cent)
30	36,719	73,540	66·6
60	45,600	84,771	65·0
120	47,624	88,100	64·8

Table 2. INCORPORATION OF ^{3}H-LEUCINE INTO THE α AND β CHAINS OF HB A AND HB HAMMERSMITH

Time (min)	Hb A (c.p.m.)		Hb Hammersmith (c.p.m.)	
	α	β	α	β
30	1,638	4,505	7,583	4,730
60	2,275	6,783	12,835	6,701
120	2,726	7,791	13,939	7,826

The "apparent" synthesis of the two haemoglobins was determined by the proportion of total counts incorporated into whole globin A and whole globin Hammersmith. Thirty-five per cent of the counts were in globin A and 65 per cent in globin Hammersmith (Table 1). When the "true" proportion of each haemoglobin synthesized was calculated from the total counts incorporated into the β A chains and β Hammersmith chains, however, it was found that they were synthesized in equal amounts (Table 2). The discrepancy between "apparent" synthesis and "true" synthesis is likely to arise from the unequal α chain labelling of the two haemoglobins. This unequal α chain labelling is probably the result of unequal exchange of labelled α chains between the Hb A and Hb Hammersmith (as was found in the Hb Köln study[4]) but requires further investigation. The equal synthesis of Hb A and Hb Hammersmith suggests that our earlier finding of unequal synthesis of Hb A and Hb Köln is probably valid because Hb Hammersmith is at least as unstable as Hb Köln, and loss *in vitro*—if it occurred—would be expected to a similar degree. The finding of equal synthesis of β A chains and β Hammersmith chains implies that the substitution of phenylalanine by the smaller, polar amino-acid serine at the CD1 position of the chain does not impede the assembly of the chain. This is in contrast to the substitution of valine by the large amino-acid methionine at the FG5 position in the β Köln chain.

Hb Köln and Hb Hammersmith are both very unstable haemoglobins, yet the degree of haemolysis caused by them differs considerably. The first produces a mild and the second a severe haemolytic disease.

It seems unlikely that the differences in haemolysis can be explained by differences in the stability of the two haemoglobins, for when heated both haemoglobins appear to precipitate with equal rapidity. The fact that the red cells of patients with Hb Hammersmith contain about three times as much unstable protein (35–40 per cent) as do the cells of patients with Hb Köln (10–15 per cent) may be relevant, for it has been shown that haemolysis is related to the interaction of the precipitated haemoglobin with membrane thiol groups[8]. The concentration of unstable haemoglobin within cells must therefore be an important factor in determining the degree to which cells are damaged. Patients heterozygous for Hb Köln may therefore be protected from severe haemolysis because the amino-acid substitution which imparts instability to Köln β chains may also result in a deficiency in the number of these chains synthesized.

Alteration of Normal Development of Drug Metabolism by Injection of Growth Hormone

GROWTH hormone (STH) may affect the normal development of the rat hepatic microsomal drug-metabolizing enzyme system, for there is a normal postnatal, age-related increase in activity of this system[1,2]. A relation between pituitary hormones and liver drug metabolism was suggested by the observation that the normal postnatal development of hexobarbital, aminopyrine and *p*-nitrobenzoic acid metabolism was prevented in young male rats which had high levels of STH (ref. 2) from a pituitary mammotropic tumour (MtT–F4) (ref. 3). In adult rats injected with STH a decrease in hepatic microsomal drug metabolism was observed[4]. This report demonstrates a reduction in the level and rate of increase with age of aminopyrine and ethylmorphine metabolism by liver from STH injected young rats and thus suggests STH as an endogenous agent responsible for the observed postnatal development pattern of this metabolism.

Fischer rats were purchased from a local distributor and placed in plastic nesting boxes or stainless steel cages over a hardwood bedding. They were given purina chow and water *ad libitum* and exposed to alternate 12 h periods of light and darkness. Soon after birth, male rat pups were selected and randomized with different dams for suckling. Rats from several litters were used for each hepatic drug metabolism determination. Injection solutions were prepared by dissolving albumin (fraction V from plasma) or STH in alkaline 0·9 per cent aqueous saline, and powdered gelatine was added to a final gelatine concentration of 14 per cent. The gelatine was dissolved by gentle shaking in a water bath at 37° C. One gram of rat liver was homogenized with 2 ml. of 1·15 per cent KCl in 0·5 M Tris buffer (*p*H 7·35) by using a glass homogenizer with 'Teflon' pestle. This homogenate was centrifuged at 9,000*g* for 20 min at 4° C to obtain the 9,000*g* supernatant fraction. An aliquot (0·25 ml.) of this fraction was added to a reaction mixture which contained cofactors, phosphate buffer and substrate (hexobarbital, aminopyrine or ethylmorphine) as previously described[4]. This mixture was incubated at 37° C in an atmosphere of oxygen for 20 min in a Dubnoff type shaking water bath incubator. Measurements of the disappearance of hexobarbital[5] and the formation of formaldehyde from aminopyrine or ethylmorphine[6,7] were used to estimate hepatic microsomal drug-metabolizing enzyme activity. Liver 9,000*g* supernatant fraction protein was measured by the method described by Lowry *et al.*[8]. Evaluation of the statistical significance between paired means was performed with Student's *t* test[9].

An alteration in the normal postnatal development of the hepatic microsomal drug metabolizing enzyme system in young rats was observed after one injection of STH. The hepatic demethylation of ethylmorphine or aminopyrine was decreased at 30, 42 and 58 days of age in rats injected once with STH compared with albumin injected controls (Fig. 1). Because activity of this enzyme system in

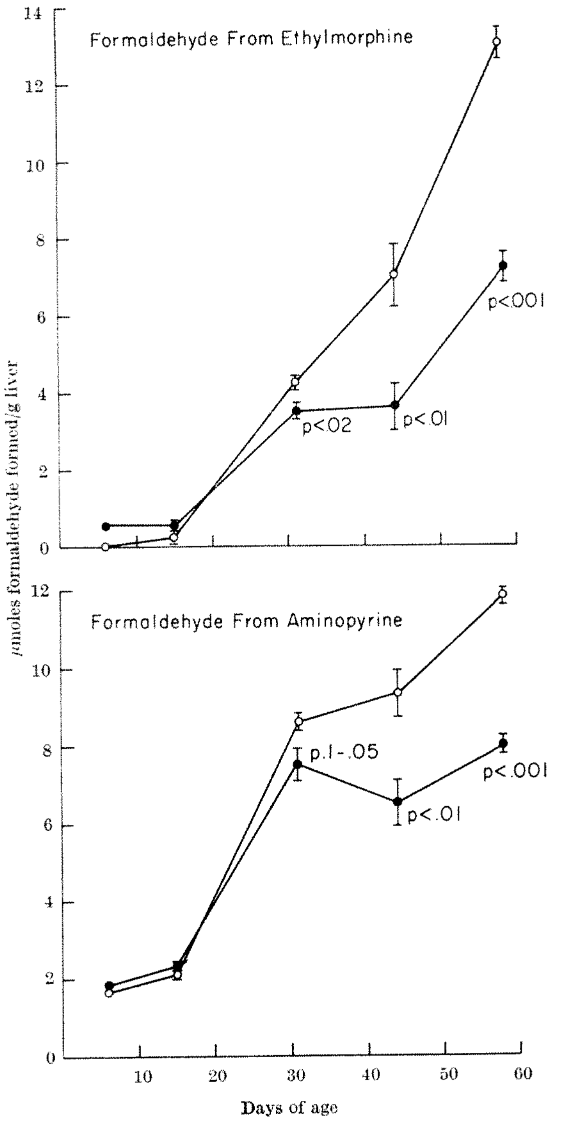

Fig. 1. Hepatic metabolism of ethylmorphine or aminopyrine in young rats after one injection of STH. Approximately eight male Fischer rats less than 28 days old were placed with a female rat for suckling. Each young suckling or older non-suckling animal was injected once subcutaneously with albumin or STH prepared as 1 mg/ml. in 14 per cent gelatine and given as 1 mg/100 g body weight. A single injection was given 48 h before each measurement, that is, 48 h before the determination at 15, 30, 42 and 58 days of age. Results are depicted as the mean ± *S.E.*, and values not shown with $P < 0{\cdot}05$ were not statistically significant as compared with albumin-injected controls. Livers from three animals were combined to produce one sample for the determination at 6 days of age; livers from six rats were combined to produce three samples at 15 days of age. Four to six rats per group were used for the other determinations. ○, Control; ●, STH injected.

control rats 5 and 15 days old is quite low, it is not surprising that further depression with STH treatment could not be detected. The normal age-related increase in the hepatic metabolism of two drugs was, however, prevented by a single injection of STH in young rats. Similar results were noted when young rats were injected every other day with a smaller dose (0·25 mg/100 g body weight) of STH (unpublished observation).

Two possible explanations for this effect on liver drug metabolism in STH treated young rats are: (i) the appearance of inhibitors in rat liver, and (ii) constant total activity with reduced specific activity secondary to hepatomegaly without an increase in enzyme. The metabolism of hexobarbital and aminopyrine was measured in 52 day old rats which had been treated with albumin or STH, and various amounts of each liver fraction were added to a reaction mixture to detect the presence of inhibitors. Mixtures which contained 1, 2 or 3 parts of control 9,000*g* liver supernatant fraction and 3, 2 or 1 parts respectively of liver fraction from STH injected rats showed the expected activity. Thus no *in vitro* inhibitors were demonstrated in liver from STH treated rats. Direct inhibition of hepatic drug metabolism by the presence of STH in liver of STH treated young rats is also unlikely, because no *in vitro* inhibition was detected when an STH containing hormone mixture was added to a reaction vessel with control adult rat liver 9,000*g* supernatant fraction[10]. No enlargement of the liver was noted after injection of STH, and in young rats injected once with STH (Fig. 1), no significant change in 9,000*g* liver supernatant fraction protein (mg/g liver) was found as compared with control rats of the same age.

The mechanism by which STH treatment decreases liver drug metabolism in the young rat remains unknown. Some insight into this problem, however, was gained by observing the effect of phenobarbital in STH treated rats (Table 1). The injection of young rats with STH did not prevent a post-phenobarbital increase in the liver metabolism of hexobarbital or aminopyrine. Similar results were found when adult rats implanted with the STH secreting pituitary tumour MtT–F4 were treated with phenobarbital[11]. These observations suggest that different independent mechanisms may be responsible for the effect of STH or phenobarbital on this system.

Table 1. THE EFFECT OF PHENOBARBITAL ON LIVER DRUG METABOLISM IN YOUNG RATS INJECTED WITH STH

Treatment	Hexobarbital metabolized (μmole/g liver)	Formaldehyde from aminopyrine (μmole/g liver)
Albumin	6·5 ± 0·3	10·8 ± 0·3
Albumin and phenobarbital	10·9 ± 0·4	15·0 ± 0·6
STH	3·2 ± 0·6	7·6 ± 0·5
STH and phenobarbital	9·2 ± 0·4	13·2 ± 0·9

Male Fischer rats, 45 days old, were injected with bovine albumin or STH (1 mg/ml./100 g body weight) subcutaneously. One intraperitoneal injection of phenobarbital sodium (75 mg/kg) was given 24 h after the hormone injection. Determinations of rat liver drug metabolism were made 48 h after the rats received albumin or STH. The μmoles of hexobarbital metabolized or formaldehyde formed from aminopyrine per g liver is expressed as the mean ± *S.E.* The metabolism found with liver from phenobarbital treated animals was statistically significant ($P < 0{\cdot}05$) as compared with that from rats which did not receive phenobarbital. There were six rats per group.

As the animal grows older, certain physiological events occur which allow for an increase in liver drug metabolic enzyme activity to adult levels. Fouts *et al.*[12,13] have proposed that an increase in activity may occur as a result of enzyme protein synthesis in the developing animal. Identification of physiological influences which allow for increased enzyme activity in the young rat may increase our understanding of the normal sequence of biochemical events in drug metabolism. Such influences may not be recognized in the adult as a result of slight changes in activity, masked by high levels of metabolism. If, however, conditions which regulate hepatic drug-metabolic activity in the young animal were produced in the adult, a level of this activity in the adult similar to that found in the young rat would be expected. High levels of STH in blood may be one of these conditions.

Maternal steroids characteristic of pregnancy and post-partum may also affect liver drug metabolism. Low levels of drug metabolism in pregnant dams and nursing rat pups may be related to high levels of gonadal hormones in the dam as suggested by Feuer and Liscio[14]. *In vitro* inhibitors (which would have produced an increase in hexobarbital sleeping time or a decrease in liver drug metabolism) were, however, not identified. A relationship between maternal sex steroids and liver drug metabolism probably exists, but does it offer a primary or secondary explanation for low levels of drug metabolism in the newborn? Studies on the mechanism of action with regard to an *in vitro* versus *in vivo* effect of specific maternal steroids and competitive inhibition by alternative substrates would be helpful.

I propose that STH is a factor which alters the normal postnatal developmental pattern of liver drug metabolism by an action *in vivo*. Alteration of this pattern by injection of STH, failure to find *in vitro* inhibitors in liver microsomes of STH treated rats, and a post-phenobarbital increase in metabolism in STH treated rats are consistent with this hypothesis. In the human newborn, elevated levels in blood of STH (ref. 15) and low levels of drug metabolism were found[16]. *In vitro* inhibitors of drug metabolism have not been demonstrated in liver microsomes from young rabbits[13], and phenobarbital increased liver drug metabolic enzyme activity in young animals[17]. Thus liver drug metabolism in young rats has certain features in common with that of STH treated rats. A high blood level of STH in the young animal may affect liver metabolism to produce a low level of drug biotransformation.

This work was supported in part by a grant from the US National Institutes of Health and a fellowship grant from the National Association for Retarded Children. J. T. W. is recipient of a research career development award from the NIH. I thank the Endocrine Study Section of the National Institutes of Health for the bovine STH.

Potent Peripheral and Splanchnic Vasodilator Peptide from Normal Gut

BIOLOGICALLY active polypeptides, such as bradykinin and angiotensin, have considerable importance in a variety of physiological, pharmacological and pathological reactions. We have recently reported on the extraction from normal lung tissue of a peptide fraction capable of causing gradual and prolonged peripheral vasodilatation[1,2]. This finding led us to pursue the search for similar vasoactive principles in extracts of other metabolically active organs. We report here on the extraction from small intestine of a highly active, hitherto unidentified vasodepressor peptide substance. The vasodilator effect of this compound, several times as prolonged as that of bradykinin, may be important as a regulator of blood flow to the digestive organs, and as a mediator in various hypotensive states.

Hog small intestine was treated as for the preparation of secretin[3,4]. Like secretin, the vasoactive peptide was concentrated in the methanol extract. This extract was chromatographed in 0·125 M sodium phosphate, *p*H 8, on a column of carboxymethylcellulose. Using the same buffer, the bulk of the secretin was eluted in one fraction, which also exhibited moderate vasoactivity. An intensely vasoactive fraction was, however, retained on the column and recovered by eluting with 0·2 M HCl. Further purification of this eluate was obtained by chromatography in 0·2 M acetic acid on a column of 'Sephadex *G*-25'.

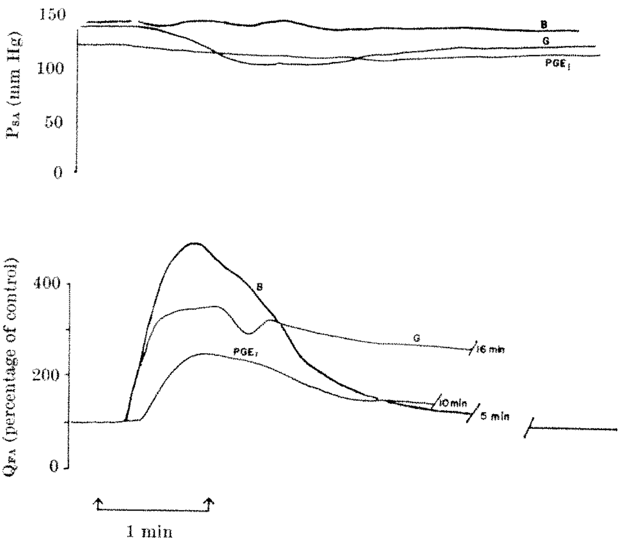

Fig. 1. Increase in femoral arterial blood flow ($\dot{Q}_{FA}$) and fall in systemic arterial blood pressure (P_{SA}) following infusion into the femoral artery of: methanol-soluble gut peptide fraction (G, 100 µg/ml.), bradykinin (B, 1 µg/ml.), and prostaglandin E_1 (PGE_1, 0·5 µg/ml.). All infusions were given at 1 ml./min for 1 min, between the two arrows. Curves, traced from the records, were superimposed to start at the same time. Interruptions in tracings show length of time until return to control value.

We assayed the vasoactivity of different preparations by measuring the increase in femoral arterial blood flow on their infusion, at a constant speed, into a cannulated branch of a femoral artery of dogs, anaesthetized with pentobarbital. Mean blood flow was measured by a square-wave electromagnetic probe (Nycotron) placed on the main artery, and recorded continuously by an Elema-Schönander amplifier and a Siemens oscillographic recorder. Simultaneously, systemic arterial blood pressure was recorded by a catheter in the aorta and a strain-gauge transducer.

Marked and prolonged increase in femoral arterial blood flow followed the intra-arterial injection of the methanol-soluble extract (Fig. 1). The onset of the flow increase was almost as rapid as from a dose of bradykinin causing a similar increase in flow, but lasted several times as long. The effect of the extract was qualitatively similar to that of prostaglandins E_1 and E_2. The increased flow was accompanied by a fall in systemic blood pressure of as much as 50 mm Hg, lasting about the same length of time.

On intravenous infusion of the purified vasoactive peptide fraction, arterial blood pressure fell and peripheral blood flow increased, both changes being dose-dependent. After a 3 min infusion of 20 µg per kg per min, the dogs remained hypotensive for 45 min. The increase in peripheral blood flow, together with systemic hypotension, clearly signifies peripheral vasodilatation.

In a group of six experiments, in collaboration with P. Olsson and L. Thulin, we recorded the blood flow in the hepatic and superior mesenteric arteries, and the portal vein, by probes placed around these vessels. Infusions of the peptide into the inferior vena cava increased the blood flow in the splanchnic vessels along with lowering the arterial blood pressure. Infusions of the same doses into the portal vein, however, caused no change in the blood pressure, suggesting that the peptide is inactivated or removed by the liver.

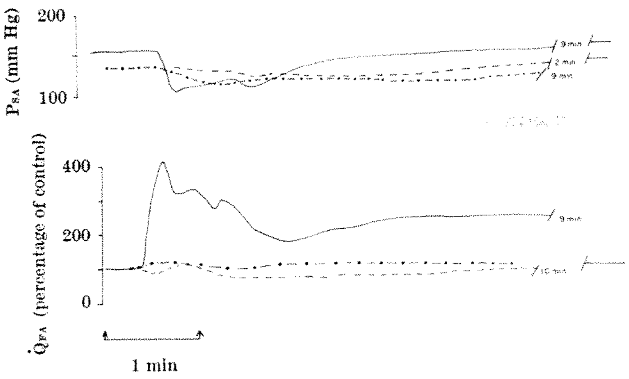

Fig. 2. Comparison of the effects on peripheral blood flow and systemic arterial pressure of equal doses (100 μg) of the vasoactive gut peptide material (——), secretin (· – · – ·) and cholecystokinin–pancreozymin (– – – –).

The vasoactivity in the peptide fraction was totally abolished by incubation with α-chymotrypsin (CDS, Worthington, 60 μg per mg), and almost completely lost by incubation with trypsin ('TRTPCK', Worthington). On high-voltage paper electrophoresis at *p*H 6·5, the peptide material moved toward the cathode more slowly than and distinctly from bradykinin.

A vasodepressor effect of intestinal extracts was observed many years ago by Bayliss and Starling[5]. Since then the gut has been shown to contain several vasoactive substances, including histamine[6], prostaglandins[7] and 'substance P' (ref. 8). In addition, the digestive hormones secretin and cholecystokinin–pancreozymin (CCK-PZ) also have certain vascular effects[9]. The gut fraction we are describing was free of histamine (eliminated by salt precipitation and 'Sephadex' chromatography), and free of prostaglandins (removed by ether precipitation at *p*H 2). It contained virtually no CCK-PZ, as this hormone is not extracted by methanol. The peptide fraction was slightly contaminated with secretin, though in concentrations of approximately 1 per cent (bioassay). To establish the possible role of any contamination with secretin and CCK-PZ, however, we measured the separate effects of equal doses of these hormones on intra-arterial injection in the femoral artery (Fig. 2). CCK-PZ (refs. 3 and 4) caused a decrease, rather than an increase, in femoral flow, along with a fall in blood pressure of about 15 mm Hg. Secretin (synthetic, Squibb) gave a 25 per cent increment in flow with a 20 mm Hg drop in pressure, compared with a three-fold increase in flow and a 50 mm Hg lowering of pressure, resulting from the vasoactive peptide fraction. Thus the vasoactivity of the newly identified gut peptide is distinct from, and many times greater than, that of secretin and CCK-PZ.

It is difficult to assess the relationship, if any, between this peptide and 'substance P', for the latter is probably a mixture of several peptides the characteristics of which may differ in different preparations[10-12]. Several lines of evidence, however, suggest that the active principle described here is unrelated to 'substance P'. The prolonged vasodepressor effect we observed contrasts with the transient effect of 'substance P' which, on intravenous infusion, decreases or vanishes even while the substance is being infused[10-12].

It will be of interest to examine what effects this systemic vasodilator peptide may have on other vascular beds, for example, the pulmonary circulation, as well as on other smooth-muscle tissues, such as the bronchial tree and the digestive tract itself. It also remains to be determined whether this peptide is in any way related to the vasoactive lung peptide[1] (for example, formed in the gut and modified by the lung). In any case, however, its strong and unusually prolonged vasodilator action on the peripheral and splanchnic circulations raises the possibility that it might have a physiological role in the regulation of blood flow to the digestive organs. This process remains poorly understood[13]. Release of this peptide could be an important mechanism in the production of systemic hypotension and splanchnic vasodilatation in such conditions as endotoxin shock[14]. It is also reasonable to speculate that, if the liver is normally the main site for inactivating this vasoactive intestinal peptide, its failure of destruction when liver function is seriously impaired, for example, in hepatic cirrhosis, could account for the peripheral vasodilatation complicating that disease[15].

We thank Professor S. Bergström, Emeritus Professor E. Jorpes and Dr E. Berglund for their support and encouragement, Dr M. A. Ondetti for a gift of synthetic secretin and bradykinin, and Mrs K. Librén, Mrs M. Christofferson, Miss A-C. Öhrlund, Mrs K. Thermaenius, Mrs L. Melin and Mr P-O. Bäckman for skilled assistance. This work was supported by research grants from the US Public Health Service, the American Heart Association, the National Tuberculosis Association and the Swedish Medical Research Council. S. I. S. is a recipient of a career development award from the National Heart Institute.

Active Water-insoluble Derivative of Renin

ALTHOUGH the action of renin on the blood pressure has been explored by many investigators, some of its basic enzymatic properties are yet to be established[1]. While studying plasma kinins, we found it to be of advantage to couple enzymes that release or inactivate kinins covalently to water-insoluble complexes[2-4]. The active insoluble derivatives of enzymes are convenient to use, because, among many other attractive properties, they are stable, re-usable and readily removed from incubation mixture by sedimentation. We have extended these investigations to renin. Our previous results with killikrein, carboxypeptidases, kallikrein and trypsin inhibitors and renin were briefly reported[3,4]. This report deals with the binding of renin to 'Sepharose 4*B*'.

Partially purified hog kidney renin was obtained from commercial sources. It contained a 4 ng of renin pressor

^{14}C Amino Acids from Schwarz/Mann

DIVISION OF BECTON, DICKINSON AND COMPANY

Examples of the unusually high specific activities available from Schwarz/Mann:

L-[^{14}C] Alanine	159mc/mM	L-[^{14}C] Lysine	320mc/mM
L-[^{14}C] Arginine	320mc/mM	L-[^{14}C] Methionine	255mc/mM
L-[^{14}C] Aspartic Acid	212mc/mM	L-[^{14}C] Phenylalanine	455mc/mM
[^{14}C] Glycine	106mc/mM	L-[^{14}C] Threonine	212mc/mM
L-[^{14}C] Leucine	320mc/mM	L-[^{14}C] Tyrosine	455mc/mM

Further re our high specific activities: ALL of our ^{14}C amino acids are higher than 50mc/mA. About purity. Every lot of phenylalanine and tyrosine is repurified every month. Every lot of everything else: reassayed every ten weeks and repurified if necessary. And *all* assay and reassay data goes onto the Product Analysis Report that you receive. About availability: these compounds are available *from stock*. For the complete story on our complete labeled amino acid line call (914) 359-2700 or write: Schwarz/Mann, Orangeburg, New York 10962. Division of Becton, Dickinson and Company.

^{3}H AMINO ACIDS FROM SCHWARZ/MANN

Examples of the unusually high specific activities available from Schwarz/Mann:

Catalytic

L-[^{3}H] Alanine	6c/mM
L-[^{3}H] Arginine	10c/mM
L-[^{3}H] Histidine	8c/mM
L-[^{3}H] Lysine	6c/mM
L-[^{3}H] Phenylalanine	7c/mM
L-[^{3}H] Valine	8c/mM

Specifically Labeled

L-[4^{3}H] Arginine	20c/mM
L-[2,3^{3}H] Aspartic Acid	15c/mM
L-[3,4^{3}H] Glutamic Acid	15c/mM
L-[4,5^{3}H] Leucine	50c/mM
L-[4,5^{3}H] Lysine	20c/mM
L-[5^{3}H] Proline	15c/mM
L-[2,3^{3}H] Valine	15c/mM

These high specific activity ^{3}H-labeled amino acids are reassayed every ten weeks—as is *every* radiochemical we make—and repurified when necessary. All relevant analytical data gets forwarded to you. For detailed information call (914) 359-2700 or write: Schwarz/Mann, Orangeburg, New York 10962. Division of Becton, Dickinson and Company.

(SEE OUR OTHER ADVERTISEMENT AND LISTINGS ON THIS PAGE.)

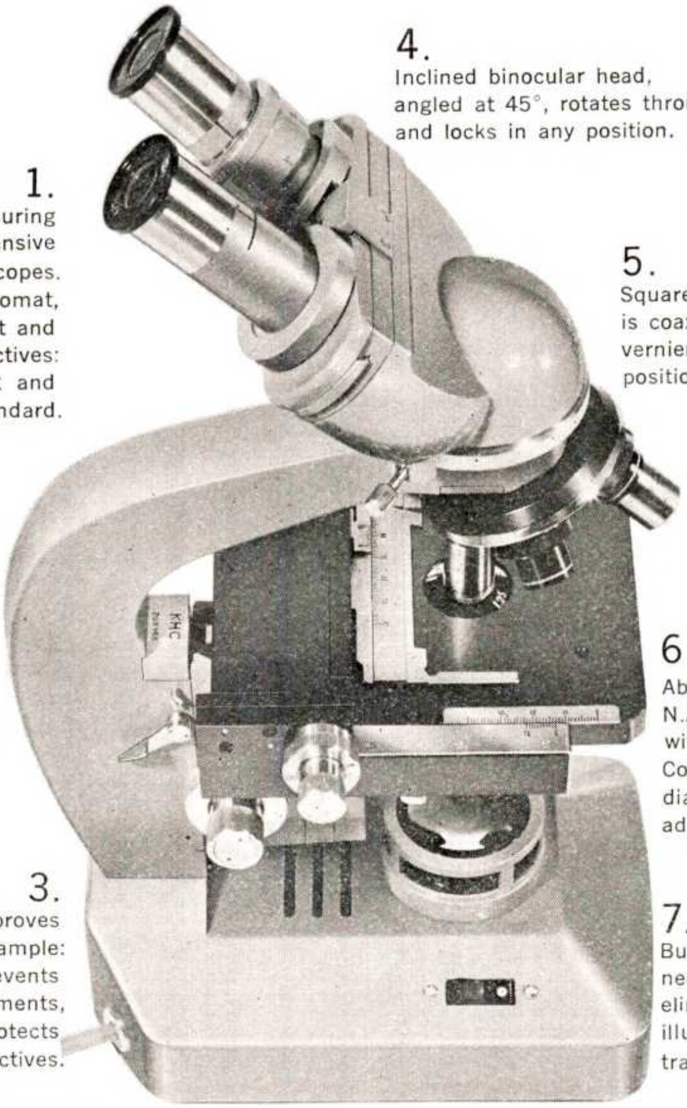
Olympus KHC is top choice for latest features and low budget



1.
Wide field or measuring eyepieces as in expensive research microscopes. Highest quality Achromat, Plan Achromat and Fluorite objectives: Achromat 4×, 10×, 40× and 100× (oil) standard.

2.
Fine and coarse focusing knob are coaxial and positioned low for ease of operation.

3.
Modern design improves handling ease. For example: vertical stage focusing prevents distracting head movements, and pre-set focus lock protects slides and objectives.

4.
Inclined binocular head, angled at 45°, rotates through 360° and locks in any position.

5.
Square mechanical stage is coaxially-controlled and vernier calibrated to give exact positioning of slides.

6.
Abbe type condenser, N.A. 125, is focusable with rack and pinion. Continuously variable iris diaphragm allows adjustment of illumination.

7.
Built-in 20-watt illuminator needs no centering, eliminates accessory illuminators and transformers.

Olympus KHC is the latest improvement for every-day laboratory work, a microscope for the lowest budget and still featuring eye-fatigue-free clearness and high precision. Its seven outstanding features have made KHC the most used and valued instrument for medical students and laboratory workers all over the world.

Total magnification: 40x～1000x

activity per mg protein[5] according to the manufacturer's specifications (Pentex Biochemicals). Renin substrate angiotensinogen was purified from hog plasma as described previously[6,7]. The activity of renin was measured by assaying the amount of angiotensin released by the enzyme on the systemic arterial blood pressure of the pithed rat against synthetic Ile^5–angiotensin I.

Renin was bound covalently to 'Sepharose *4B*' according to Axen *et al.*[8] and Cuetrecasas *et al.*[9], after 'Sepharose' was activated with cyanogen bromide. Twenty ml. of settled volume of 'Sepharose *4B*' were coupled with 100 mg renin. Renin was allowed to react with 'Sepharose' for 18 h at 4° C. Afterwards the complex was washed in a column with 2 l. of 0·1 M $NaHCO_3$ containing 1 M NaCl followed by 2 l. of distilled water. The release of angiotensin by the water-insoluble complex was done under constant shaking at 37° C. Five mg of angiotensinogen was dissolved in 1 ml. 0·05 M phosphate buffer of *p*H 6·5 containing 0·9 per cent NaCl. The solution was incubated with 0·5 ml. settled volume of the covalently bound renin–'Sepharose' (RS) complex and 0·5 ml. water. Samples were withdrawn at regular intervals. In one group of control studies equal amounts of soluble renin were used. In other control experiments, human albumin was coupled to 'Sepharose', and the albumin–'Sepharose' complex was used instead of the RS complex. Albumin–'Sepharose' did not release angiotensin from angiotensinogen.

The water-insoluble RS complex liberated a peptide from angiotensinogen that on intravenous injection raised the blood pressure of the rat. The activity of the vasopressor released expressed in terms of synthetic Ile^5–angiotensin I is summarized in Table 1. About half of the soluble renin used was bound to 'Sepharose' in our conditions; the renin so complexed had about half the activity of the equivalent amount of soluble enzyme (Table 1). The vasopressor material released from angiotensinogen by RS was inactivated by trypsin[7]. The trypsin preparation used was a water-insoluble complex of trypsin with 'Sepharose *4B*' (5 mg per ml. 'Sepharose'). The disappearance of the biological activity of angiotensin incubated with trypsin was followed on the isolated rat colon[10]. This inactivation by trypsin also indicated that the liberated vasopressor substance was a peptide. The RS preparation was stable when kept in the refrigerator for several months. After the completion of the reaction, RS can be sedimented in the centrifuge, washed and used again.

Table 1. RELEASE OF ANGIOTENSIN BY WATER-INSOLUBLE RENIN–SEPHAROSE DERIVATIVE

Amount of enzyme coupled with 'Sepharose' (mg per ml.)	Per cent $A_{280\,nm}$ absorbing material bound	Amount of peptide released from 5 mg substrate per h*	Per cent activity of bound renin
5	58	2·8	61

* In μg of synthetic Ile^5–angiotensin I equivalents.

The experiment showed that renin stayed active after being complexed with the agarose polymer 'Sepharose' and cleaved off a vasopressor, very likely angiotensin I, from the high molecular weight plasma protein substrate, angiotensinogen. Angiotensin I was subsequently converted to angiotensin II in the circulation of the rat.

The use of stable, water-insoluble enzyme preparations may have particular importance in systems which depend on the interaction of a number of factors that result in the release and inactivation of vasoactive peptides. Here the role of insoluble components can be studied by adding them or removing them at will. In future investigations stable RS preparations may serve as standards for renin activity or RS could be used in columns for concentrating and purifying renin inhibitors by means of affinity chromatography.

We thank Miss Deborah R. Downs for assistance. These studies were supported in part by a grant from the National Institutes of Health, US Public Health Service, by the US Office of Naval Research and by a fellowship (T. S.) of the Oklahoma Heart Association.

Net Synthesis of ATP by Reversal of the Sodium Pump

A FEW years ago, Garrahan and Glynn[1,2] described experiments in which very steep concentration gradients of Na^+ and K^+ across the membranes of human red cell ghosts led to a ouabain-sensitive incorporation of ^{32}P-labelled inorganic phosphate into ATP, apparently by a reversal of the cation transport system. These findings have been confirmed and extended in experiments on ghosts[3,4] and in experiments on intact red cells[5–7] in which the incorporation of phosphate was shown to parallel the ouabain-sensitive downhill movements of the cations. Although the interpretation of these experiments seems clear, attempts in a number of laboratories to demonstrate a net ouabain-sensitive synthesis of ATP at the expense of downhill ion movements have not been successful. The failure of these attempts can be attributed to the relatively low rate of ouabain-sensitive phosphate incorporation in human cells, ATP breakdown by processes unconnected with the pump being rapid compared with the expected rate of formation of ATP by reversal of the pump. Nevertheless, in the absence of a demonstrable increase in the amount of ATP, it is difficult to be certain that the observed incorporation of radioactivity is brought about by the formation of new ATP rather than by some kind of exchange reaction. The finding that guinea-pig red cells showed a surprisingly large ouabain-sensitive efflux of K^+ into K^+-free high-Na^+ media[8] suggested that it would be worth looking for a net ouabain-sensitive synthesis of ATP in these cells, and we now report that such a synthesis does in fact occur.

The results of three experiments are summarized in Table 1. In each experiment, washed, pooled, guinea-pig red cells were pre-incubated in a nominally glucose-free high-K^+ medium for 2 h or more. During at least part of this period iodoacetamide (5 mM) was present. In the first two experiments, after the pre-incubation, the cells were loaded with inorganic phosphate by incubating them for 15 min in a phosphate–citrate medium[7]; this step was omitted in the third experiment because phosphate loading did not seem to have much effect on the magnitude of the ouabain-sensitive K^+ efflux from guinea-pig red cells. The

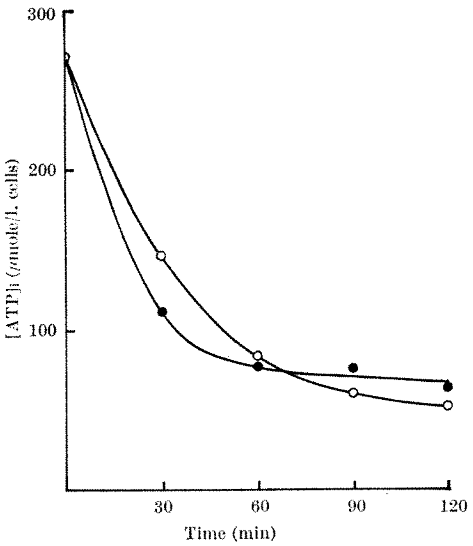

Fig. 1. The change in ATP concentration with time when guinea-pig red cells that had been stored for 24 h at 5° C in the presence of glucose were incubated at 37° C in a medium containing 150 mM NaCl, 10 mM Tris–HCl (pH 7·4 at 37° C) and 5 mM iodoacetamide. ○—○, Ouabain absent; ●—●, ouabain 5×10^{-5} g/ml. Loss of K^+ from the cells raised the K^+ concentration in the medium from 0·032 mM at the beginning of the incubation to 1·04 mM at the end. The cells used in this experiment were from the same batch as those used in the third experiment of Table 1. Note that at first the ATP level fell less steeply in the absence of ouabain, presumably because hydrolysis of ATP was partly offset by synthesis through reversal of the pump. The crossing of the curves can be explained by the accumulation of K^+ in the initially K^+-free medium. During the latter part of the incubation the K^+ concentration in the medium was sufficient to allow the pump to run forwards, so that ouabain at this stage must have been inhibiting hydrolysis more than synthesis.

cells were then washed thoroughly in a high-Na^+, K^+-free medium and resuspended at a haematocrit of about 5 per cent in more of the same medium to which iodoacetamide had been added to give a final concentration of 5 mM. At the end of the incubation period the concentration of ATP in the cells that had been kept at 0° C, and in the incubated cells, was measured[2].

In all three experiments, the concentration of ATP in the cells that were not exposed to ouabain increased during the incubation. In the presence of ouabain the ATP concentration did not change during the incubation in experiments 1 and 3; in experiment 2 there was an increase in concentration, though a much smaller increase than was found in the cells not exposed to ouabain. The increase in ATP concentration in the presence of ouabain in experiment 2 is, at first sight, surprising, for at the concentration at which it was used ouabain should have inhibited the pump completely. When guinea-pig red cells are incubated with iodoacetamide, however, the ATP concentration falls steeply at first (Fig. 1) but then levels off, presumably when the rate of hydrolysis of ATP equals the rate of formation from 2,3-diphosphoglycerate plus—if conditions are suitable—the rate of formation by reversal of the pump. If the steady state is attained in a high-K^+ medium, that is, when the pump is running forwards, the addition of ouabain will decrease ATP hydrolysis and may therefore cause an increase in the ATP level.

Table 1. CHANGES IN ATP CONCENTRATION DURING INCUBATION IN A HIGH-Na^+ K^+-FREE MEDIUM, WITH AND WITHOUT OUABAIN

	ATP content		
Experiment	Before incubation (μmole/l. cells)	After incubation without ouabain (μmole/l. cells)	After incubation with ouabain (μmole/l. cells)
1	179 ± 5	243 ± 16	170 ± 3
2	292 ± 7	391 ± 7	333 ± 5
3	44·5 ± 0·2	62·6 ± 1·0	46·6 ± 0·7

Guinea-pig red cells, pretreated as described in the text, were incubated for 30 min in a medium containing 150 mM NaCl, 10 mM Tris–HCl (pH 7·4 at 37° C) and 5 mM iodoacetamide. The ouabain concentration was 5×10^{-5} g/ml. Each figure is the mean of three estimates ± *S.E.* The details of the preliminary incubation were different in the three experiments. In the first, the cells were incubated for 5 h at 30° C in a medium containing 150 mM KCl and 10 mM Tris–HCl (pH 7·4 at 37° C), and then for another hour at 37° C in a similar medium containing 5 mM iodoacetamide. In the second experiment, the cells were incubated for 2 h at 37° C without iodoacetamide and for 40 min with iodoacetamide present. In the third experiment, the preliminary incubation was for 2 h at 37° C and iodoacetamide was present during the whole of this period. The cells used in the third experiment had been stored overnight in a medium containing glucose, and some of this glucose was probably transferred with the cells to the nominally glucose-free solution used for the preliminary incubation. The use of ATP in the conversion of glucose to triose phosphate may account for the very low ATP levels found later in the experiment[9].

The finding, in all three experiments of Table 1, that incubation in a high-Na^+, K^+-free medium led to an increase in the concentration of ATP which could be wholly or partly prevented with ouabain provides strong evidence that reversal of the pump is associated with a net synthesis of ATP.

Phosphorylase Activity in Acutely Exercised Muscle

MUSCLE glycogen serves as an important source of energy for muscular contraction. The initial glycogen degradation reaction is catalysed by the enzyme, phosphorylase.

A controlled histochemical approach to the study of phosphorylase in resting and exercised skeletal muscles has enabled us to localize phosphorylase responses to treadmill running in specific muscle fibres. Phosphorylase activity has previously been studied in homogenates and frozen sections of skeletal muscle immediately following electrical stimulation but not after exercise[1-3].

Twelve adult guinea-pigs (mixed strain) were run on a treadmill at a rate of 1·6 km/h for 5 min, 10 min or to exhaustion. Each exercised animal was paired with a non-exercised control animal of the same age. Immediately after the run, each experimental animal was removed from the treadmill and killed with a sharp blow to the head. The left plantaris and soleus muscles were removed; the belly of each muscle was ablated and frozen with isopentane which was previously cooled to a viscous fluid with liquid nitrogen. Muscle samples from the control and exercised animals were mounted in a frozen state on the same chuck; 6 μm sections were cut, thawed onto coverslips at room temperature, briefly air-dried and simultaneously incubated on the same day the animal was killed. A slightly modified technique of Eränkö and Palkama was used to demonstrate phosphorylase[4]. To determine which fibre types showed the phosphorylase reaction, serial sections were also tested for succinate dehydrogenase (SDH), malate dehydrogenase (MDH), reduced nicotine-adenine dinucleotide diaphorase (NADH–D), menadione linked α-glycerophosphate dehydrogenase, and "myosin" adenosine triphosphatase activity[5-8]. Activity of each of the enzymes in each fibre type has been described earlier[9,10]. The terms white, intermediate and red muscle fibre types are used in this paper and correspond to the classification of A, B and C, respectively, first suggested by Stein and Padykula[9]. A modified trichrome was used for demonstration of morphological details[11]. Analyses were completed from black-and-white photographic prints. The relatively white (high proportion of white fibres) and red (high proportion of red fibres) regions of the plantaris[10] and the central portion of the soleus, which consists of only intermediate type fibres, were studied. Approximately 150 fibres from each of the three regions were analysed.

Table 1. HISTOCHEMICAL PHOSPHORYLASE ACTIVITY IN EXERCISED MUSCLE

Exercise duration	No. of experiments	Percentage of fibres lacking phosphorylase activity Region of muscle "Red"	"White"
None	12	0	0
5 min	1	7	4
10 min	4	10	21
Exhaustion	7	61	36

Table 1 summarizes the results obtained for the histochemical demonstration of phosphorylase. In control animals, neither the red nor the white regions of the plantaris contained any phosphorylase-negative fibres. Fibres with moderate SDH, MDH and NADH–D activity contain moderate amounts of phosphorylase in control animals (Fig. 1*A* and *B*). With increasing durations of exercise, higher proportions of phosphorylase-negative fibres were found (Table 1). Because red fibres were found to be the most susceptible to phosphorylase "inactivation", the relatively high percentage of negative fibres in the red region relative to the white region of the acutely exercised plantaris muscles is to be expected. On the other hand, white fibres were the most resistant to becoming phosphorylase-negative after exhaustive exercise (Fig. 2*A* and *B*). No consistent changes were observed in the soleus. This may be because the soleus is composed of intermediate fibres, which normally show negligible phosphorylase activity even in control guinea-pigs.

It could be suggested that the relatively greater resistance of white fibres to loss of phosphorylase activity was due to higher glycogen levels in white than red fibres which may, in turn, affect the histochemically measured level of phosphorylase[12]. It is more likely that red fibres were used selectively during the treadmill exercise. The latter suggestion has some merit, for it has been proposed that white fibres are innervated by large motor horn cells having higher thresholds for activation than do smaller motor horn cells which innervate the red fibres[13]. This suggests that the motor horn cells which innervate red muscle fibres are more susceptible to activation than those that innervate white fibres. This would result in greater red than white muscle fibre activity and, consequently, a preferential phosphorylase "inactivation" of red fibres might be expected. This explanation fits well with the idea that the biochemistry of white fibres is geared mainly to short bursts of high intensity work, and hence may not be activated to contract during prolonged, lower intensity work such as treadmill exercise.

Localization of an either strongly negative or strongly positive histochemical reaction for phosphorylase in specific fibre types clearly demonstrates significant differences between individual fibre types during exercise. Kugelberg and Edström have reported similar results with electrical stimulation in that fibre responses were localized in specific fibre types and apparently motor units[3]. They observed, however, that white fibres were selectively depleted of phosphorylase activity, whereas some red fibres were never depleted. This is exactly the reverse of our observations in animals that were run on a treadmill. These findings leave some question as to the appropriateness of making biochemical inferences about normally exercised muscles from electrically stimulated muscles.

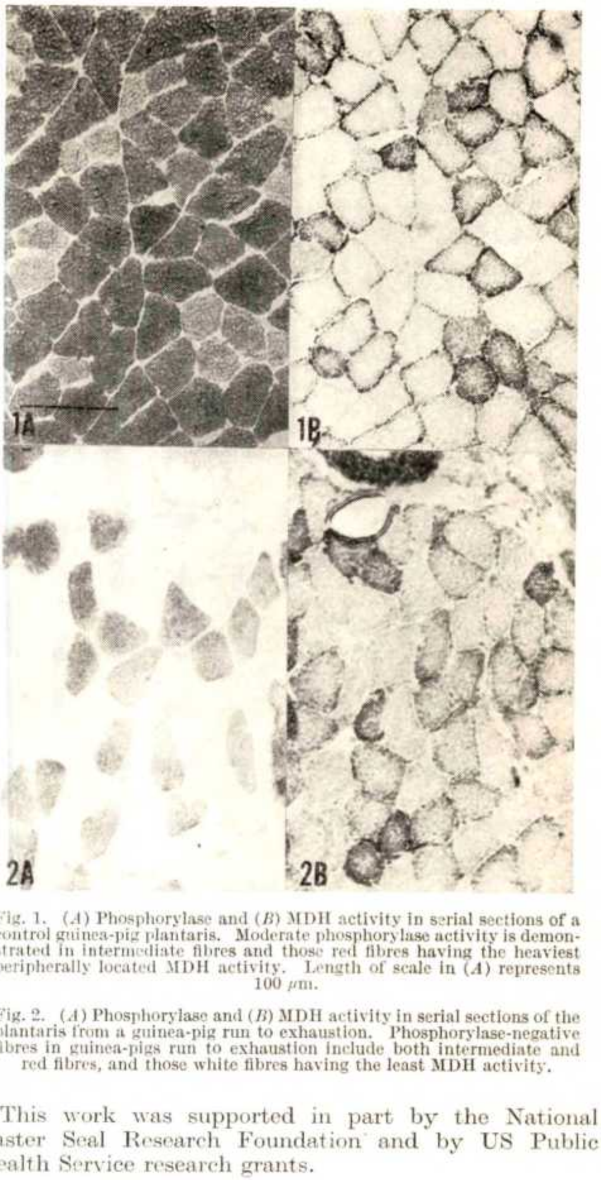

Fig. 1. (*A*) Phosphorylase and (*B*) MDH activity in serial sections of a control guinea-pig plantaris. Moderate phosphorylase activity is demonstrated in intermediate fibres and those red fibres having the heaviest peripherally located MDH activity. Length of scale in (*A*) represents 100 μm.

Fig. 2. (*A*) Phosphorylase and (*B*) MDH activity in serial sections of the plantaris from a guinea-pig run to exhaustion. Phosphorylase-negative fibres in guinea-pigs run to exhaustion include both intermediate and red fibres, and those white fibres having the least MDH activity.

Dopamine Excretion in Affective States and following Li_2CO_3 Therapy

THE interrelated biochemical changes which occur in severe recurrent depression and in mania include a disordered metabolism of cerebral monoamines[1]. It has been suggested[2,3] that in severe depression, especially of the endogenous type, there is a deficiency of amines, and in particular of norepinephrine, at certain sites in the brain. On this hypothesis, mania is marked by an excess of amines at the same sites. Determination of the urinary excretion of dopamine, the precursor of norepinephrine, and its chief metabolite vanillylmandelic acid (VMA), may therefore help to test the validity of this hypothesis. In this connexion it is relevant to note that the manic state may be associated with increased muscular activity; it has, moreover, been reported that epinephrine and norepinephrine excretion increase following muscular activity[4,5] while dopamine excretion does not increase under the same circumstances[5].

We have investigated the urinary excretion of dopamine and VMA in manic and depressive states and after stabilization with lithium carbonate. Psychiatric judgments, using an analysis of the Overall and Gorham brief psychiatric rating scale, were made on patients receiving lithium carbonate on the days of urine collection. Twenty-four hour urine collections were obtained during a period in which seven patients were in a manic phase and six other patients were in a depressive state. Urinary excretion rates of dopamine and VMA were determined during these states and following lithium therapy when the patients were essentially normal.

Creatinine was determined by the Folin procedure[6] and VMA by the method of Pisano *et al.*[7]. Dopamine was isolated from urine by adsorption on Amberlite 'CG-50' that had been cycled by a modification[8] of the procedure of Hirs *et al.*[9]. The column effluent served for the determination of conjugated dopamine after acid hydrolysis. The hydrolysate, after adjustment to *p*H 6·6, was applied to a second column. The fluorometric assay for the quantitative determination of dopamine[10] was similar to that reported by Laverty and Taylor[11]. The fluorophor formed in the 5,6-dihydroxyindole reaction was developed at *p*H 5·2 for 90 min at 100° C and its fluorescence measured at 390 nm with excitation at 332 nm.

The results are summarized in Table 1. Dopamine excretion in twenty normal volunteers, aged 22–58, did not vary with sex or age. During the manic phase, both conjugated and free dopamine excretion increased for six of seven patients. The patient P.B. was moderately hypomanic at the time of urine collection. During the depressive state, the dopamine excretion rate remained within normal limits, except for one (C.S.) of two patients (C.S. and Y.B.) with affective disorders which were highly cyclic. Following treatment with lithium carbonate, the excretion of dopamine by all patients in the manic group returned to normal levels. The excretion of dopamine by three patients in the depressed group was not significantly changed throughout administration of lithium. For one (C.S.) of the two cyclic cases, however, there was no change; in the other (Y.B.) there was an unexplained increase. Excretion of VMA was unaltered in both groups before and after therapy.

Excreted dopamine has been reported to be largely of peripheral origin[12]. Circulating and excreted norepinephrine arises from the adrenals or other chromaffin tissue or from adrenergic components of the autonomic nervous system, with little contribution from the brain[13]. It is of interest, however, that decreased dopamine excretion observed in extrapyramidal syndromes[14] seems to be correlated with a decreased concentration of this amine in the basal ganglia[15]. Moreover, a gradual decrease in urinary excretion of dopamine with increasing severity of the illness has been reported[16].

The data suggest that an increased excretion of dopamine is one of the biochemical changes associated with the manic phase of an affective disorder. This is compatible with previous single case reports of cyclothymic patients[12,17]. In another study[18], excretion of dopamine was significantly increased in only one of three cases studied. Normal excretion rates of VMA in the manic phase found in this study do not agree with a previous report[12]. The fact that lithium ion in low concentration inhibits the electrical stimulation-induced release of norepinephrine and serotonin[19] may be related to the observation that, after treatment with lithium carbonate, excretion of dopamine by patients in the manic group decreased to amounts found for the control group.

* Thioridazine, † chlorpromazine, administered during this period and before lithium carbonate.

t Corresponds to correlated means on square root transformation data.

The significance of these biochemical changes remains to be determined. It will be of particular interest to learn whether the brain is a significant source of the increase in dopamine excretion. Alternatively, a disturbance in catecholamine metabolism in the peripheral nervous system may reflect a similar disturbance in the central nervous system.

We thank Dr R. W. Von Korff for encouragement and discussions and Dr T. E. Hanlon for the statistical analysis.

Nervous Activity and RNA Metabolism in the Visual Cortex of Rat Brain

THERE is increasing evidence that nervous activity and brain RNA metabolism are closely related[1–5]. The present investigations were instigated to obtain further evidence for a connexion between RNA turnover and nervous activity in the visual cortex. We wished to accomplish this without recourse to electrical, chemical or any other form of non-physiological stimulation, and were fortunate in having available two strains of rats which seemed to be ideal preparations for this purpose.

One strain, of inbred, tan-hooded albinos (originally described by Tansley *et al.*[6]), was totally blind[7], with a condition resembling human retinitis pigmentosa, in which there is a failure in the final stages of development of the rod layer of the retina. It can therefore be assumed that after the rats have attained the age of 3 weeks, their visual cortices receive negligible nervous stimulation. The second strain was a normal sighted strain (PVG rats). Rats belonging to this strain very rarely, if ever, show spontaneous retinal degeneration. Direct ophthalmoscopic and electroretinographic observations confirmed that these rats were sighted (personal communication from A. Sorsby), so that it was possible to assume that the visual cortex would be stimulated throughout life by light falling on the retina. We considered that by comparing RNA turnover in the visual cortices of rats of both strains, any differences in RNA metabolism associated with nervous activity in a particular area of brain would be maximal. All rats used were 3 months old, of either sex, and weighed between 200 and 250 g.

Rats of both strains were injected intraventricularly with 4 μCi of 6-^{14}C-orotic acid (specific activity 60·8 mCi/mmole, Radiochemical Centre, Amersham) under mild halothane anaesthesia. In some experiments, the rats were merely kept in a constantly illuminated room, and in others the rats were exposed to a flashing light source (60 W bulb. 30 flashes per min). At given time intervals after the injection of the nucleic acid precursor, the rats were killed by decapitation, and the brains removed.

The visual cortex from each brain was removed by dissection and simultaneously a sample of equal size was removed from an area of the motor cortex equidistant with the visual cortex from the site of the orotic acid injection. All operations were performed as rapidly as possible after chilling the brain. The area of cerebral tissue taken as the visual cortex corresponded to that described by Adams and Forrester[8].

RNA was extracted from the sample of brain tissue by the method of Scherrer and Darnell[9], modified by deproteinizing with a mixture in the following proportions: 500 g phenol, 70 ml. *m*-cresol, 55 ml. water and 0·5 g 8-hydroxyquinoline. RNA precipitates obtained were dissolved in 1 ml. of 0·01 M acetate buffer, *p*H 5·1, containing 10^{-4} M EDTA, 0·05 M NaCl and 0·005 per cent polyvinyl sulphate. Samples (0·1 ml.) of these solutions were layered onto a 5–20 per cent continuous sucrose gradient (volume 2·5 ml.) and centrifuged at 45,000*g* for 4 h at 5° C on an MSE Superspeed 50*TC* centrifuge using a 3 × 3 ml. swing out rotor. Fractions were then collected and the RNA in each estimated spectrophotometrically at 260 nm. The absolute radioactivity in each fraction was determined by liquid scintillation counting, using a dioxane based scintillant. The specific activities of the RNA in each fraction could thus be calculated.

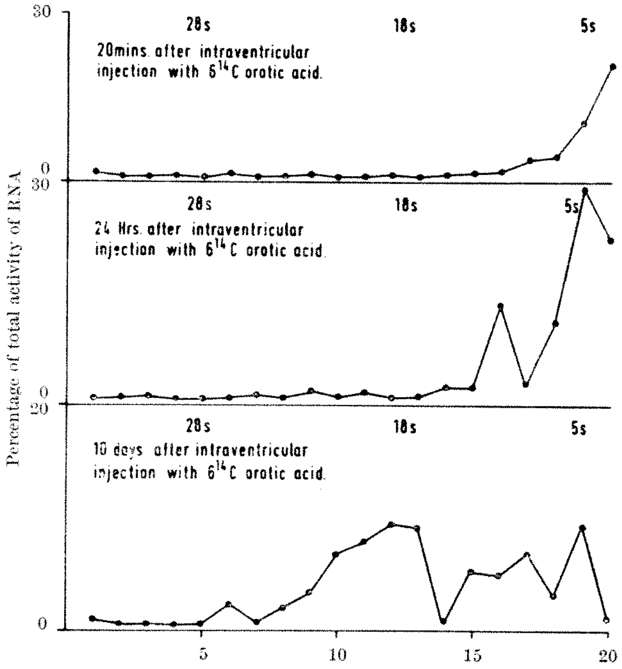

Fig. 1. The pattern of labelling of cerebral RNA fractions from PVG rats following the intraventricular injection of 4 μCi of 6-^{14}C-orotic acid.

Fig. 1 shows how the pattern of labelling in cerebral RNA fractions after the intraventricular injection of 6-^{14}C-orotic acid varies with time. These results were obtained using the whole forebrain of PVG rats, and those obtained with the whole forebrain of blind rats were identical. There is an initial labelling of the "rapidly labelled" 5S RNA followed by labelling of 5–8S fraction, and subsequently labelling of ribosomal RNA. Fig. 2 shows the pattern of labelling in the RNA fractions obtained from the visual cortex and motor cortical sample of the blind strain. The RNA from the motor cortical sample shows a pattern of labelling similar to that in Fig. 1, whereas the visual cortex RNA is labelled to a considerably lesser extent. The specific activity of the visual cortex RNA is lower, and the labelling of the 5–8S RNA and the ribosomal RNA is retarded. In Fig. 3, however, which shows the labelling patterns obtained from the visual cortex and motor cortical sample of the PVG rats, the labelling pattern from the motor cortical sample is identical to that seen in Fig. 1, but the labelling of the RNA from the visual cortex is considerably increased, both in magnitude and extent. There is a far greater labelling of the heterogeneous 5–8S RNA and ribosomal RNA. This effect is enhanced by using a flashing light source. Thus the increased nervous activity in the rat visual cortex is apparently accompanied by an increase both in the speed and the extent of the labelling of the

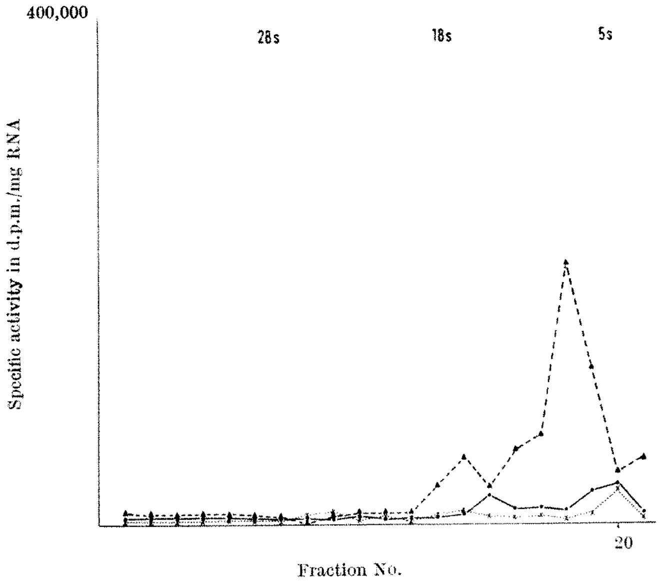

Fig. 2. The pattern of labelling of cerebral RNA fractions from the blind rats 24 h after the intraventricular injection of 4 μCi of 6-^{14}C-orotic acid. ▲- - -▲, RNA obtained from sample of motor cortex from rats subjected to a flashing light source of 30 flashes/min. Identical results were obtained using constant illumination. ●—●, RNA obtained from visual cortex of rats subjected to constant illumination. × . . . ×, RNA obtained from visual cortex of rats subjected to a flashing light source of 30 flashes/min.

RNA fraction, whereas a reduction in nervous activity seems to result in a retardation of the RNA labelling.

A possible explanation of the decrease in RNA synthesis in the visual cortex of the blind rats is that cellular degeneration had occurred. When sections from "sighted" and "blind" visual cortex were compared after thiamine blue and cresyl-fast violet staining, however, the distribution of Nissl granules was very similar, and there was no sign of gross cellular degeneration. It has, however, been established that deprivation of light causes a number of morphological changes in the visual cortex of rats[10,11]; we merely wished to confirm that the "blind" visual cortex had the potential for RNA synthesis. We intend to investigate this further by electrical stimulation of the visual pathway in the blind rats and observation of any change in the rate of RNA synthesis.

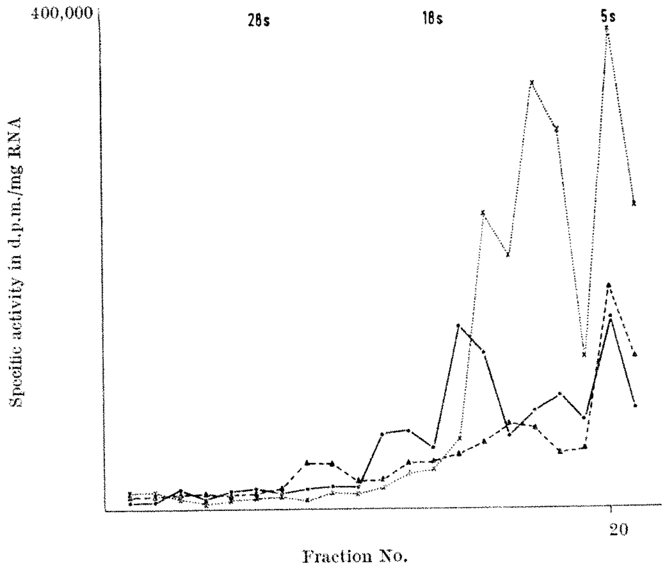

Fig. 3. The pattern of labelling of cerebral RNA fractions from the PVG rats 24 h after the intraventricular injection of 4 μCi of 6-^{14}C-orotic acid. ▲- - -▲, RNA obtained from sample of motor cortex from rats subjected to a flashing light source of 30 flashes/min. Identical results were obtained using constant illumination. ●—●, RNA obtained from visual cortex of rats subjected to constant illumination. × . . . ×, RNA obtained from visual cortex of rats subjected to a flashing light source of 30 flashes/min.

These results lend additional support to those of Kogan[3] and Baranov and Pevzner[4], but contradict those of Talwar *et al.*[12], who found that, in monkey occipital cortex, synthesis of RNA measured by incorporation of ^{32}P increased in the dark. The consequences of an increased RNA synthesis after nervous excitation are obscure; the most obvious consequence—an increase in protein synthesis—has been observed by Talwar *et al.*[13], but this seems to be contradicted by the work of Metzger *et al.*[14], who, by using a monkey split brain preparation, found that visual stimulation had no effect on the rate of protein synthesis in the occipital cortex. The observation of Rose[15], that the first exposure of rats to light produces an initial stimulation of protein synthesis in the visual cortex followed by a depression in protein synthesis, may explain some of the apparent contradictions in the literature.

We thank Miss K. F. Mackay for technical assistance.

Rhodopsin Content of Frog Photoreceptor Outer Segments

VISUAL receptor rod outer segments transduce the energy of absorbed photons into nerve signals. These membranous organelles can be isolated in quantities sufficient for biochemical studies, and are a favourable preparation for studying the chemistry of sensory nerve membrane excitation. Unlike other nerve membrane systems they contain an excitable protein component which binds an easily identified prosthetic group. This prosthetic group, 11-*cis*-retinaldehyde, combines with the protein opsin to form the light sensitive visual pigment rhodopsin. Retinaldehyde has been used as a label in the isolation and analysis of the opsin protein[1-3]. Opsins prepared from frog, cattle and rat outer segment membranes by detergent solubilization and column chromatography are now reported to have molecular weights in the range of 27,000 to 40,000 g per mole of retinaldehyde bound[3-6]. These opsins are thought to constitute a significant fraction of the total protein present in outer segment membranes[6-8].

The purpose of this communication is to present the data shown in Table 1 which demonstrate that intact and unfractionated frog rod outer segments contain not more than 28,500 g of protein per mole of retinaldehyde bound in visual pigment. This suggests that a single protein species, opsin itself, may account for virtually all of the protein present in frog photoreceptor membranes.

Table 1

a. COMPOSITION OF *Rana catesbeiana* OUTER SEGMENT PREPARATIONS

Preparation number	Amino-acid residues per prosthetic group	Protein molecular weight per prosthetic group
41	247	27,900
42	256	29,000
44	273	31,100
48	254	29,000
50	228	26,100
51	237	27,300
53	239	27,400
54	265	29,800
56	254	28,500
Average	250	28,500 ± 500

b. PUBLISHED COMPOSITION VALUES FOR PURIFIED RHODOPSINS

Frog rhodopsin[3]	237	26,600
Rat rhodopsin[3]	236	26,500
Cattle rhodopsin[3]	235	26,400
Cattle rhodopsin[4]	255	27,700
Cattle rhodopsin[5]	267	28,600

The ratio of protein/retinaldehyde found for frog rod outer segments in these studies is lower than previous estimates[6,8]. This is most likely because of preparation procedures which minimize contamination from other retinal membranes and protect outer segments from severe mechanical disruption and osmotic shock. In preparation for each of the analyses shown in Table 1, retinas were removed from five large dark adapted frogs (*Rana catesbeiana*), and 6 ml. of Ringer's solution containing 'Ficoll' (Pharmacia) was added to each ml. of retinal material. This suspending solution was made by dissolving 33 g of 'Ficoll' to a final volume of 100 ml. in Ringer's solution: 115 mM NaCl, 2 mM KCl, 2 mM $CaCl_2$, 10 mM N-2-hydroxyethyl - piperazine - N′ - 2 - ethanesulphonic acid ('HEPES', Calbiochem), *p*H 7·5. The retinas were homogenized by slow passage through a No. 17 syringe needle whose tip had been blunted on a grinding wheel. All manipulations were carried out under red light at 4° C. The homogenate was divided into three portions, each of which was layered under 1–2 ml. of 20 per cent (w/v) 'Ficoll' in Ringer's solution in Beckman–Spinco 302232 centrifuge tubes. These tubes were centrifuged using a Spinco *SW* 25.1 rotor for 30 min at 18,500 r.p.m. The outer segments floated up to form a thick "carpet" at the interface between 20 per cent and 33 per cent 'Ficoll' and were withdrawn in a minimum volume using a syringe. These outer segments were suspended in 10–12 ml. of 20 per cent 'Ficoll', layered over 1–2 ml. of 33 per cent 'Ficoll' in three similar centrifuge tubes, and centrifuged again as here. Outer segments which sedimented to the interface to form a "carpet" were again withdrawn. Microscopic examination revealed both intact and broken outer segments which retained their characteristic *in vivo* shape and birefringence. To remove most of the 'Ficoll' present, these outer segments were diluted with 10 ml. of Ringer's solution, sedimented in a Spinco 40 rotor for 10 min at 10,000 r.p.m., and the supernatant discarded. The outer segments were then used without further manipulations in the analyses shown in Table 1.

While these procedures yielded outer segment suspensions with fairly consistent protein/retinaldehyde ratios, there clearly was some variation between different preparations, reflected by small differences in total amino-acid composition (Table 1*a*) and rhodopsin yields. In some experiments outer segments which collected at the 'Ficoll' interface during centrifugation did not form a "carpet" of material which could be easily withdrawn, but rather formed a diffuse layer. Such preparations contained relatively more protein than those shown in Table 1.

Amino-acid analyses were performed on the Beckman model 120 *C* analyser[9]. Samples were hydrolysed for 24 h in glass tubes which had been evacuated and sealed; longer times of hydrolysis did not produce significantly different results. Cysteine and methionine were analysed after performic acid oxidation according to Moore[10]. Tryptophan was measured in preparations solubilized with 0·04 M hexadecylammonium chloride (Eastman) in 10 mM HEPES, *p*H 7·5 (ref. 11). Retinaldehyde bound in rhodopsin was determined from difference spectra caused by bleaching, using the established molar extinction coefficient at 500 nm of 42,000 (refs. 5 and 12). Rhodopsin yields varied from 0·8 to $1 \cdot 6 \times 10^{-8}$ moles/retina. No analyses of the six sugar residues which Heller[3] reports covalently bound to rhodopsin were performed. Phosphorus analyses[13] of ten different preparations indicated an average of 80 (± 8) moles of phosphorus per mole of retinaldehyde present. Ninhydrin analyses[14] of these same preparations after alkaline hydrolysis gave values varying from 270 to 377 leucine equivalents/mole retinaldehyde. The data of Table 1*a* are expressed as moles of amino-acid present (determined by amino-acid analysis) per mole of retinaldehyde bound in visual pigment (determined by difference spectroscopy). Total protein weight per mole of retinaldehyde bound in rhodopsin was calculated separately for each preparation from the amino-acid analyses.

The averaged data from nine different preparations indicate that frog outer segment suspensions contain not more than 28,500 ± 500 g of protein per mole of retinaldehyde bound in visual pigment (Table 1*a*). Because these outer segments consist almost entirely of extensively folded photosensitive membranes, one is chiefly considering the protein of these membranes. The low levels of soluble enzymes thought, however, to be present in outer segments[15] should also contribute to the total analysis, for it seems unlikely that they would be lost during the gentle preparation procedures used. The value of 28,500 is very similar to molecular weights recently reported for the protein (opsin) portions of purified frog, rat and cattle rhodopsin (Table 1*b*). If Heller's value[3] for the protein weight of a single preparation of *Rana pipiens* (26,600) is taken for reference, this opsin represents approximately 92–95 per cent of the total protein of outer segments. With opsin present in these concentrations, the enzyme activities which have been associated with outer segments[15] must be accounted for by less than 10 per cent of the total protein present. Other outer segment components such as elements of the ciliary stalk or plasma membrane must also contribute relatively little to the total analysis.

The composition data listed in Table 1*a* and 1*b* suggest then that frog photoreceptor membranes contain only one major protein component, in striking contrast to most biological membranes. The recent work of Hall *et al.*[7] is consistent with this interpretation. The high concentration of visual pigment protein (opsin) in these membranes optimizes their quantum gathering capacity and has probably been favoured by selection processes. Opsin is thought to be a single polypeptide chain[3–5], and preliminary efforts in this laboratory to dissociate it further have been unsuccessful. This polypeptide chain then may be the major structural and functional protein of outer segment membranes. The X-ray diffraction data of Blaurock and Wilkins[8] would indicate further that this polypeptide is constrained in these membranes to two layers approximately 10·5 Å thick which enclose a lipid bilayer.

If rhodopsin is the main component of vertebrate photoreceptor membranes individual rhodopsin molecules must be surrounded chiefly by other rhodopsin molecules. The decrease in apparent current flow across these membranes which can be caused by the photoexcitation of one rhodopsin molecule[16,17] might then involve cooperative interactions between this excited molecule and adjacent rhodopsin molecules, or between rhodopsin and other membrane proteins present in much smaller amounts. Such cooperative interactions could be involved in either of the two mechanisms currently suggested to account for visual excitation: that light causes an increase in the resistance of the outer segment membrane system, or that light activates an electrogenic pump which utilizes metabolic energy to move ions across the membrane[16]. If the 10^7–10^9 rhodopsin molecules present in an outer segment's membrane system were equally involved in maintaining its resistance to an observed dark current of approximately one to two cations/rhodopsin/second[17], then the alteration of just one of these molecules by photoexcitation could not cause the net movement of 10^5 cations within milliseconds, which Penn and Hagins have observed in rat outer segments[17]. Any change in resistance would have to be a cooperative phenomenon, with the excited rhodopsin molecule influencing adjacent areas of the photoreceptor membrane. Activation of an electrogenic pump, unless the pump were rhodopsin itself, would also require cooperative interaction between rhodopsin and the presumed pump molecules. Sodium–potassium activated adenosine triphosphatase activity in outer segments, which might be involved in active ion movements, is not greater than 10^{-1} moles ATP hydrolysed/mole rhodopsin/minute (D. B., in preparation), and no effect of illumination has been observed on this activity.

We thank Dr A. Gordon-Walker, Dr G. Craven and C. Sakowski for their advice and assistance. This work was supported by a grant from the US National Institutes of Health.

Interocular Transfer of Suppressive Effects of Retinal Image Displacement

WHEN the retinal image of the visual field is suddenly displaced by a saccadic eye movement, perceptual sensitivity to a weak test flash at the time of displacement is reduced. Flashes presented from 40 ms before until at least 100 ms after the displacement may be affected. I have discovered[1] that visibility is similarly reduced when the visual field is displaced as a whole before a stationary (fixating) eye. This throws doubt on the idea that either oculomotor activity[2] or mechanical acceleration of the eyeball[3] is required to account for such effects. It suggests rather that the surge of neural activity caused by the rapid displacement of the retinal image has side-effects that interfere with processing of the signals generated by the test flash, and so raise the perceptual threshold[1].

If such interference between the two signals took place only at the retina or in the early stages of the visual pathway before signals from the two eyes were combined, then with dichoptic presentation, exposing only one eye to the moving visual field and presenting the test flash to the other, one might expect to find no corresponding suppressive effects. A reduction of visibility in these circumstances would imply that the interference had a more central origin.

I have now found that interference is not abolished when the two stimuli are presented dichoptically. On the contrary, the frequency of seeing drops quite as convincingly as when both the flash and the moving field were presented to the same eye; and once again the time range over which flash visibility is reduced begins about 40 ms before onset of displacement of the field presented to the other eye.

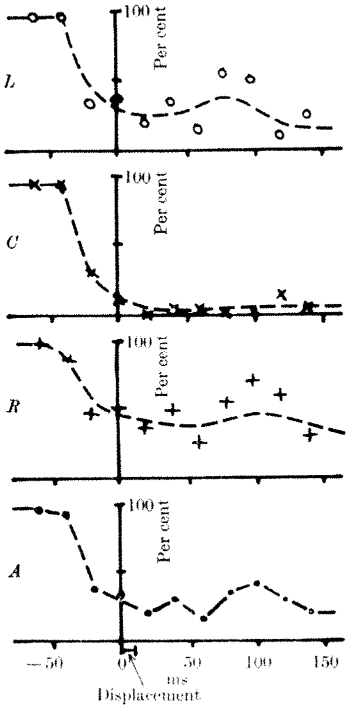

Fig. 1. Typical frequency-of-seeing curves for fixation to left (*L*), right (*R*) and on centre (*C*) of test spot. Abscissa shows time from onset of image displacement in right eye to onset of test flash to left eye. Average for *L*, *R*, *C* combined is shown at *A*.

The same sizes and dispositions of field and test spot were used as in the previous experiment[1]; but the 2° test flash, now controllable in duration, was presented via a mirror to the subject's left eye only. The right eye viewed the 10° circular field, which was displaced by 4° in 10 ms from right to left about the time of each flash, at intervals of 1 s, returning 0·5 s later. Both eyes viewed a fixation field of three luminous red dots, optically superposed via a semitransparent mirror. The dots formed a horizontal row, their separation being equal to the diameter of the test spot. The subject was instructed to fixate each dot in turn in a pseudo-random order, so as to reduce the effects of retinal adaptation in the eye exposed to the faint test flash.

The time interval between flash and field displacement was also varied at random, and the frequency of seeing was calculated separately for each interval and fixation position. Typical results on a coarse time-scale are shown in Fig. 1, for the same subject as in the previous report[1].

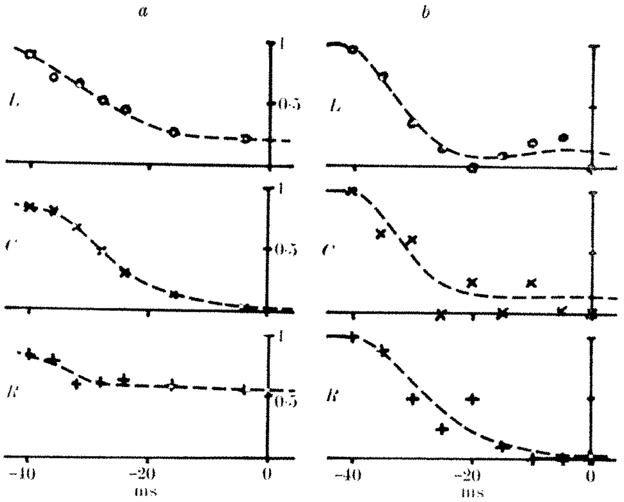

Fig. 2. *a*, Cumulative frequency-of-seeing curves for five experiments, expanded time-scale, dichoptic condition. Notation as in Fig. 1. *b*, Corresponding curves obtained when both stimuli were presented to both eyes (see ref. 1).

The drop from 100 per cent in the neighbourhood of −40 ms (that is, when the flash occurred 40 ms before displacement) is marked in every case. The detailed form of the curves in the region from −40 to 0 ms was explored in a separate series of experiments, spread over 5 successive days. The general features (though not the mean sensitivity level) were remarkably consistent from day to day, and the cumulative results shown in Fig. 2*a* are typical.

The sensitivity curves with dichoptic presentation are very similar in form and timing to those obtained when the same eye viewed both stimuli[1]. For ease of comparison, the curves of Fig. 3 in ref. 1 are re-drawn as Fig. 2*b*, on the same scale. The maximum elevation of threshold measured was of the order of 3 dB; but to avoid unduly prolonging experiments this measurement was made only in a few typical cases. It should be noted that any tendency to interocular rivalry would have had the effect of raising the "threshold" as statistically defined, quite apart from the interference between signals from the two stimuli, which is our present concern.

Significant differences were found between results for different fixation points. Visibility was lowest overall with foveal presentation of the test spot (curve *C*). This is to be expected, for the left eye is in scotopic condition (see below). More interesting is the marked and consistent contrast between response frequencies with fixation left (*L*) and right (*R*) of the test flash. Subjects reported the flash to be "much easier to see" when presented to the left of the fixation point.

In control tests with the moving field occluded, no comparable asymmetry was found between the thresholds with *L* and *R* fixation. In a total of 123 trials, using a flash duration close to scotopic threshold, the frequencies of seeing were 0·7(8), 0·7(7) and 0·1 with fixation on left, right and centre respectively. This confirms that the difference in scotopic sensitivity between extra-foveal and foveal areas is more than enough to account for the difference between curves *L* and *C* in Fig. 2; indeed, it suggests that the interference effects may be stronger with fixation on *L* than with central fixation. It also, however, shows clearly that the difference between curves *R* and *L* cannot be put down to a bias in scotopic sensitivity.

It remains to be seen whether this difference reflects a weakening of the interference process, or whether a flash in the left half-field of the left eye is "helped over the threshold" at some central stage by the breakthrough of signals from the corresponding half-field of the right eye. Because the area of the right eye-field actually corresponding to that of the test flash in the left eye does not change in luminance (the 10° field is displaced by only 4°), it seems more likely that it is the asymmetry of the disturbance caused by the displacement which accounts for the bias in favour of signals from the left half-field.

In any case, the results suggest that the effects of a moving field on the visibility of a test flash depend mainly on central rather than purely peripheral physiological interactions.

I thank Miss M. A. Steele and other subjects for their patient cooperation, and the MRC and SRC for financial support.

Effect of Presenting Novel Verbal Material during Slow-wave Sleep

THE topic of sleep learning has come increasingly to the fore during the past decade, partly because of the considerable scientific interest that has been shown in the Soviet Union, where a number of unusual claims have been made[1-3], and also because of the growing commercial interest in marketing devices designed to enable individuals to make use of the supposedly "waste periods" of sleep by storing useful, if perhaps dull and repetitive, material while in a state of unconsciousness. In principle the idea is attractive, but it depends on at least two assumptions: (1) that during sleep no other important process is taking place which would be disrupted by input of data; (2) that it is indeed possible for the brain to store (and subsequently extract) information fed in during those periods of sleep known as levels *C* to *E*[4], during which consciousness is generally believed to be absent. The function of sleep is still largely not understood, but present evidence suggests that important information processing may be taking place at frequent periods throughout the night. Experimental evidence for the second assumption is contradictory[5-7] and often obscure. Fox and Robbin[5], for example, seem to have obtained clear-cut evidence for "sleep learning" (of Chinese–English equivalents) but their experiment is open to criticism because the subjects were not actually observed while the material was being fed in and it is possible that the learning took place when the subjects were at least partially awake.

It is now generally agreed that there is no reliable way of monitoring the state of sleep other than by the use of the electroencephalogram (EEG). This precaution was taken by Emmons and Simon[6,7] in their series of experiments, and the result was a clear correlation between fall in cerebral vigilance and fall in the amount of retention or learning as indicated by subsequent recall and recognition tests. For example, with the exception of those cases where the subject had been drowsy and immediately aroused by the signals, subjects who had had words repeatedly played to them during sleep showed no evidence of recall and were no better than control subjects in selecting the test words from a list of fifty. Although the experimental techniques were more satisfactory in the Emmons and Simon study, it is still possible to raise objections on the grounds of inadequate control. For example, in each experiment the tests of recall or recognition were carried out the next day. It is therefore possible to argue that learning might have taken place during the sleep presentations but have been vitiated by the retroactive interference effect of experiences intervening between presentation and test.

In an attempt to improve the adequacy of control, we combined some of the features of the Fox and Robbin and Emmons and Simon studies with certain additional precautions. Three reasonably well matched groups of subjects, most of whom were students (none reading psychology), were made up on the basis of pre-test learning performance, the material being fifteen pairs of nonsense syllables of low association value[8] the response members of which had to be anticipated. This material was chosen for use in the experiment to reduce the possible effect of differential experience.

Subjects were divided into three groups—"facilitation", "interference" and control. During sleep, subjects allocated to the "facilitation" group were presented with fifteen further pairs of low association value nonsense syllables, the pairing being as for the post-test which all subjects would subsequently undergo; members of the "interference" group were given the same material, but with the syllable pair items scrambled. The input for each subject was twenty repetitions of the nonsense syllable list, the order of pairs being randomized from trial to trial. Subjects in the control group were presented with computer-generated random musical noise for an equivalent period of time (half an hour). Our hypothesis was that if information was being stored during the sleep period, this would (*a*) assist the "facilitation" group which should show some saving on post-test learning, (*b*) have no effect on the post-test learning of the control group (which had heard only music) and (*c*) should have a deleterious effect on the post-testing of the "interference" group which would have been exposed to conflicting input data. The taped presentation was made to each subject via a pillow speaker, and EEG monitoring was continuous. Input was started when subjects had reached stage *E* sleep and maintained regardless of level unless subjects showed signs of approaching stage *B*. If this degree of arousal occurred, the input was cut and not resumed until the subject had returned to a deeper level of sleep. None of our subjects entered REM sleep during the experimental session. Subjects were allowed a few minutes continuation of sleep after the completion of the stimulus presentations; they were then woken, given a cup of coffee, and when thoroughly alert were asked to undertake the post-test learning. By reducing the interval between sleep presentation and subsequent test of retention to a minimum, we hoped that any retroactive interference effect would be precluded.

Table 1

	"Facilitation"		"Interference"		Control	
Subject	Pre	Post	Pre	Post	Pre	Post
1	16	20	16	11	17	30
2	18	15	18	50	20	10
3	19	13	24	33	21	14
4	23	26	25	16	24	24
5	25	33	29	15	27	27
6	32	32	30	15	31	27
7	36	22	35	27	38	40
Mean χ	24·1	23·0	25·3	23·9	25·4	24·6
SD	7·1	7·2	6·2	12·8	6·8	9·2

The results of the experiment are shown in Table 1, where the number of trials to criterion (one errorless set of anticipations) for the three groups on pre and post-test is compared. In each case the group means show a slight downward shift from pre to post-test, perhaps attributable to practice, but these differences are not statistically significant. There is no indication of the clear differences between groups on post-test such as those reported by Fox and Robbin[5]. Isolated individuals show more pronounced differences, in line with expectations based on the assumption of sleep learning—for example, subject 7 in the "facilitation" group and subject 2 in the "interference" group—but there is no detectable overall pattern of improvement and deterioration in performance. The differences in the number of trials to reach criterion for matched subjects show no clear trend (Table 2).

The experiment thus shows no evidence to support the suggestion that learning can occur during sleep, although information may of course be absorbed and retained when the individual is in a drowsy state. Previous work, for example that quoted by Emmons and Simon, has already indicated that such learning takes place—though efficiency is drastically reduced compared with the waking state.

Table 2

High Frequency Haploid Production in Barley (*Hordeum vulgare* L.)

HAPLOIDS have been sought and investigated in many plant species since their first identification in *Datura*[1]. The chief limitation in using them to produce homozygous lines for plant breeding programmes or genetic research has been the lack of techniques by which large numbers of haploids can be obtained from any given stock[2]. Reports[3,4] of haploid plants obtained from anther cultures offer a potential technique and here we report our first observations on interspecific crosses, followed by embryo culture, illustrating an equally promising method for obtaining haploids in barley and perhaps other species.

Interspecific crosses between 28-chromosome autotetraploid cultivated barley (*H. vulgare*) and tetraploid *H. bulbosum* were made reciprocally and the progeny were nearly all 14-chromosome "diploid" plants resembling cultivated barley[5]. The progeny contained gamete chromosome numbers, so investigations on crosses between the diploid forms of these species were carried out and haploid plants were obtained.

The percentage seed set obtained from the crosses between the diploids was high, as illustrated in Table 1. The average seed set was 51·5 per cent on nineteen different lines or plants, including one "diploid" plant that set no seed on the few florets that were pollinated. The "diploid" parental plants (Table 1) were fertile *H. vulgare*-like progeny obtained from crosses between lines of induced autotetraploid *H. vulgare* and naturally occurring tetraploid plants of *H. bulbosum*. The female parent was chosen mainly on the basis of plants available in the growth room at the time when the diploid *H. bulbosum* pollen parent (consisting of two plants from PI No. 318,649 of the U.S.D.A. *Hordeum* species collection) was flowering.

The induced seeds from the crosses listed in Table 1 develop vigorously for about 10 days and then begin to

Table 1. SEED SET INDUCED FROM INTERSPECIFIC CROSSES BETWEEN *H. vulgare* ($2n=14$) AND *H. bulbosum* ($2n=14$)

H. vulgare, female parent		No. of florets	No. of seeds	Percentage of
Type	Nos. used	pollinated	induced	seed set
Varieties	3	516	223	43·2
F_1 hybrids	5	196	124	63·3
"Diploid" plants*	11	526	291	55·3
Total	19	1,238	638	51·5

* Fertile *vulgare*-like plants with 14 chromosomes, derived from crosses between *H. vulgare* ($2n=28$) and *H. bulbosum* ($2n=28$).

Table 2. PLANTS OBTAINED FROM INTERSPECIFIC CROSSES BETWEEN DIPLOID *H. vulgare* AND DIPLOID *H. bulbosum* USING EMBRYO CULTURE TECHNIQUES

Method of embryo culture	Number of embryos cultured	Number of plants obtained	Percentage of embryos giving plants
1. Fruit with stigmatic end cut off	38	7	18·4
2. Fruit coat removed	131	11	8·4
3. Embryo dissected from seed	40	5	12·5
Total	209	23	11·0

show signs of abortion, making it necessary to rely on embryo culture methods to obtain the haploid plants. (The embryo culture medium we used in this study was the B5 medium described by Gamborg *et al.*[6], modified by omitting the 2,4-dichlorophenoxyacetic acid, and adding 0·7 g agar per 100 ml. of solution.) Although experiments are still in progress on embryo culture techniques, a small number of studies have been summarized in Table 2. The culture of the undissected fruit on the medium has been unsuccessful, whereas the three different degrees of dissection listed in Table 2 have made haploid plant development possible. The dissections were all performed 8–10 days after pollination. It would seem that the removal of the top half (stigmatic end) of the fruit may be as successful as attempting to dissect out the very small embryo that is present 8–10 days after pollination. After development on medium from 6–10 days using method 1, the embryo is much easier to remove from the fruit coat and endosperm.

The chromosome numbers of all twenty-three plants so far obtained from inter-specific crosses between the diploid forms have been checked by root-tip squash techniques and found to be haploids with seven chromosomes. These plants are vigorous, *vulgare*-like and produce numerous tillers with well formed spikes. They are, however, only about three-quarters of the size of diploid plants. The spikes on ten plants that have now headed are completely sterile. The pollen grains are empty and shrivelled, resulting in anthers that remain small and non-dehiscent.

Further evidence that the induced seeds contain haploid embryos was obtained from cytological observations on embryos collected and fixed 4–7 days after pollination. In each of the twenty-three embryos thus examined, most of the dividing cells contained seven chromosomes. In six embryos, however, there was one dividing cell that contained more than seven but fewer than fourteen chromosomes, the range being from eight chromosomes and a fragment to eleven chromosomes.

The elucidation of the mechanism for the development of this high frequency of haploids needs further detailed cytological and genetical studies. The present evidence, however, leads us to suggest that, rather than parthenogenesis of the gametes from *H. vulgare*, fertilization of the egg cell has occurred in at least as many cases and that the chromosomes of *H. bulbosum* have been subsequently lost during the first few mitotic divisions of the embryo. This evidence comes from four sources. (*a*) The observation of an occasional cell in the young embryo that contained more than seven chromosomes—frequently fragments of chromosomes. (*b*) The percentage seed set (equivalent to haploid frequency) is much higher than in previously reported instances of haploidy attributed to parthenogenesis, even when the techniques of pollen irradiation or delayed pollination have been used. On some spikes, pollinated two days after emasculation, we have observed 100 per cent seed development. (*c*) When diploid *H. vulgare* plants were pollinated with tetraploid *H. bulbosum* the percentage seed set obtained was similar to that from diploid crosses. Fertilization had occurred in the former because all the progeny obtained were triploid hybrids[5]. This phenomenon leads us to suggest that a certain chromosome balance is necessary in order to obtain chromosomally stable hybrids between these species. (*d*) Haploids of the *H. vulgare* type are also consistently obtained when *H. vulgare* is used as the pollen parent in crosses with *H. bulbosum*.

The unusual and important aspects of our findings are that (1) a very high frequency of haploid embryos can be obtained; (2) only haploids have been obtained from the cross between the diploid forms; (3) these haploids can apparently be obtained from any given line of cultivated barley; and (4) the haploids always apparently have the cultivated barley genome.

These observations lead us to suggest that haploidy could be used in barley breeding programmes. By selecting haploids in the first generation (F_1) from a cross and subsequently doubling their chromosome number, homozygous lines could be obtained within two generations. Present conventional barley breeding methods require six to seven generations of selfing in order to obtain an adequate level of homozygosity. The success of the application of haploidy to barley breeding programmes depends on efficient embryo culture techniques and the achievement of doubling of the haploids into homozygous diploid lines.

The discovery of a similar mechanism for producing haploids in other species might be directed on the basis of certain characteristics. First, it must be possible to induce seed set with the interspecific cross. Second, actual hybrids may only be obtained between specific ploidy levels of the species, indicating that hybrid stability requires a certain chromosomal or genomal balance. Third, embryo culture techniques may be essential for the development of haploid plants. Although embryo culture techniques have not been attempted, the interspecific cross in alfalfa between *Medicago sativa* and *M. dzhawakhetica* would appear to meet the first two requirements[7,8]. Because cultivated alfalfa tends to behave genetically like an autotetraploid, the desirable application of haploidy for breeding programmes would be to derive diploids from the tetraploid forms. This approach is being used in the potato, where dihaploids (diploids) are obtained from the tetraploid potato (*Solanum tuberosum*) by crossing with pollen from the diploid *S. phureja*[9,10]. Again, embryo culture techniques have not been used and only a portion of the very few seeds obtained per cross give rise to dihaploids. It is possible that the mechanisms of haploid production from interspecific crosses in *Hordeum* and in *Solanum* are similar.

We thank Dr E. Reinbergs for his suggestions and encouragement. Financial support from the National Council of Canada is gratefully acknowledged.

Note added in proof. Since the submission of our manuscript, a publication on haploid barley from the interspecific cross of *H. bulbosum* by *H. vulgare* has appeared (S. Symko, *Canad. J. Genet. Cytol.*, **11**, 602; 1969). This cross was made reciprocally to the one we are reporting and the haploids obtained exhibit some characteristics of both *H. vulgare* and *H. bulbosum*, probably due to the presence of *H. vulgare* chromosomes in the cytoplasm of *H. bulbosum*. Although of scientific interest, such haploids are less suitable in a barley breeding programme.

Carbon Monoxide as a Basis for Primitive Life on Other Planets

In considering the possibility of life on other planets, we are naturally prejudiced towards some variant of the terrestrial photosynthetic mechanism for CO_2 fixation. Such a prejudice is reasonable: photosynthesis is efficient and we know that it works. But there are reasons why such a cycle may not be likely on a planet such as Mars. The chemical machinery required for photosynthesis is exceedingly complex and is unlikely to be available to the most elementary organisms. Furthermore, on many planets, such as Mars, there is a considerable flux of high energy ultraviolet radiation which reaches the planetary surface[1] and which will tend to rupture bonds in organic molecules. Because photosynthetic organisms must be exposed to light, it seems unlikely that they could survive for long in the face of this radiation. It is, of course, conceivable that an organism could develop protective or self-repairing capabilities, but this would be particularly difficult for primitive life: in these conditions, life would be easiest in the shade. This would disfavour, but not exclude, an energy cycle based on photosynthesis.

In looking for an alternative metabolic cycle and energy source, we should consider the fact that the atmosphere of primitive planets may well be predominantly CO_2. This is the case for Mars and Venus[2]. A small but significant fraction of the solar flux striking the atmosphere will be absorbed to dissociate CO_2 to carbon monoxide[1,3]:

$$CO_2 \xrightarrow{h\nu} CO + O$$

Reoxidation of the CO (or a CO derivative) within an organism would provide a ready source of energy to drive metabolic reactions in which carbon is fixed and transformed into organic compounds. The complex chemical machinery required for transforming light energy into high energy chemical compounds is unnecessary, for this function is now carried on outside the organism. Furthermore, the living entity need not expose itself to any destructive ultraviolet flux.

A metabolic energy cycle based on oxidation of CO will certainly be far less efficient in terms of the utilization of the total solar energy striking the planetary surface. Only a fraction of a percentage (2×10^{-3} per cent) of the total light energy flux is in the form of photons sufficiently energetic directly to dissociate CO_2 (refs. 1 and 3), whereas of the order of 10 per cent may be useful for photosynthesis[4]. Thus very primitive life forms subsisting on CO would eventually tend to be supplanted by more sophisticated photosynthetic organisms. Perhaps this has happened on Earth. On a planet like Mars, however, this subsequent phase might well not have occurred in view of the continuing presence of the destructive ultraviolet flux, and because of the shortage of water.

There are two facts which further support this hypothesis of a metabolic energy cycle based on CO. The first is that CO metabolizing organisms are known to exist on Earth. An example is *Bacillus oligocarbophilus*[5], which seems to be widely distributed, and is particularly abundant in mines which contain appreciable amounts of CO.

The nature of the Martian atmosphere itself provides an interesting clue. If the CO_2 is slowly photodissociated to CO and oxygen, why do we not see more of these latter species? Plausible mechanisms for efficient atmospheric recombination of CO and oxygen are hard to find, not only on Mars but on Earth[3,6]. It was on this basis that we suggested some years ago[6] that terrestrial ^{14}CO produced by ^{14}C arising from cosmic radiation, as well as ^{12}CO, was biologically oxidized by *B. oligocarbophilus* and similar organisms. Certainly, biological activity on Mars based on the oxidation of CO would provide a natural answer to the problem of why the Martian atmosphere is predominantly CO_2 and contains so little of the expected CO and oxygen photodissociation products.

There are some obvious objections to this hypothesis. Perhaps the most serious is the inefficiency of the postulated process. But then, as has already been said, efficiency is not a requirement of the most primitive forms of life. It is only necessary that there is no more efficient process in direct competition. Another objection is the low concentration of CO and of oxygen, its probable oxidant. The molar fraction of CO in the Martian atmosphere is only 0·1 per cent[2,7]. Measurements of O_2 have so far only given a rather high upper limit, 0·3 per cent (ref. 7 and personal communication from C. Barth). Because O_2 is presumably produced by the same process which yields CO, it is, however, plausible that these two species are present in similar concentrations. Obviously simultaneous collisions of CO and O_2 molecules with an active site on an organism are unlikely. But relatively simple chemical forms are known to be capable of complexing and holding both CO and O_2. It seems plausible that an organism can thus accumulate both types of molecule and then cause the oxidation to proceed by an indirect route (Lederberg[8] mentions the possibility of CO conversion on Mars, and suggests that the exergonic reaction $2CO + H_2O \rightarrow CH_2O + CO_2$ might be involved). This mechanism provides a good example of the indirect path probably involved in such metabolism. Oxygen will be required for the eventual oxidation of organic material so produced, and this oxidation would then close the cycle. Finally, the fact that terrestrial organisms make do with a 0·03 per cent concentration of CO_2 implies that low partial pressures are not necessarily a limitation.

This hypothesis seems to be in accordance with known facts, but there may well be unknown factors which make it unlikely. It is not suggested that on a planet like Mars a life cycle based on CO, or for that matter any life, is probable. But, if there is biological activity, it seems necessary to consider the hypothesis that it is based on the metabolism of CO.

It should be possible to search directly for CO-fuelled life cycles by incubating planetary soil with ^{14}CO and looking for labelled metabolic products.

These views have been stimulated by laboratory experiments supported by the US National Aeronautics and Space Administration and the US Atomic Energy Commission and discussions with W. F. Libby and others.

Book Reviews

MULTIFARIOUS ORGANELLES

Lysosomes in Biology and Pathology

Edited by J. T. Dingle and Honor B. Fell. Vol. 1: Pp. xxiii + 543. Vol. 2: Pp. xxiv + 668. (North-Holland Research Monographs: Frontiers of Biology, Vols. 14A and 14B.) (North-Holland: Amsterdam and London, 1969.) 490*s* for the 2 vols.

According to de Duve, "The lysosome introduced itself to us on December 16, 1949", brought in by what he describes as a subtle gremlin. Only a great scientist could welcome such a gremlin and realize, from a series of "dismal failures", the fact that he had, in his hands, a "structure-linked latency". His essay in this book should be compulsory reading for all scientists—an essay on the true experimentalist's philosophy of science. As he says, "As scientists we do not simply read the book of nature. We write it. . . . But we must accept our concepts for what they are, provisional approximations that are as much fictions of our minds as they are faithful depictions of facts". During the first surge of excitement over the newly established concept it was considered fashionable by the scientific intelligentsia, as distinct from the scientific experimentalists, to dismiss lysosomes as being predominantly mental fiction. The wealth of detailed information on the structure and function of these organelles now presented in these two volumes shows how justified were those who welcomed the first sketch of the lysosome concept and recognized its heuristic value.

The editors have been faced with the almost impossible task of ordering the plethora of information on the lysosomal and vacuolar systems, in both the plant and animal kingdoms. Moreover, because the lysosomal system is a real depiction of a biological fact, it is constantly changing in any one type of organism. This is typified by the enormous variety of its morphological forms, as discussed by Daems and his colleagues; by the different types of lysosomes, with their own special characteristics, found in plants (Matile); and even by the complexities of unravelling the biochemical features of lysosomal systems in the heterogeneous lymphoidal tissues which makes such fascinating and instructive reading in the chapter by Bowers.

The first volume consists of five separate parts; the second volume has four. "Lysosomes in Pathology" is dealt with in both volumes and consists of twelve chapters including reviews on the role of these organelles in teratogenesis, muscular dystrophy and arthritis. Two chapters deserve special mention. Slater's description of the behaviour of lysosomes in experimentally induced tissue injury should give reasoned order to a subject which has been a vortex of controversy for many years. The admirably clear and concise account by Coombs and Fell of the place of lysosomes in tissue injury mediated by allergic reactions is both timely and most welcome especially in the light of the recent rapid increase in interest in this field both from the medical and the scientific viewpoints. Other chapters of both fundamental and applied interest are those by Hers and van Hoof on genetic abnormalities of lysosomes and by Allison on lysosomes and cancer.

The other main parts of these volumes deal with lysosomal form and function; lysosomal physiology in vertebrate tissues; lysosomes in reproductive physiology in mammals; lysosomal physiology in non-vertebrate tissues, including insects, sponges and plants; structure and enzymology; lysosomes in secretion and digestion; and a section on methods. The valuable contributions of Weissmann on the effects of steroids and drugs and of Roels on the influence of vitamins A and E on lysosomes are included under "Physiology of Vertebrate Tissues"; the closely related topic of the extracellular secretion of lysosomal enzymes is reviewed by Dingle in a stimulating chapter in the section dealing with secretion and digestion.

In dealing with such a complex and all-embracing subject, the reader must realize that the subject of his interest may be treated in different chapters, often disguised under a more generalized title. For example, if his concern is with arthritis he will find much value in the chapter on connective tissue catabolism (Reynolds) as well as in the two chapters formally devoted to this subject by Lack and by Page Thomas. The student of lysosomes in microbiology and infection is well served by two chapters, one on bacterial infection (Allen) and the other on cell–virus interactions (Dale), but will be well rewarded by the chapter by Cohn and Fedorko on the fate and formation of lysosomes which deals with these organelles in polymorphs and macrophages. As might be expected in a vast and developing subject, some facets have been intensively investigated whereas others, possibly newer or dealing with more refractory tissue such as bone, are less well documented and sometimes even involve special pleading to relate observable effects to the general concept.

The second volume is completed by several chapters dealing with methods used in lysosome research. These contain much valuable and detailed information and several superb colour reproductions illustrate dramatically the chapters on vital staining and special methods. Many chapters have fine examples of cytochemical techniques with convincing photographs which match those, published some years back, of such pioneers in this subject as Novikoff and Holt. It is regrettable that the chapter in this book devoted explicitly to histochemistry and electron microscopy does not approach this standard.

These volumes fill an essential need in the scientific literature and should be treasured in all bio-scientific departments. Lucille Bitensky

LIPOPROTEIN SYSTEMS

Structural and Functional Aspects of Lipoproteins in Living Systems

Edited by E. Tria and A. M. Scanu. Pp. xxiii + 661. (Academic Press: New York and London, November 1969.) 170*s*; $26.

This book represents an attempt to cover lipoproteins in the widest sense. About one half of it is devoted to "soluble" lipoproteins and less than one third to "structural" or membrane lipoproteins. Most of the chapters seem to have been written during 1967 but some references for 1968 have been added. They provide very thorough reviews of progress in the studies of the major classes of lipoproteins and, on the whole, they constitute a very informative and readable book. There are extensive author and subject indexes which were perhaps compiled by a "literary assistant"—I felt compelled to look up the first entry under "S" which was "Salts, 210", and discovered that the extractability of protein from tissue by organic solvents was affected by (among other things) salts.

The chapters by Chapman and by Pethica are concerned with the contributions to knowledge of lipoprotein interactions made by a variety of physico-chemical methods. Pethica's contribution provides a particularly realistic and welcome new assessment of the significance of measurements made on phospholipid monolayers. Sjostrand provides the very high resolution electron micrographs of membranes, especially of mitochondrial membranes, and also speculations as to how they might be interpreted at the molecular level. Tria and Barnabei contribute a brief independent assessment of progress towards a detailed knowledge of membrane structure but are equally concerned with the possible ways in which phospholipids and lipopeptides are involved in some membrane functions. Criddle makes a remarkably good case for a biological significance for "structural protein", and Lebaron covers the very varied facets of proteolipid chemistry; Lebaron concludes that there are several lipid–protein complexes which are constituents of myelin. In a very brief chapter, entitled "A Physico-chemical Model of Nerve Membrane", Liquori derives a qualitatively satisfactory explanation of resting potential and action potential in terms of a three layer model for the axonal membrane in which a central layer of protein is preferred. The longest and certainly one of the most useful contributions comes from Utrecht. Op den Kamp, Van Deenen and Tomasi have collected together extensive information on bacterial lipids, their metabolism and their role in membrane structure. Blood lipoproteins are very extensively covered. Chylomicrons (Zilversmit), low density (Margolis) and high density (Scanu) lipoproteins, their biosynthesis (Marsh), the hormonal control of their levels in blood (Galli, Sirtori and Paoletti) and their involvement in blood coagulation (Barton) are all reviewed very thoroughly. To complete the lipoprotein scene there are two authoritative contributions on milk lipoproteins (Brunner) and egg lipoproteins (Cook and Martin).

This is perhaps the most extensive coverage of lipoproteins attempted in one book since the first international conference on lipoproteins (*Discussions of the Faraday Society*, No. 6, 1949). The topics covered are remarkably similar in both books, but only one person, Oncley, who contributes the foreword to the present volume, has contributed to both. A comparison of the two volumes provides an interesting assessment of twenty years of progress in this field. The most striking advance has been in the quantity and quality of the analytical data. Lipid components are now very precisely characterized and there is a great deal of chemical, physical and immunological data relating to the protein components. A greater emphasis on the significance of non-polar interactions between lipid and protein components is also evident, but there is continued uncertainty as to the precise molecular basis of most of the specific activities of these lipoprotein systems.

J. B. FINEAN

MANUAL OF METHODOLOGY

Fluorescent Antibody Techniques and their Applications

Edited by Akiyoski Kawamura, jun. Pp. xiii + 203 + 8 colour plates. (University of Tokyo Press: Tokyo; University Park Press: Baltimore and Manchester, England, June 1969.) $16.50.

THIS is a compilation on immunofluorescence from the experience of forty Japanese exponents of the technique, and it deals with the subject in two sections: the first on theoretical and general aspects, the second on practical applications, chiefly in virology.

In a manual of methodology, such as this claims to be, the first section should include a straightforward account of the immunochemistry relevant to labelling and to the reactivity of labelled antisera, of the common causes of non-specific staining, and of how the conditions of excitation of fluorochromes conjugated to globulins govern the choice of lamps and filters for microscopy. Here, alas, there is scant attention to the requirements essential for the different components in immunofluorescence—substrates, antisera, microscopy. Instead, the reader is plunged into a flurry of detail on serum fractionation, immuno-analysis, formulae, absorption spectra, and molar ratios that cannot but confuse the beginner. Indeed, some of the splendidly coloured plates—on the direct and indirect methods, and on fluorescence microscopy, for example—are less illustrations than obfuscations.

The second part of the book is a series of notes on applications of immunofluorescence, arbitrarily selected by the many workers who have contributed them. These give us glimpses into laboratory notebooks recording mostly identification procedures for a range of human and animal viruses and their antibodies in clinical and experimental material, and are as unrewarding as might be expected of this method of communication. The bacteriological section is even more severely limited; a section on treponemal antibody, for instance, is concerned only with methods of determining its immunoglobulin classes and types. The reader looking for help in studying tissue antigens and autoantibodies will find only a very incomplete account of antinuclear antibodies, a note on nephrotoxic serum, and some remarks on staining of arteries by sera from cases of pulseless disease. The illustrations of the two latter have transposed captions.

E. J. HOLBOROW

SCHOLARLY BOTANY

Précis de Biologie Végétale

Vol. 1: Cytologie. By A. Nougarède. Pp. xii + 598. 130 francs. Vol. 2: Nutrition et Métabolisme. By R. Heller. Pp. viii + 578. 115 francs. Vol. 3: Croissance Morphogenèse Reproduction. By P. Champagnat, P. Ozenda and L. Baillaud. Pp. viii + 510. 115 francs. (Précis de Sciences Biologiques.) (Masson: Paris, 1969.)

THESE three volumes are part of a library, "Précis de Sciences Biologiques", under the editorship of P. P. Grassé. Grassé's aim is that each volume should be scholarly but not esoteric, and up to date but not neglecting the "classical" observations on which our knowledge of biology is founded. Let me say at once that these books fulfil these aims to a very large degree. Such an aim, however, inevitably leads all the authors to assume a pedagogic (though never pedantic) style of writing. As for the content of the volumes, emphasis is laid on the presentation of established facts; consequently, controversial topics tend to be dismissed briefly with "malgré les progrès realisés le déterminisme reste encore mal connu", and there is no place for speculation in these pages. All the major areas of plant biology are covered with a clarity that never allows the reader to become bogged down by details. Yet the exposition of fundamental truths often makes for informative rather than interesting reading.

Nougarède's contribution is "cytologie" in its widest sense. The first section of her book is devoted to the techniques used in cell biology (chromatography, the centrifuge, isotopes and the like). Microscopy is well described, though curiously the interference microscope is not mentioned, while the still experimental proton microscope is. Description of cytoplasmic organelles occupies a large part of the remainder of the book. The emphasis here is on how their structure and function are interrelated. In the case of the mitochondrion, a good deal of space is devoted to Green's proposals on this subject. I felt that some areas of organelle biology merited a fuller discussion. For instance, rather more is known about the structure and function of lysosomes, flagella, plasmodesmata, microtubules (subunits are not mentioned) and the Golgi apparatus than the author admits. The description of the function of the nucleolus is rather out of date, and one experiment described in detail in this connexion is of equivocal value.

The details given of the genetic code are quite obsolete; it is a pity that Heller in his discussion of nucleic acid metabolism does not give more information on this point as the few RNA codons and their corresponding amino-acids that he mentions are correct. These omissions give the impression that the writing of *Cytologie* was completed some years ago; but nevertheless it is an excellent volume, especially if the reader wants a general description of cell components.

Heller, in *Nutrition et Métabolisme*, presents a thorough account of the physical chemistry and thermodynamics encountered in cell physiology and of the biosynthesis of cell constituents. In the section dealing with the biochemistry of respiration and photosynthesis, the exposition becomes splintered by quantities of short chemical equations without there being a good scheme which shows how they are related to one another. I felt that rather better summaries of these subjects could be found in Nougarède's book.

Champagnat contributes a chapter on "Croissance, Morphogenèse et Développement" in volume three. His principal theme seems to be that growth is regulated by growth substances. Unfortunately, the real problem of the relation of these substances and growth regulation is hardly considered: in what form do auxins and the like exist in plants; where are they located; how do they interact with the machinery of cell growth ?—these questions are never raised. The problem of growth is continued by Baillaud with a section on "Les Mouvements". Here again I felt that the subject had not been done justice, especially the section on photo- and geotropism. As in Champagnat's chapter, a lot of words are needed to describe relatively trivial observations, while there is too little discussion of the major topics.

The third volume is concluded by Ozenda, who, in two hundred pages, neatly covers flower and seed biology, embryology, life cycles of algae to archegoniates and the physiology and genetics of sex in fungi and algae. Neither Nougarède nor Ozenda describes meiosis; it seems as though each author thought the other was going to cover it. Even Nougarède's description of the multitudinous varieties of mitosis cannot save the authors from being awarded a black mark for this omission.

References to original papers are kept to a minimum in volume one, and there are none at all in volumes two and three. The quality of printing is high and these volumes are a handsome and useful set. Whether they will find a market in English speaking countries I cannot say; there are rival volumes in English, *Plant Cells* (by F. A. L. Clowes and B. E. Juniper) and *Plant Biochemistry* (by D. D. Davies, J. Giovanelli and T. Ap Rees) in Blackwell's "Botanical Monographs" being the closest in outlook and content. The price of the set is high, but I hope that libraries will give biologists the opportunity to read these books.

PETER BARLOW

ANTIMITOTIC AND ANTIBIOTIC

Rubidomycin

A New Agent against Cancer. Edited by J. Bernard, R. Paul, M. Boiron, Cl. Jacquillat and R. Maral. (Recent Results in Cancer Research, No. 20.) Pp. xiv + 181. (Springer-Verlag: Berlin, Heidelberg and New York, 1969.) DM 48.

THIS compact summary of all aspects of the antimitotic antibiotic rubidomycin, or daunomycin, has been compiled through the efforts of more than ninety listed authors, guided by five editors. Most published work on the substance, from the time of its first isolation simultaneously in France and Italy in 1962 to late 1968 when the monograph went to press, is included in the 274 bibliographic references and mentioned somewhere in the text, but the work is essentially a compendium of French and Italian studies on the chemistry and pharmacology of rubidomycin, and of French experiences with its clinical use.

In spite of its comprehensive character the monograph is of doubtful value. If it had been published as a series of review papers in appropriate specialist journals, the complex details of structure analysis and physico-chemical properties, the mass of *in vitro* and *in vivo* work on biological activity and pharmacological characteristics, and the clinical therapeutic trials could each have been received with interest and profit by an informed specialist readership. But the monograph as now presented is likely to be partially indigestible to all save the most erudite; the clinician will not appreciate the chemistry, nor the chemist the therapeutics. And for each man with his expertise the book has little new to offer that has not already been published.

Nevertheless, as a source of references and illuminating case data the monograph should come down often enough from the library shelves not to collect dust for the next year or two.

F. G. J. HAYHOE

HEREDITY OR ENVIRONMENT?

Social Status and Psychological Disorder

A Causal Inquiry. By Bruce P. Dohrenwend and Barbara Snell Dohrenwend. (Wiley Series on Psychological Disorders.) Pp. xiii + 207. (Wiley (Interscience): New York and London, October 1969.) 90*s*.

FOR many years there has been reasonably consistent evidence that psychological disorders occur more frequently among the "lower" socio-economic classes than among the "higher". To anybody who looks for simple explanations there are two possibilities. First, psychological disorders may be the result of genetic factors: those affected drift into the lower classes because of their disabilities, and swell the proportion of psychological illness in these classes. Alternatively, living conditions among the underprivileged may often cause stress, and this greater exposure to stress raises the incidence of psychological disorders. The simple choice is between an explanation in terms of heredity and environment.

Social Status and Psychological Disorder on balance comes down on the side of the "environmental" explanation, but only after showing that the choice is not easy, that the evidence is confused and inadequate, and that the issue cannot be resolved simply by attributing all the evidence to either environment or genetics. The authors make two contributions of their own. First, they provide a most useful review of the literature, distinguished by a very lucid analysis of the conceptual and methodological problems which bedevil studies of the etiology and epidemiology of psychological disorders. This alone makes their book an intelligent and a convenient source of reference. Second, and more important, they suggest a novel and rather elegant approach towards resolving the controversy about the role of heredity and environment. Their central assumptions are the existence of a norm which makes upward social mobility desirable, and of social barriers which limit mobility for certain subgroups of the population; for example, ethnic minorities. They suggest that comparisons between rates of disorders for such subgroups within a given class could help to decide between the genetic and environmental types of explanations. If rates of disorder in any one class are caused by social pressures, then these rates would be higher for, say, Negroes and Puerto Ricans than for other ethnic groups. If, however, disorder is caused by genetic factors, they would be lower; the able would rise irrespective of ethnic group. But there are barriers which block the rise of Negroes and Puerto Ricans: therefore, there should be more able (healthy) people among Negroes and Puerto

Ricans, diluting the overall rates of disorder within their particular class/minority combination.

Evidence from the authors' own research is still exploratory and ambiguous; the conceptual refinement of their approach nonetheless warrants careful consideration by anybody concerned with these problems.

PETER KELVIN

RADIATION PROTECTION

Basic Radiation Protection

Principles and Organization. By C. W. Easley. Pp. 132. (Gordon and Breach: New York and London, October 1969.) 125*s*; $15.

IT is very difficult to decide what basis was used for the selection of the material for this little book. In his preface, the author states that the book contains the information which has been useful to him and that he felt the desire to pass it on. The publishers obviously thought very highly of this collection of notes and happily charge accordingly.

The author covers the field in ten chapters and there are thirty pages of appendices. The equipment described is usually commercially available in the United States. The style of writing is certainly not verbose and the layout of the chapters is systematic. The brevity in the technical descriptions is good, but any background information suffers from it. Appendix A contains about thirty entries of two to three lines each. One finds definitions, for instance, for the atom, dosimetry, electron, molecule, roentgen, rem, but not for the rad, which I would have thought was most important. Appendix B contains sixteen full-page facsimile reproductions of forms of the type used in many laboratories handling radioactive material and usually designed by the laboratories according to their own needs. The literature of this large field is covered by five sources of information; the most recent one is a textbook published in 1960. It is surprising that the publishers believe they can find a market among scientists for this expensive little book and that they believe readers of *Nature* might be at all interested.

M. EBERT

CHOQUET'S THEORY

Lectures on Analysis

By Gustave Choquet. Edited by J. Marsden, T. Lance and S. Gelbart. Vol. 1: Integration and Topological Vector Spaces. Pp. xix + 382. Vol. 2: Representation Theory. Pp. xix + 336. Vol. 3: Infinite Dimensional Measures and Problem Solutions. Pp. xix + 341. (W. A. Benjamin: New York and Amsterdam, 1969.) Cloth $12.50 each; paper $4.95 each.

THIS book is an edited account of a graduate course of lectures delivered at Princeton by Professor Choquet in the fall term of 1967. It is a notable addition to the large number of books on functional analysis, chiefly because it provides the most complete account to date of what is justly called Choquet representation theory.

The first half of the course was an introduction to general topology, integration and topological vector spaces. The reader is supposed to know the rudiments of topology and conventional (set-function) measure theory: what is needed here is summarized without proof. The course proper opens with some lectures on selected topics from general topology: nets, filters, uniform spaces, embedding and metrization, and Baire spaces.

The treatment of Baire spaces is original in its use of the notion of a winning tactic from the theory of games. Two players, α, β, play a certain game with the open sets and points of a topological space. The latter is called α-favourable if α has a winning tactic: this is sufficient for the space to be a Baire space. Besides being elegant, the notion of an α-favourable space is more pliable than that of a Baire space. For instance, it survives the formation of topological products, which is more than can be said (it is an open question) of the property of being a metric Baire space. The use of Baire spaces in analysis is illustrated by a wide variety of examples.

There is a substantial introduction to Bourbaki integration theory in later lectures. This opens with an account of Choquet's theory of capacities, which, with the Reisz representation theorem, serves *inter alia* to link conventional measure theory and the Bourbaki theory.

There follows an introduction to topological vector spaces, with some emphasis on convexity and partially ordered vector spaces.

Having thus introduced the reader to many of the basic tools and concepts of functional analysis, the author has also set the stage for Choquet representation theory, which occupies most of the second half of this work.

According to the Krein–Milman theorem, each nonempty compact convex set K in a Hausdorff locally convex space is the closed convex hull of its extreme points. Every point of K then is a limit of convex combinations of extreme points. Can the limit always be realized by an integration ? This is the question that Choquet theory, in its original form, answered affirmatively: every point of K is the barycentre of a probability measure that is carried, in a certain sense, by the extreme points of K. Early versions of this theorem appeared in 1956, and the basic theory was perfected (by the joint efforts of a number of mathematicians) by the early 1960s. Since then it has been much developed, and this account shows us the state of the subject in 1967.

The theory is applied here to prove Bochner's theorem, Bernstein's theorem on completely monotone functions, and the ergodic decomposition of invariant measures. Other applications to potential theory and operator theory are sketched (much work has been done in these two fields, and in simplex theory, since these lectures were given).

The work concludes with a treatment of measures in infinite-dimensional vector spaces which includes a proof, by use of Choquet theory, of the Umemura–Choquet theorem that every rotation-invariant affine measure in an infinite-dimensional pre-Hilbert space is an average of Wiener measures. There is an appendix on potential theory.

The book omits certain proofs that were omitted by the lecturer, but in such cases references to standard works are usually given. There is a large collection of problems, many of them solved in an appendix. There are a good many minor misprints. All foreign words are printed without diacritical marks.

D. A. EDWARDS

CLASSIC ASTRONOMY

Celestial Mechanics

Vol. 5. By the Marquis de la Place. In French. Pp. ix + 508. (Chelsea: Bronx, New York, 1969. First published 1825.) $17.50.

THE reprint of Bowditch's English translation of Laplace's *Mécanique Céleste* has now been completed by a reprint of the fifth volume of Laplace's great work, which Bowditch did not manage to translate. In this volume, which was published many years later than the main body of his work, Laplace collected various supplements to the matters treated in the previous volumes. For us, however, the chief interest of the fifth volume lies in the historical sections, in which Laplace gives, for each topic, a critical account of the work preceding his own. Taken together, these sections present an outline of the whole progress of theoretical astronomy, distinguished by exquisite precision and unequalled mastery in bringing out the essential points. They are not made superfluous by the historical part of the *Exposition du Système du Monde*, in which Laplace had given a more continuous narrative of the same history, treated with less technical detail and a greater display of eloquence; they still deserve to be consulted for any deeper study. Their first-hand assessment of the extremely active and fertile period extending from Newton's *Principia* to Laplace's own researches is particularly valuable. The reprint is made, not from the original edition of 1825, but from the typographically neater and more correct edition of Laplace's collected works, sponsored by the Académie des Sciences (1882). It is not only a useful addition to Bowditch's translation; it will also afford those many collectors and librarians whose set of the original work lacks the fifth volume a welcome opportunity of completing it.

L. ROSENFELD

Correspondence

DDT in Milk

SIR,—In the biased review on DDT by T. H. Jukes (*Nature*, **225**, 301; 1970), I was personally attacked and misquoted. The fact is that I was invited to the DDT hearing in Madison, Wisconsin, in May 1969 by the Assistant Attorney General of the State of Wisconsin, Robert McConnell, who was the public intervenor in the case.

The presence of DDT in human milk was first reported in 1951. The general public was, however, not told about DDT in human milk until I and others in 1968 and 1969 pointed it out. It was then also pointed out that breast-fed babies ingest more DDT compounds than the acceptable daily intake (ADI), and that the ADI was set without considerations to the long-term effects of DDT compounds on the metabolism of endogenous and xenobiotic compounds as well as to the carcinogenic action in mice of low DDT doses.

The review by Jukes is not even modest—it is meagre. He apparently thinks that possible negative effects of DDT only are acute toxicity symptoms—exactly as the arguments of those who have a vested financial interest that DDT is used indiscriminately—completely disregarding the possible late, long-term effects.

We know now some of the late effects of DDT compounds on wildlife; partly from multi-generational studies. Man has not yet been exposed to the organochlorine pesticides for a full lifetime. As we have very few anamnestic data, we will probably never be able to acquire the epidemiological variables which are necessary for an evaluation of the possible actual hazards.

The use of DDT and other organochlorine compounds has been so ingeniously advocated that we no longer have any proper controls. This is a sufficient reason to ban these almost persistent compounds completely. We may argue about the time to complete the de-escalation, be it one year, two or at most five years, but no other discussions are necessary.

Yours faithfully,
GÖRAN LÖFROTH

University of Stockholm,
Stockholm, Sweden.

Enzymes in Crystals

SIR,—In response to the recent article by your Molecular Biology Correspondent on "Enzymes in Crystals" (*Nature*, **225**, 225; 1970), we would like to clarify his statement concerning the "pardonable satisfaction" with which Professor Lipscomb is said to "contradict with confidence" the amino-acid sequence of carboxypeptidase A as deduced in our laboratory (Bradshaw *et al.*, *Proc. US Nat. Acad. Sci.*, **63**, 1389; 1969). While the interpretation of the X-ray data by Professor Lipscomb and co-workers (Lipscomb *et al.*, *Proc. US Nat. Acad. Sci.*, **64**, 28; 1969) may contradict three points in the chemical sequence, we, in turn, take a certain degree of satisfaction in being able to supply unequivocal chemical evidence in support of our reported assignments.

It has been established that there are two forms of the enzyme differing at three sites in the polypeptide chain (Pétra *et al.*, *Biochemistry*, **8**, 2762; 1969). Professor Lipscomb believes—solely on the basis of X-ray assignments—that the enzyme used in his studies was of the valine type (Pétra and Neurath, *Biochemistry*, **8**, 2466; 1969). Taking this report at face value, we have prepared pure valine enzyme, by chromatographic means, in order to avoid the allotype controversy. An analysis of the tryptic peptides was conducted specifically to re-examine the residue in position 151. In agreement with our previous report, we have found this residue to be phenylalanine, whereas Professor Lipscomb and co-workers interpreted it to be tryptophan. Although re-examination of the other two sites (residues 93 and 245) in genetically pure enzymes has not been made, there is no question that in the pooled enzyme preparations used in the original studies the chemical identification is correct. At worst, these discrepancies may be due to allotypic variations not previously uncovered.

We do not enjoy a polemic of the relative merits of X-ray and chemical methods for the determination of the structure of an enzyme since, in the final analysis, a combination of both of these methods is the most expeditious approach to the total determination of structure. We feel compelled, however, to set the record straight, to avoid misinterpretation of the report of your Molecular Biology Correspondent.

Yours faithfully,
HANS NEURATH
KENNETH A. WALSH
RALPH A. BRADSHAW

Department of Biochemistry,
University of Washington,
Seattle, Washington,
and
Department of Biological Chemistry,
Washington University School of Medicine,
St Louis, Missouri.

Our Molecular Biology Correspondent writes:

It was certainly not my intention to whip up from the ringside a contest between the sequencers and the crystallographers. And to be fair, Lipscomb and his colleagues did firmly make the point that sequencing by X-ray structure analysis is not on, and probably never will be. It is interesting, just the same, to see how many errors in sequences have been uncovered by crystallographic studies, and indeed how few sequences since insulin have proved correct in every detail—which proves merely that sequencing is still an arduous trade. Professor Neurath's interesting letter shows that there can be other problems than the purely chemical to make life hard for sequencers and crystallographers alike. At the same time there is clearly a conflict still to be resolved between the chemical and crystallographic data. Meanwhile, to set the record straight, Professor Neurath's satisfaction is no whit less pardonable than that of Lipscomb *et al.*

Sternglass's Assumptions

SIR,—Lindop and Rotblat state in their article in *Nature* (**224**, 1257; 1969) that they see no reason why the logarithm of infant mortality should decrease linearly with time; in fact, such a law follows from the simplest of hypotheses. The probability S of an infant surviving a given year is assumed given by the formula $S = \underset{i}{\pi}(1-p_i)$, with p_i the probability of succumbing to the ith hazard in that year; thus $\ln S = \underset{i}{\Sigma}\ln(1-p_i)$. It is now reasonable to assume that a given fraction k of the existing hazards is removed each year, so that $d(\ln S)/dt = -k \ln S$, from which $\ln\ln S = A - kt$, with A another constant. Since the annual infant mortality I is equal to $1-S$, we find that $\ln\ln(1-I)$ varies linearly with time. When I is small compared with unity (the case considered by Sternglass) a linear variation of $\ln I$ itself is predicted; for larger values of I a departure from linearity occurs.

Yours faithfully,

PHILIP L. TAYLOR

Case Western Reserve University,
Cleveland, Ohio 44106.

View that may Upset Scientists

SIR,—Your editorial of January 31 (*Nature*, **225**, 397; 1970) attacked the Thames documentary "And on the Eighth Day" as a symptom of a current "sense of hysteria" over pollution. I will happily defend the programme both in detail and overall, but I think the most important point for your readers is that you misinterpret the message of the film. It is not at all "an attack on rationalism and the pursuit of scientific knowledge". Quite the contrary. What the film queries is whether what today passes for scientific method is a sufficiently sophisticated instrument to cope with complex environmental problems.

In the programme we were arguing that pollution was certainly a cost that ought to be taken into account by industry and had not been. But we were also warning that scientific research could be just as narrow and misleading as old fashioned accountancy. Laboratory results may be incontestable in the laboratory but utterly misleading if too readily applied to the more complex circumstances of the environment. The interaction of variables may mean that the picture as a whole is quite different from the sum of its parts. I am not a scientist, but it seems to me that scientists ought to be examining (more humbly than your editorial) the appropriateness of their methods and outlook to the solution of complex problems.

I think they will also have to accept that if these problems affect all of us then non-scientists will have views on them. If in some respects the world is now a laboratory in which we are all experimental animals, we are unlikely to be reassured by a scientific outlook (or an industrial one) that says that because a danger is not proven with full scientific rigor nothing should be done about it. We cannot wait for proof if the proof may simply confirm that harm is already happening to us.

This view may upset some scientists. Let me make it clear that I do not suggest that a scientist as a scientist should deviate from the most rigorous search for scientific proof. But scientists are also citizens and if, before they have definite proof, they begin to fear that what they are investigating may point to widespread and long term dangers for everyone, they have a duty as citizens to say so. This should not then influence the scientific investigation of these possible dangers, but it most assuredly should influence public policies that may be creating dangers. It should transfer the onus of proof from the critics of hazards to the creators of them—the industrialist, the Atomic Energy Commission, the food manufacturers, the local authorities, the fertilizer producers, the drug manufacturers and so forth.

We cannot continue to assume that any scientific or technological innovation is fine until someone has spent 10 years proving otherwise. That is what the argument is about. You ask confidently, "Must man really be forbidden to use fire?" Your choice of metaphor is unwise. There are many occasions when men are forbidden to use fire, and rightly. And there are few things more terrifying than fire carelessly used and out of control.

Yours faithfully,

IAN MARTIN

Thames Television Limited,
Kingsway,
London WC2.

University News

Dr Baruj Benacerraf has been appointed Fabyan professor of comparative pathology and head of the Department of Pathology at **Harvard Medical School. Professor Ralph Mitchell** has been appointed Gordon McKay professor of applied biology in the Division of Engineering and Applied Physics at **Harvard University.**

Professor H. Jones has been appointed Pro Rector of the **Imperial College of Science and Technology, University of London,** and **Professor J. D. Smyth** has been appointed to the chair of parasitology at the College.

Dr Eric R. Bryan has been appointed professor of structural engineering in the Department of Civil Engineering, **University of Salford.**

Appointments

Mr Reginald G. Voysey has been appointed deputy director at the **National Physical Laboratory.**

Professor Lloyd Motz, Columbia University, has succeeded Dr Irving J. Selikoff as president of the **New York Academy of Sciences.**

Professor Walther Manshard, Justus Liebig University, has been appointed director of **Unesco's Department of Environmental Sciences and Natural Resources Research.**

Dr Alan L. Pinkerson has been appointed assistant chief of the **Myocardial Infarction Branch of the National Heart and Lung Institute, US National Institutes of Health.**

Captain A. A. Murphy has been appointed director of the **Guided Weapons Research and Development (Naval) Branch, Ministry of Technology,** in succession to **Captain K. A. W. Pilgrim.**

Dr L. Rotherham, vice-chancellor of Bath University of Technology, has been appointed chairman of the **Advisory Committee for Scientific and Technical Information, Department of Education and Science,** in succession to **Dr F. S. Dainton.**

Announcements

Professor B. L. Horecker, Albert Einstein College of Medicine, has been elected vice-chairman of the **Pan-American Association of Biochemical Societies** for 1971, and will succeed **Dr D. R. Whitaker,** National Research Council of Canada, as chairman, in 1972.

Professor F. S. LaBella, University of Manitoba, has been awarded the **1969 Steacie Prize** in natural science.

The third **Clark Kerr award** for extraordinary and distinguished contributions to higher education will be presented to **Sir Eric Ashby.**

The managing trustees of the **Drummond Trust** invite applications for a senior Drummond fellowship for research in nutrition. The fellowship will normally be tenable for 2 years and preference will be given to biochemists with interests in the field of inherited metabolic disease. Further details can be obtained from the Honorary Secretary, Drummond Trust, University College London, Gower Street, London WC1.

Sabbatical Itinerants

In the hope of providing some practical assistance in the good cause of mobility between laboratories, *Nature* advertises the needs for housing of families about to take up periods of sabbatical leave. To begin with, no charge will be made for advertisements like this. It is hoped that a period of experiment will show what form these advertisements could most usefully take and whether they are effective.

Wanted: Pharmacologist, wife and boy of 3, en route from Addis Ababa to Hong Kong, wish to rent small furnished house for 2 weeks only from June 27 to July 11, 1970. Preferably W, NW or SW London suburban area. Please contact Dr M. Roberts, PO Box 30015 MA, Addis Ababa, Ethiopia.

Wanted: Small furnished flat in London for American academic couple, June through August. Please contact J. K. DeVries, Department of Microbiology, New York University Medical Center, 550 First Avenue, New York, NY 10016, USA.

Wanted: 2 or 3-bedroomed furnished house or flat for visiting fellow at Clare Hall, Cambridge, June 1 to August 31, 1970. Children aged 14 and 20. Please contact J. M. Smithells, White Cottage, Godstone, Surrey.

Wanted: 4-bedroomed furnished house in or near Cambridge for 1 year from either July 1 or August 1, 1970 (by arrangement), by Canadian professor, wife and family of four children aged 9–15. Garage desirable but central heating essential. Please contact Professor G. H. Dixon, Department of Biochemistry, University of British Columbia, Vancouver 8, Canada, or Mr and Mrs Derek Anderson, 11 Spring Lane, Bottisham, Cambridgeshire (telephone Bottisham 583).

Wanted: Small house or flat for married couple in Pittsburgh, Pennsylvania, from summer 1970 for 12 months. Please contact J. L. Finney, Department of Crystallography, Birkbeck College, Malet Street, London WC1.

Vacant: Small, furnished 3-bedroom 1930s style house in West London to let for 6 months from March 27, 1970. Near Hanger Lane underground and shops, 30 min to West End by train. £65 a month. Please contact Dr A. Goldsworthy, Botany Department, Imperial College, London SW7.

Vacant: From June 1 until August 31. 4-bedroom ranch-type house in select location, fully furnished, with air-conditioning and air purification, 2 bathrooms, 2 fireplaces, full basement, garage. Rent reasonable. Owner going abroad for summer. Please contact Dr D. F. Moore, 327 Engineering Sciences Building, West Virginia University, Morgantown, West Virginia 26506, USA.

Vacant: Furnished house in London, with 4 bedrooms, central heating. Available June to September 1970. Please contact Dr L. V. Crawford, 63 Swain's Lane, Highgate, London N6.

Vacant: 3-bedroomed, centrally heated house in Blackheath, SE London. Newly decorated and fully furnished. Large garden, and close to woodland and the river. Frequent train service to Charing Cross (25 minute journey) or easy drive. Available between July 1970 and September 1971. Please contact J. L. Finney, Department of Crystallography, Birkbeck College, Malet Street, London WC1.

British Diary

Monday, March 2

Developments in the Use of Plastics in Railway Rolling Stock (6 p.m.) Mr B. J. Hawthorne, Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

Physics Exhibition (four days) Institute of Physics and the Physical Society, at Alexandra Palace, London.

Stereophonic Transmission (7 p.m.) Mr G. J. Phillips, Institution of Electrical Engineers, at the Royal Star Hotel, Maidstone, Kent.

Structural Enzymology (1): Conformations of Enzyme Molecules (5 p.m.) Professor D. C. Phillips, University of London, at the Middlesex Hospital Medical School, Mortimer Street, London W1.

The Competition for Cash between Innovation and Extension (6.30 p.m.) Dr D. S. Davies, Society of Chemical Industry, at 14 Belgrave Square, London SW1.

The First Steps Into Space (8 p.m.) Professor R. A. Lyttleton, FRS, University of Hull, in the Middleton Hall. (The St John's College, Cambridge, Lecture.)

The Value of Polymer Blends (7.30 p.m.) Mr P. W. Milner, Institution of the Rubber Industry, at the Midland Hotel, Burton-on-Trent.

Tuesday, March 3

Banking and Automation (5.30 p.m.) Mr P. J. V. Ashurst, Institution of Electrical Engineers, at Savoy Place, London WC2.

Indirect Pressure Measurement (5.30 p.m. discussion) Institution of Electronic and Radio Engineers, Joint IEE/IERE Medical Biological Electronics Group, at the Institution of Electrical Engineers, Savoy Place, London WC2.

Pulse Code Modulation (7.15 p.m.) Mr G. H. Bennett, Institution of Electrical Engineers, at the Aylesbury College of Further Education, Aylesbury, Bucks.

Safety in the Design of Process Plant (6 p.m. discussion) Institution of Mechanical Engineers, Process Engineering Group, at 1 Birdcage Walk, London SW1.

Some Bronze Age, Iron Age and Early Medieval Settlements in the Netherlands (5.45 p.m.) Professor H. T. Waterbolk (Groningen), University of London, at the Institute of Archaeology, 31–34 Gordon Square, London WC1. (Further lectures on March 5 and 10.)

The Biology of Dolphins (5.30 p.m.) Professor R. J. Harrison, Royal Institution, at 21 Albemarle Street, London W1. (Lecture for Sixth Form Pupils from Schools in London and the Home Counties. To be repeated on March 4, 10 and 11.)

The Development of the Hypothesis of Continental Drift (5.30 p.m.) Professor H. Martin (Göttingen), University of London, at Senate House, London WC1. (Further lecture on March 5.)

Ultrastructure of Blue-Green Algae (5.30 p.m.) Professor Norma J. Lang, University of London, in the Botany Lecture Theatre, University College London, Gower Street, London WC1. (Further lecture on March 4 at King's College Department of Botany, 68 Half Moon Lane, Herne Hill, London SE24.)

Wednesday, March 4

Electroluminescence Solid State Devices (5.30 p.m. Joint IEE/IPPS Conference), at Savoy Place, London WC2.

Interferometric Determination of EHL Contact Pressures (6 p.m.) Mr D. L. Cope and Mr D. J. Haines, Institution of Mechanical Engineers, Tribology Group, at 1 Birdcage Walk, London SW1.

Mathematical Notation (1 p.m.) Dr H. R. Calvert, Royal Institution, History of Science Discussion Group, at 21 Albemarle Street, London W1.

Measurement of Stress Cracking Resistance (2.30 p.m.) Mr R. A. Horsley, Plastics Institute, at 11 Hobart Place, London SW1.

Recent Developments in Test Sieving (5.30 p.m.) Dr J. E. English, University of London, at King's College, Strand, London WC2.

Some Other Turbid Medium Theories (3 p.m.) Mr S. Orchard; **The Optical Variables in White Paint Films** (4.05 p.m.) Mr D. F. Tunstall, The Colour Group (Great Britain) in the Physics Department, Imperial College, Prince Consort Road, London SW7.

Structural Enzymology (2): Enzyme Substrate Interactions (5 p.m.) Professor D. C. Phillips, University of London, at the Middlesex Hospital Medical School, Mortimer Street, London W1.

Superconductors: With Us Today or Tomorrow? (7.30 p.m.) Dr W. T. Norris, Institution of Electrical Engineers, at the Martineau Hall, Dorking Halls, Dorking, Surrey.

Surface Area Determination (2 p.m.) Mr I. C. Edmundson, Mr A. S. Joy, Mr R. W. Lines and Mr N. G. Stanley-Wood, Society for Analytical Chemistry, Particle Size Analysis Group, in the Chemical Engineering Department, University of Technology, Loughborough.

The Continuing Education and Development of Professional Electronic Engineers (6 p.m.) Dr K. G. Stephens, Institution of Electronic and Radio Engineers, at 9 Bedford Square, London WC1.

Toxicity in Polymers (6.45 p.m.) Institution of the Rubber Industry, at John Dalton College of Technology, Chester Street, Manchester.

Why Sociology? (1.15 p.m.) Dr Ernest Krausz, City University, at the Graduate Business Centre, Gresham College, Basinghall Street, London EC2.

Thursday, March 5

Automation of Thermal Power Stations in the USSR (6 p.m. discussion) Institution of Mechanical Engineers, and the Institution of Electrical Engineers, at 1 Birdcage Walk, London SW1.

Direct Digital Control Without a Computer (6 p.m.) Mr C. C. Lawson, Institution of Electronic and Radio Engineers, at 9 Bedford Square, London WC1.

Effective Incentives for Productivity (all-day discussion) Institution of Mechanical Engineers, Manufacture and Management Group, at 1 Birdcage Walk, London SW1.

Psychological Aspects of Short-Term and Long-Term Memory (4.30 p.m.) Dr D. E. Broadbent, FRS, Royal Society, at 6 Carlton House Terrace, London SW1.

Radar Meteorology (5.30 p.m.) Dr E. Eastwood, Institution of Electrical Engineers, at Savoy Place, London WC2.

The Influence of Freezing Practice on the Quality of Fish and Meat (6 p.m.) Dr C. L. Cutting, Institute of Refrigeration, at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London SE1.

Friday, March 6

How Plants Grow (9 p.m.) Professor F. C. Steward, FRS, Royal Institution, at 21 Albemarle Street, London W1.

Photochemistry of Quinones in Solution (1 p.m.) Mr D. Kemp, Royal Institution, Photochemistry Discussion Group, at 21 Albemarle Street, London W1.

Saturated Leakage Reactance of Cage Induction Motors (5.30 p.m.) Dr B. J. Chalmers and Mr R. Dodgson, Institution of Electrical Engineers, at Savoy Place, London WC2.

Structural Enzymology (3): The Evolution of Enzymes (5 p.m.) Professor D. C. Phillips, University of London, at the Middlesex Hospital Medical School, Mortimer Street, London W1.

Monday, March 9

Management by Objectives (6 p.m. discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

Myrtos: an Early Bronze Age Settlement in Crete (5.45 p.m.) Dr P. Warren, University of London, at the Institute of Archaeology, 31–34 Gordon Square, London WC1.

Training—a Systems Approach (5.30 p.m.) Captain G. Huggett, Institution of Electrical Engineers, at Savoy Place, London WC2.

New Fabri-Tek 1010

True Signal Averaging

at a new low price . . .

$4,400*

FEATURES

■ Low Cost ■ True Signal Averaging ■ Ease of Operation ■ Input Filter ■ Sweep Speeds From 20 Microseconds/Address to 200 Seconds/Sweep ■ Visual Sweep Counter ■ Autostop After Selected Number of Sweeps ■ Pushbutton Calibration for Oscilloscope and X-Y Recorder Outputs

The Fabri-Tek Model 1010 Signal Averager is not a stripped down version of a more versatile unit. This low cost computer utilizes the most up-to-date technology (it's made almost entirely of integrated circuits) and sacrifices none of the essentials of a complete signal averaging system. It is a completely digital system with a 256 word magnetic core memory.

The unique circuitry does not resort to unequal weighting of individual inputs (weighting techniques which emphasize more recent data), but rather presents the user with a true average of the input signal regardless of the number of sweeps.

Automatic data normalization is one of the key features of this single input signal averaging computer. A completely new approach automatically provides the user with normalized data regardless of the sweep speed or the number of sweeps selected. At the same time this computer is easier to use than most laboratory oscilloscopes. Pushbutton programming, for instance, greatly simplifies and speeds up the operation.

The input signal can be viewed for set-up purposes while adjusting the sensitivity and trigger threshold. External address advance is included. A pre-filter is provided for optimizing the signal-to-noise ratio improvement as well as avoiding "aliasing" errors due to high frequency noise. Calibration of X-Y plotter or oscilloscope outputs is simplified by means of pushbutton controls. A meter is provided to indicate the number of pre-set sweeps completed. "Real-time" readout is available for comparing averaged signal to raw signal or for spectral analysis.

*U.S.A. and Canada

CENTRAL ELECTRICITY GENERATING BOARD

South Western Region

Scientific Services Department

HATCHERY SUPERVISOR

Applications are invited for the above post at the Board's established Salmon Hatchery and Smolt Rearing Station situated on the River Cynrig, near Brecon. The Hatchery is part of the Environmental Science Section of the South Western Region Scientific Services Department which is based at Portishead, near Bristol.

The main function of the Hatchery is to incubate and rear salmon from the ova to the smolt stage but there is scope for experimental feeding programmes and fish husbandry methods to optimize smolt production.

In addition, there could be opportunities within the Environmental Science Section for general activities concerned with River Boards and fish farming projects within the Region.

Applicants should hold a qualification in Biology, or have considerable practical experience in hatchery operation, or alternatively have worked for some time in a fisheries laboratory. The successful applicant will be responsible for running the Hatchery with one full time assistant.

Salary will be within the range £1,479–£2,139 plus £60 per annum allowance.

Point of entry will depend on qualifications and experience. The supervisor is required to live in a modern house on the Hatchery site for which a rent will be charged.

Good holidays, sick pay and superannuation schemes are in operation.

Applications on form SF/1 obtainable from the **Personnel Manager, Central Electricity Generating Board, 15-23 Oakfield Grove, Clifton, Bristol BS8 2AS,** *should be completed and returned to him (quoting vacancy number 95/70) by not later than 30th March 1970.* (868)

IMPERIAL CANCER RESEARCH FUND

Department of Tumour Virology

POST-DOCTORAL BIOCHEMIST required to study cell membranes, especially the function of their contained lipid. Three- or five-year appointment. Starting salary in the range £1,700 by £115 to £2,275 plus £60 London Allowance p.a.

Applications accompanied by a curriculum vitae and the names of two referees should be sent to:

The Secretary, Imperial Cancer Research Fund,
P.O. Box 123, Lincoln's Inn Fields, London W.C.2.,

to arrive by March 21, 1970.

(880)

CITRUS RESEARCH

Applications are invited for the post of AGRONOMIST, Citrus Research, University of the West Indies. Appointment will be made by the British Caribbean Citrus Association on a salary scale: $J2,800 by $J180 to $J3,160 by $J200 to $J4,560 by $J220 to $J7,200 ($J2 = £1 sterling). The post is tenable in Jamaica. Preference will be given to persons with qualifications and/or experience in pathology.

Applications (four copies), giving brief details of education, experience, personal information and nominating three referees, should be submitted on or before March 31, 1970, to: Head, Citrus Research, University of the West Indies, St. Augustine, Trinidad, W.I., from whom further particulars can be obtained. (696)

UNIVERSITY OF SHEFFIELD

DEPARTMENT OF HUMAN BIOLOGY AND ANATOMY

LECTURER required commencing October, 1970. Applicants should be capable of teaching topographical anatomy to medical students. Excellent research facilities are available. An interest in neurological anatomy or experimental haematology would be desirable but not essential. Initial salary according to qualifications and experience on the scale £1,240 by £115 to £2,850 with F.S.S.U. provision. Candidates should write informally in the first instance to Professor R. Barer giving details of training and interests. Quote Ref. R.2/G. (808)

For further Classified advertisements see page va

THE BRITISH COUNCIL

LEBANON

THE LEBANESE UNIVERSITY, BEIRUT, requires a LECTURER IN THERMODYNAMICS by mid-October, 1970. Candidates should have a Ph.D. degree, or its equivalent from a university in Britain. Some teaching and research experience at university level is desirable.

Salary: £2,335 to £2,910 per annum according to qualifications and experience. Terms for a two-year period as follows: Married overseas allowance within the following ranges: accompanied £593 to £418, unaccompanied £373 to £198. Children's and home education allowances. Income tax refunded if levied. Free furnished accommodation. Outfit grant. Employer's superannuation contribution paid. Medical and insurance schemes. Fares paid for Lecturer and family, including mid-tour passages for children in Britain. Assistance with freight and import duty on approved car. Contract guaranteed by the British Council.

Write quoting reference number 9PU61 to Appointments Division, The British Council, 65 Davies Street, London W1Y 2AA, for further particulars and application form to be returned completed as soon as possible. (804)

UNIVERSITY COLLEGE CARDIFF

DEPARTMENT OF PHYSIOLOGY

Applications are invited for two LECTURESHIPS IN PHYSIOLOGY from October 1, 1970, or an earlier date to be arranged. Salary within the range £1,240 by £115 to £2,850 with F.S.S.U. benefits: initial salary according to qualifications and experience. For medical or dental graduates this will normally be not less han £1,585 per annum.

Medical or dental graduates who wish to have one or more years' experience of preclinical work are eligible to apply, or to make preliminary inquiries from either Professor R. C. Jordan or Professor V. R. Pickles (Head of Department). One post may be of interest to applicants preparing for the **Primary F.R.C.S.** examination, who would be given appropriate facilities. In such cases the post would be limited to the period October 1970-June 30, 1971, and the salary would be at the rate of £1,355 per annum.

Applications, with curriculum vitae and the names of 2 referees, should be sent by March 16 to the Registrar, University College, P.O. Box 78, Cardiff CF1 1XL, from whom further details can be obtained. (817)

WOOLWICH POLYTECHNIC

LONDON, S.E.18

DEPARTMENT OF BIOLOGY AND CELL SCIENCE

A vacancy exists for the post of

LABORATORY TECHNICIAN

Preference will be given to applicants in the field of animal physiology; experience of animal house maintenance would be an advantage. Day release by arrangement.

The work of the Department includes courses leading to a B.Sc. in Applied Biology and to M.Phil. and Ph.D. by research.

Salary scale: £745 (unqualified) to £1,125 (qualified) plus £75 London Weighting Allowance.

Commencing salary according to age and qualifications.

Further particulars and application form, to be returned by March 17, 1970, from the Clerk to the Governing Body, Woolwich Polytechnic, Wellington Street, London, S.E.18 (01-854 9624, Ext. 12). (832)

Physical Organic Chemist

The Medicinal Chemistry Department of our expanding Research and Development Group in Loughborough has a vacancy for an Organic Chemist with experience and a pronounced interest in all physical techniques required in modern drug research. This will include a sound familiarity with all types of spectroscopy and a basic knowledge of molecular-orbital theories.

The successful candidate will be in charge of a group of staff concerned with the establishment of routine physico-chemical data related to compounds designed in the Medicinal Research Laboratories. In the context he will also provide a service to other departments.

His main function will be to participate in and supervise all investigations of a physico-chemical nature related to problems arising from drug research. In this responsibility he will liase closely with the Project Leaders and research personnel both inside and outside the department. He will be expected to keep himself informed on all new developments in his area of interest and he will be required to introduce new and useful techniques when they become available. As a senior member of our research staff he will be encouraged to attend scientific meetings and to publish scientific papers.

The man appointed will work in a modern, well-equipped department at our new Research and Development Laboratories at Loughborough.

We are a member of the Fisons Group providing a first class pension scheme, generous holidays, assistance with removal expenses where applicable and other welfare benefits which come from being part of a large internationally known British Group. Applications quoting job reference No. 308 should be addressed to Divisional Personnel Manager, Research Laboratories,

FISONS

Fisons Pharmaceuticals Limited,
Bakewell Road,
Loughborough,
Leics.

(814)

The STATE UNIVERSITY of LEIDEN

invites applications or suggestions for a

FULL PROFESSOR in GENETICS

He will be charged with lectures and courses in general genetics and with the direction of the research in population genetics and development genetics.

Applications, including curriculum vitae and references or suggestions, should be sent as soon as possible to: The Faculty of Science, University of Leiden, Rapenburg 46, Leiden, The Netherlands.

(836)

THE UNIVERSITY COLLEGE OF WALES

ABERYSTWYTH

DEPARTMENT OF BOTANY

Applications are invited for the post of LECTURER. Candidates should have a special interest in Physiological Ecology (preferably Microclimatology) and/or Whole Plant Physiology.

Application forms and further particulars are available from the Registrar, quoting reference LEB/3, and should be returned as soon as possible. (873)

TECHNICIAN

For the Department of Microbiology and North West London Public Health Laboratory, Central Middlesex Hospital, Park Royal, London, N.W.10. This post offers progressive training in both public health and clinical bacteriology, providing excellent opportunity for further study in microbiology.

Applications to Dr. C. E. D. Taylor, Director, at the above address. (874)

IMPERIAL COLLEGE
(Physics Department)
LECTURER OR RESEARCH ASSISTANT

A vacancy exists for a Lecturer or Research Assistant in Solid State Theory in the Physics Department at Imperial College (for Lectureship some post-doctoral experience would be required). The person appointed will work in a small but growing solid state theory group with strong links with the experimental group working in superconductivity and magnetism.

Salary will be in the range £1,240 by £115 to £2,850 plus £60 London Allowance, depending upon age and experience.

Applications, with full details and names of two referees to Professor B. R. Coles, Physics Department, Imperial College, London, S.W.7, by March 10, 1970.

(736)

INSTITUTE OF OPHTHALMOLOGY
(UNIVERSITY OF LONDON)
JUDD STREET, LONDON, W.C.1

DEPARTMENT OF PATHOLOGY

An opportunity now occurs for an experienced TECHNICIAN to join the research staff of the above Department in studying the retinal vasculature in health and disease.

Preferably candidates should have at least O.N.C., I.M.L.T., or equivalent. A knowledge of immunology, histology or animal experimentation would be an advantage.

Please apply in writing, stating age, sex, qualifications, experience, and giving the names of two referees to The Director, Department of Pathology, at the above address. (887)

AGRICULTURAL RESEARCH COUNCIL

FOOD RESEARCH INSTITUTE

An industrial grant has been made to the Food Research Institute for research on the chemical nature of the compounds responsible for the fishy taint in poultry meat and on the relationship of the compounds to the lipids in the diet. The grant, which is for two years in the first instance and which may be extended for a third year, is for the support of one POST-DOCTORAL RESEARCH WORKER and an assistant.

Applications are invited from CHEMISTS/BIOCHEMISTS with post-doctoral experience to work on this subject. A suitable candidate would be a lipid chemist with experience of instrumental analysis of fatty acid oxidation products. The successful candidate will work in the lipid section of the Chemistry Division.

Salary will be according to experience in the £1,600 to £2,000 per annum range. Superannuation under F.S.S.U.

Further information may be obtained from the Secretary, A.R.C. Food Research Institute, Colney Lane, Norwich NOR 7OF, to whom applications, in the form of a curriculum vitae, a bibliography and the names of three referees, should be sent by March 1, 1970. (810)

THE SCHOOL OF PHARMACY

UNIVERSITY OF LONDON

LECTURESHIP IN PHARMACOGNOSY

Applications are invited from suitably qualified persons for an appointment as a Lecturer in the Department of Pharmacognosy, commencing on September 1, 1970. The successful candidate will be expected to carry out teaching and personal research in a field acceptable to the Head of the Department.

Salary on an incremental scale from £1,240 per annum to £2,850 per annum, plus London Allowance of £60 per annum. Point of entry on the scale will depend on qualifications and experience. Membership of F.S.S.U. and normal University terms of service apply to this appointment.

Applications in the form of a letter accompanied by a curriculum vitae and names of at least two persons to whom references may be made, should be submitted not later than March 31, 1970, to the Clerk to the Council, The School of Pharmacy, University of London, 29/39 Brunswick Square, London, W.C.1, from whom further details may be obtained. (877)

GOVERNMENT OF NORTHERN IRELAND
MINISTRY OF AGRICULTURE

Parasitologist

Applications are invited for a permanent and pensionable post in the Veterinary Research Laboratories, Stormont, Belfast.

The laboratories are of recent construction and are equipped for a wide range of techniques. A total of 120 professional and technical staff are employed in the major disciplines of pathology, bacteriology, virology, biochemistry and parasitology. The work of the laboratories consists of routine diagnosis and research on diseases of farm animals.

QUALIFICATIONS: MRCVS or veterinary degree. Postgraduate experience in parasitology is essential.

DUTIES: The officer appointed will take charge of the Parasitology Department and will be required to provide a routine diagnostic service but the major portion of his time will be available for research on parasitic diseases of farm animals.

SALARY SCALE: Senior Veterinary Research Officer (Grade II) £3,043–£3,883

Veterinary Research Officer (Grade I) £2,349–£2,846

Grading and starting salary will be related to qualifications and experience. Application forms and further information, obtainable from the Secretary, Civil Service Commission, 45 Chichester Street, Belfast, BT1 4JU, must be returned by March 23, 1970. Please quote SB.37/70/64.

(830)

SALMON AND FRESHWATER FISHERIES LABORATORY

Ministry of Agriculture, Fisheries and Food
Fish Pathology Unit, Weymouth, Dorset.

VIROLOGIST/BACTERIOLOGIST (graded Experimental Officer/Assistant Experimental Officer) required for research on viral and bacterial diseases of fish with special interest in those affecting salmon. This entirely new field of work offers the opportunity for applied research in relation to a specific and urgent problem the solution of which is of considerable economic importance.

This post will involve mainly laboratory work, though some field work will also be undertaken, and there will be collaboration with other Laboratories in Scotland and Ireland working on similar problems.

Qualifications: Degree HNC or equivalent in appropriate subject. It is desirable that candidates should be **either** Fellows of the Institute of Medical Laboratory Technology with experience in virological techniques and tissue culture methods, **or** Associates of the Institute, with Final Virology, preferably with some experience in bacteriology: or that they should have a degree in Microbiology. Age: AEO under 28. EO normally 26–30. Non-contributory pension; prospects of promotion.

Salary: AEO £940 (at 22) to £1,208 (at 26 or over) to £1,454; EO £1,590 to £2,006.

APPLICATION FORMS are obtainable by writing to the Civil Service Commission, Savile Row, London W1X 2AA, or by telephoning 01-734 6010, ext. 229 (after 5.30 p.m. 01-734 6464 "Ansafone" service). **Please quote S/94/MAF/8.**

Closing date March 17, 1970.

(812)

UNIVERSITY OF NEWCASTLE UPON TYNE

SECOND CHAIR OF ELECTRICAL ENGINEERING

APPLICATIONS are invited for the newy created Second Chair within the Department of Electrical and Electronic Engineering. Candidates should have a special interest in the field of light electrical engineering or in electrical materials technology. The successful candidate will be required to take up duty at a date to be arranged as early as possible in the academic year 1970/71. Salary in accordance with the professorial scale (£3,780 by £140 to £4,480 per annum) with membership of F.S.S.U.

Further particulars may be obtained from the Registrar of the University, 6 Kensington Terrace, Newcastle upon Tyne, NE1 7RU, with whom applications (15 copies), giving the names of not more than three referees, must be lodged not later than March 3, 1970. (678)

THE UNIVERSITY OF LEEDS

Applications are invited for posts in the following Departments:

HOULDSWORTH SCHOOL OF APPLIED SCIENCE

RESEARCH STUDENTSHIPS

for a variety of interesting investigations into the preparation, structure and properties of high-temperature non-metallic materials, including oxides, silicon nitride, silicates (both crystalline and vitreous), and chrome-magnesite and other refractories. The research areas include mechanical properties, electrical conduction, optical transmission, kinetics and mechanisms of chemical reactions, chemical aspects of friction, crystal structure and microstructure, computer work with mathematical models and fabrication science of ceramics and glasses. Grants will be in accordance with S.R.C. rates.

Applications (two copies), stating age, education, qualifications and experience, together with the names of three referees, should reach Professor J. P. Roberts, Department of Ceramics, The University, Leeds, LS2 9JT (from whom further particulars may be obtained) as soon as possible.

MECHANICAL ENGINEERING

RESEARCH MATHEMATICIAN or ENGINEER

on the new phase of the hydrofoil research programme planned for the coming three years. Applicants should possess a good honours degree in applied mathematics, engineering or physics and preferably be experienced in hydrodynamic theory and experimentation. In contact also with the Applied Mathematics Department of the University, the appointment would aim at further improvement of understanding of ventilating and cavitating flows round hydrofoil systems. Salary dependent on age and qualifications, which could rise to £2,235 a year.

Applications (one copy), with names of at least two referees, should be addressed to **Professor B. N. Cole, The University, Leeds, LS2 9JT** (from whom further particulars may be obtained). (851)

POSTDOCTORAL RESEARCH POSITION available as soon as possible. Minimum salary $US7,000. Temple University School of Medicine, Philadelphia, Pa., U.S.A. Research of immunological tolerance and immunological aspects of myeloma tumours.—Further details from Dr. H. Francis Havas, Department of Microbiology, Temple University School of Medicine, 3400 N. Broad Street, Philadelphia, Pa., U.S.A. (621)

Unicam UV Spectrophotometers make light work

What does this mean to you? In research, results you can trust and repeat. In routine applications, error-free operation by the least experienced member of your staff.

When you come to Pye Unicam, even the selection of your UV spectrophotometer is simple. There is a choice of instruments broad enough to meet your every requirement and to match your budget, with a staff of experienced application specialists to back them up.

Just look at what is available . . . **SP500 Series 2** and **SP600 Series 2** quantitative single beam spectrophotometers, **SP700** for research, **SP1800** for low-cost double-beam operation, **SP3000** automatic digital instrument, **SP8000** for the ultimate in flexibility, and th **SP1300 Series 2** low-cost colorimeter.

Write or 'phone for free information today. That's simple too, isn't it.

The History of Difco Quality Control...

and what it means to you today

Difco was developed by producing better products through control of quality.
Now there is a history of more than seventy years of dedication to accuracy and dependability, specialized equipment, exacting materials control.
It's a history of a unique kind of control. Difco tests each ingredient before it is accepted for use. Testing throughout preparation assures compatibility.
The finished product is then tested for dependable performance under the conditions for which the product is intended. Result? Perfectly standardized products that give reproducible results every time.
What does it mean to you?
Assured reliability. Savings in time and money.
Dependable microbiological results in your laboratory.

DIFCO
B&T

B&T are the sole concessionaire for DIFCO products.
A complete line of microbiological reagents and media.

Pollution is Always with Us

ONE cynical but not necessarily misguided view of the wave of concern about the condition of the environment is that it has served marvellously to concentrate the interest of university students on issues other than student power or the supposed lack of it. A year ago, the young people at San José State College in California, who buried a brand new motor car in a hole in the ground as a symbol of their devotion to clean air, might well have been scrawling obscenities on the walls of university administration buildings or pelting administrators themselves with various kinds of food. It is true, of course, that the young people's passion may simply be another way of protesting that older generations have made a mess of things, but even this is probably irrelevant. And the fact remains that young people are not alone in their devotion to environmental causes. Whatever public policies eventually emerge from all the present excitement, it is an important question to know why there has been such a rapid growth of concern about the environment.

The notion that the photographs of the Earth returned by the Apollo astronauts have served to emphasize what a fragile place the Earth must be has been widely canvassed, most eloquently perhaps by Professor Fred Hoyle at the Houston conference about the Moon in January. No doubt there is something in this, although the Apollo photographs have probably done more to rationalize and make explicit a tendency which must already have been well under way. Indeed, both in western Europe and the United States, the origins of the present concern about the environment have been evident for several years. The smog over Los Angeles became in the sixties what the cloud of smoke over Pittsburgh used to be in the days before clean air legislation, and served as a focus for legislation about motor vehicle exhausts. In Britain, the condition of the Thames became first a public scandal and then an incentive for the kinds of administrative actions which have now helped to make the river almost tolerable. In the same way, the Rhine has been the chief stimulus to the development of regulations for international waterways. It is, in circumstances like these, something of a surprise that public anxiety of the kind which has now led to the creation of a standing Royal Commission in Britain, a Federal Council on the Environment in the United States, and a permanent organization within OECD should have come to a head in such a dramatic way. Is it that there really is a crisis around the corner ?

The importance of a level headed appraisal of the threats to the environment is that exaggeration either way is likely to be damaging. This, for example, is what seems to have happened with the hasty ban on cyclamates at the end of 1969—exaggerated solicitude for the environment has engendered disbelief. In exactly the same way, the talk now widely to be heard of "environmental crisis" is likely to do more harm than good. The truth is that the environment is a good deal better now than it used to be for those generations which were decimated by tuberculosis and even scarlet fever as recently as the 1930s. And even now, a great many populations live in circumstances in which the most serious scourges—malaria, for example—must be fought with means such as DDT which are now considered to be polluting in Britain, the United States, Canada and Sweden. One man's potential crisis is, in other words, another's potential salvation. Exaggeration of the threat to the environment, however valuable as a means of concentrating public energy, will therefore smack of what used to be called "neo-colonialism" if advanced societies are not careful. Worse still, too simple a view of what the danger is may seriously hamper attempts to get the cleanest environment for the least money.

In these circumstances, there are a great many things which responsible societies could do to improve their environment by simple and comparatively cheap devices. In Britain, the Clean Air Acts have done a lot to improve conditions in the large cities, even though their enforcement leaves a lot to be desired. There is obviously plenty of scope for clean water legislation. On the mainland of Europe and in the United States, geographical size has complicated many problems, but it is still a mystery that opportunities for straightforward remedial legislation are so consistently ignored. In the United States, for example, raw sewage is still discharged into open rivers either in defiance of regulations or with impunity. Although research is at once necessary and interesting, there is no reason why advanced societies should not be able to make respectable progress towards a more carefully controlled environment by the use of simple administrative devices. The international problem is more serious, if only because international agreements are inherently hard to achieve. Governments will doubtless try to negotiate, for cases such as the Torrey Canyon wrecking, agreements similar to those which regulate insurance against radioactive accidents at nuclear power plants. But issues like that are bound to take years to resolve. The institutions, both national and international, which will eventually be needed for regulating the environment will similarly be slow to emerge. This is why it would be best if some of the red hot passion about the environmental crisis could be converted into a more durable form even if one result might be a resurgence of the interest of students in conditions on the campus.

Premature Birth of Test Tube Baby

THE test tube baby has struck again. Several years, perhaps even decades, in advance of it being even theoretically possible to grow mammalian embryos to full term outside the uterus, the test tube baby has been forcibly delivered and morally agonized over. "The era of the test tube baby has begun" was the annunciation made by one newspaper to its readers; "One step nearer to the super race" was the *Nunc dimittis* of another. It seemed to be generally felt that the test tube baby had arrived trailing clouds of thorny ethical problems in its wake.

The genesis of the affair was the announcement last week on the BBC television programme *Horizon* that a technique of *in vitro* fertilization was shortly to be attempted at Oldham General Hospital as a treatment for infertile patients. The procedure was first outlined a year ago by Edwards, Bavister and Steptoe (*Nature*, **221**, 632; 1969). It involves removing oocytes from a woman's follicles, fertilizing them with her husband's sperm and replacing an embryo in the uterus for it to implant in the usual manner. By all accounts the technique is a courageous and imaginative way of overcoming a blocked Fallopian tube, which is the commonest single cause of infertility in women.

What has all this to do with the test tube baby? In terms of scientific fact, almost nothing at all. The test tube baby, as this phrase is usually understood, refers to the growing of a human embryo to full term outside the body and the chief obstacle to this feat (not that anybody has proclaimed it as a goal) is the formidable problem of maintaining the embryo after the stage at which it would normally implant in the uterus. The Oldham procedure concerns only the pre-implantation embryo which, except in the trivial sense that fertilization is carried out *in vitro*, can hardly be equated with the test tube baby. Moreover, it is difficult to see that the wastage of embryos occasioned by the procedure raises moral problems any knottier than those to do with the IUCD, a device that probably prevents the embryo from implanting in the womb.

What then was all the fuss about? Part of the reason, it seems, was that the implications of the Oldham procedure were genuinely misunderstood in some quarters, and publicists with scientific doctorates who spoke of genetic engineering did not help to clarify the issue. It may also be a side-effect of the present concern about pollution that people are prepared almost by reflex to equate the new knowledge with new dangers. Public interest in scientific and technical developments is all to the good, but it would be a pity if a wail of premature jeremiads were allowed to drown the occasional eurekas before they had a chance to be heard. This, of course, is one of the dangers prompted by the overreaction to the Oldham procedure; the other is the obvious peril of crying wolf too soon and too often.

A curious feature of the public debate is that the letter writing segment of the public, at least, seemed to believe that human life was about to be created from nothing in the test tube. For example, a correspondent in *The Times* voiced the fear that "The ability of scientists to develop the technique of creating life in a test tube is so serious that I feel human beings should be given the opportunity to express their views on whether or not this line of research should be pursued. . . . Personally I find the idea of creating life at man's will terrifying". These are indeed dark atavistic fears which have been nurtured, perhaps, by the views of Dr Edmund Leach that scientists have usurped the creative powers and should assume the moral responsibilities formerly attributed to gods. Whatever the merit of Dr Leach's thesis, those who are engaged in research that is at all liable to be misinterpreted will doubtless take the present episode as a warning of the misunderstandings that can arise, particularly if the true facts are not readily available from authoritative sources. There is always the danger that lack of information or misinformation may convert legitimate public concern about new knowledge into a paranoia that impedes research.

What Eclipses are Worth

THE eclipse on Saturday in North America has brought to the surface a number of important and interesting issues in the organization of research. Although this week's phenomenon will by sheer good luck pass near several of the best equipped laboratories for observations of this kind, it is being followed with a programme of observation which is modest compared with the effort that would have been spent on it ten years ago.

Indeed, the National Science Foundation, which has coordinated the programme of observation, has no separate allocation of money for this work, which is being financed out of the ordinary budget for solar and terrestrial physics. One way and another, the foundation is likely to spend a good deal less than $500,000 on its own work. It is improbable that the total cost of all the work being carried out will exceed $3 million. A good many worthwhile plans have been abandoned for lack of money. The most spectacular casualty is the scheme which NASA had been canvassing for flying a supersonic aircraft along the track of totality, thus extending the duration of observation from 3 to 90 min, so allowing a longer study of motion in the corona. The cost of modifying the aircraft would have been $10 million.

But how much is it worth spending to observe an eclipse with extra care? The most important objective is of course the observation of the corona and the chance of filling in gaps in present understanding of what happens in the high atmosphere of the Sun. A century ago, when *Nature* was constantly at loggerheads with the British government for what then seemed to be parsimony in supporting observations of eclipses, an opportunity such as that on Saturday to observe such a favourable eclipse would have been invaluable. It is only fair to say that times have changed a little. For one thing, the high atmosphere of the Sun is now much better understood and there is every chance that in time the data which are accumulating about the solar wind will support accurate and complete inferences about the Sun's outer atmosphere.

But how is it possible to give this chance a numerical value, in dollars or pounds? Unhappily, the yardsticks which are available for comparison are probably misleading. The fact that the first Apollo applications satellite, with its steerable solar telescope, will be equipped for direct observation of the corona is hardly any guide—that is a much more expensive operation than any eclipse observer would expect to participate in. In the long run, in any case, it may well be that eclipses are to be valued most as occasions when people make collective and simultaneous observations in a way that evokes some of the old spirit of the international geophysical year (which is why nobody should weep too much if it is cloudy in Mexico on Saturday). But this is why it is a pity that this week's occasion is not more fully equipped. The real worry will be to make sure that the next eclipse, in 1972, is properly observed in the parts of Africa from which it will be visible.

100 Years Ago

M. Radau falls into the schoolboy blunder of making the *ratio between the friction and pressure constant throughout the motion*, confounding the actual friction with its limiting maximum value! It is, indeed, surprising that such a perversion of the facts of the case should have found insertion in a serious journal, such as that published by the Ecole Normale Supérieure, and I might fairly have expected from M. Radau the courtesy habitual with his adopted countrymen, of applying to me for information on anything in my paper which might have appeared to him obscure or erroneous, before rushing into print with such a *mare's nest.*

In a future number of your esteemed journal (as time at present fails me) I propose to show how, by the simplest contrivance in the world, a downright material top of ellipsoidal form may be actually made to roll, with its centre fixed, on a fixed plane and so exhibit to the eye the surprising spectacle of a motion precisely identical *in time*, as well as in its successive displacements of *position*, with that of a body, turning round a fixed centre, but otherwise absolutely unconstrained.

From a letter from the mathematician J. J. Sylvester whose conclusions about the motions of a free rotating body had been criticized by M. Radau. From Nature, **1**, 482, *March* 10, 1870.

OLD WORLD

Battle for Atlantic Salmon

THE antipathy of Denmark, Sweden and West Germany to a ban on salmon fishing in international waters of the North Atlantic has now prompted Mr Harold Wilson to send a personal message to their heads of government—an appeal the Danish Premier has already rejected. Last summer the delegates of these countries were the only people to oppose the call for a ban on salmon fishing made at meetings of the North East and North West Atlantic Fisheries Commissions, which have no powers to enforce their recommendations. The present disagreement has been caused by the rapidly growing exploitation of salmon on their feeding grounds on the high seas, which several countries (especially Britain and Canada) believe is frustrating their efforts to breed and conserve salmon for coastal and freshwater fishing.

There is a strong case for countries in whose rivers the salmon breed to have a prior claim on the harvest. In Britain, for example, more than £1 million a year is spent on salmon protection and conservation, and on top of this sum there is a large "invisible" expenditure by industry in terms of effluent treatment and by power stations in keeping young migrating fish out of their water intakes. Fishing is also strictly controlled by by-laws and close seasons, and the number of licences available for fishing in estuaries can be restricted as a conservation measure within river authority areas, while only about a dozen licences have been issued for coastal fishing elsewhere in England and Wales. Coastal fishing off Scotland is prohibited. In Canada and the state of Maine, according to Sir Hugh Mackenzie, director of the Atlantic Salmon Research Trust, the annual cost of protecting salmon runs to about $5 million.

On the other hand, Denmark, where there are only a very few rivers in which salmon are found, gets the lion's share of the high seas catch. The chief fishing area is off the west coast of Greenland, where drift netting began in 1965. By 1967 seven or eight boats were fishing there, in 1968 eighteen, and in 1969 at least thirty-seven. Eighteen of the fishing vessels came from Denmark, six from the Danish-owned Faroes, eleven from Norway and two from Sweden. Table 1 (top row) shows the growth in catches since 1965. But claims that the coastal fisheries of Greenland or Britain are suffering as a result are not directly supported by the available figures. In Greenland a drop in the 1968 catch was reversed in 1969 (Table 1, second row); for England, Wales and Scotland there is so far no clear effect on the total catches that can be

Table 1. SALMON CATCHES, GREENLAND AND GREAT BRITAIN (1965–69), IN METRIC TONS

	1965	1966	1967	1968	1969
Greenland (international waters)	36	119	318	548	1,300*
Greenland (coastal fishery)	825	1,251	1,283	579	900*
Great Britain (coastal and freshwater)	1,922	2,011	2,553	1,845*	2,315*

* Provisional figure.

All figures from the Ministry of Agriculture, Fisheries and Food.

attributed to the high seas fisheries (Table 1, third row), although reductions in the number of salmon found in certain rivers are hard to explain otherwise.

The justification for a ban on salmon fishing in the high seas seems to be a matter of principle rather than fact. German fishermen, who fish for salmon to the north of Norway, are opposing a ban on the grounds that it would amount to a restriction of the freedom to fish in the open sea. Abolitionists contend that because the salmon is not a "free" fish, arguments of this kind are irrelevant. They also have the support of people who fear that the salmon may be overfished if restrictions are not forthcoming. Sir Hugh Mackenzie warned that "the situation could become calamitous very quickly", and there is a body of opinion believing that it would be prudent to call a halt until more is known.

Britain, Canada and Denmark have been running a research programme in the West Greenland area for five years. Salmon caught in the coastal and offshore regions are being tagged to give information about the size of the exploited population, the proportions returning to home rivers, and the increase in weight during the return journey. But it will take some time to collect enough data, for the chances of recapturing tagged fish are small.

The next attempt to protect the inshore fisheries will presumably be made at the meeting later this month of the ministers for fisheries of Denmark, Sweden and Norway. Denmark may be willing to make concessions if international opinion demands them—for example, larger net meshes could be used, or there could be a close season. But Sir Hugh Mackenzie has pointed out that there is, in effect, an automatic close season, for the salmon are only fished off Greenland from August to November; he believes that anything short of a complete ban will be useless in preventing further increases in exploitation. The Fisheries Commissions in which the ban was originally recommended meet again in May and June.

CONSERVATION

No Votes in European Sewage

THERE have been enough conferences encouraging the breast-beating type of conservationist. Their cries of wolf are already having an immunizing effect, and the danger is that the topic of pollution will have become a bore before any worthwhile action has got under way.

For this reason the Council of Europe's February conference at Strasbourg on "The Management of the Environment in Tomorrow's Europe" is to be welcomed. This was an intergovernmental conference and its object was action. Three hundred participants came from 27 countries (17 Council of Europe countries, plus 11 more with observer status). Members were drawn from the people who actually structure the European environment from one decade to another—planners, government and local government servants, industrialists, landowners, politicians. Four hefty reports were tabled and discussed, on urbanization, industry, leisure, farming and forestry, each written by a single rapporteur. Each concluded with a list of conclusions and recommendations. These provided the groundwork for a declaration that was drawn up at the end of the conference and was accepted unanimously. It contained 30 policy guidelines for Europe's decision makers.

A conference of senior government ministers is called for by the parent body, the Council of Europe, "as a matter of urgency"—that is, it should meet within a year. This will provide an opportunity to put European governments on the spot as to what they are actually doing or proposing to do about the policies and measures agreed last month by their representatives.

The introductory declaration of the document clarifies the issues:

"(1) Rational use and management of the environment must have high priority in national government policy and be adequately financed, and clear ministerial responsibility must be established for the planning and use of land and other natural resources and the conservation of nature.

"(2) Policies should be strengthened or introduced to control pollution of air, water and soil, and internationally agreed standards for those purposes should be devised as soon as possible.

"(3) Legislation and regulations introduced to safeguard the environment and its quality should be harmonized to the extent necessary at European level."

Five points are referred for the attention of the European ministerial conference in particular. The numerous intergovernmental bodies nibbling at these problems need to be sorted out; for instance, both NATO and OECD are flirting with pollution and environmental matters. Neither seems appropriate, especially in view of the interest in the Strasbourg plans displayed by East European countries, three of which took part in the conference.

Point two is that there is a need for internationally agreed standards to be adopted for European industry, especially in the sphere of pesticides, car exhausts, the noise and pollution products of aircraft engines. Steps should also be taken to "harmonize" national legislation relating to the environment.

The two final points for ministerial attention are a proposal for "a political authority at European level" with the task of supervising and guiding the management of the European natural environment, if possible irrespective of political frontiers; and a proposal (sponsored by the French minister of agriculture) for a European fund to fight pollution.

The most significant, perhaps, of the guidelines for national governments is an imperative to establish an "infrastructure" (as they say) and a chain of command. Otherwise, most of the national guidelines relate to the use and treatment of land—rational use, reclamation and re-use of derelict land, unspoilt coasts to stay unspoilt and spoilt coasts improved, upkeep of landscape, classification of all land for its most appropriate use, and so on. Five guidelines are directed at industry. Here cooperation is emphasized and the point made that both sides of industry should appreciate that "the rational use of natural resources is in their long-term interest".

This is one aspect of a theme that was emphasized by the chairman of the Strasbourg conference, Mr R. E. Boote of the Nature Conservancy. This is, that the individual pays, as consumer, taxpayer and ratepayer, for despoiling the environment and for pollution.

Perhaps the underlying concept of the Strasbourg conference is in line with another of Boote's main preoccupations, that as long as society gives certain terms of reference, these get fulfilled. "The need now is for society to get these terms of reference changed." Most politicians would agree with this, though what they are going to do about it remains very much an open question in a European and indeed a British context. The assumption that there are no votes in sewage seems still to hold both government and local government in thrall.

SCIENCE RESEARCH COUNCIL

Boost for Ion Implantation

THE bombardment of solid surfaces by ions is a technique which is providing new devices in electronics and a new tool for physicists and chemists as well as being a fascinating phenomenon in its own right. An admirably comprehensive survey of British work in the field has just been published by the Science Research Council (*Ion Implantation Panel Report*, available from the SRC free of charge). The report recommends that the universities should receive £200,000 of grants over the next two years, but that thereafter support should return to its present level of about £60,000 a year.

Ion implantation has developed over the past ten years, encouraged by the realization that because of the phenomenon of channelling, ions penetrate deeper into the lattice along certain preferred directions than along random directions. Although comparatively few people are deeply concerned with ion implantation, the subject is of marginal interest to many more. The report necessarily describes a hotch-potch of work on the physics of ion implantation, its use in making new materials and electronic devices, and the development of implantation equipment. The thinking behind the two-year boost in expenditure is to identify the most promising areas for university research. The development of new electronic devices based on the alteration of the characteristics of materials by ion bombardment is best left to government and industry, for example, but there is room for university work to improve implantation machines—ion sources are a particular problem—and on future applications of ion beams in the electronics industry.

It ought to be possible, for instance, to replace the conventional photographic and chemical method of manufacturing microcircuits by using electron beams and vacuum evaporation to deposit the masks, and ion beams for doping and mask removal, in a process that would be amenable to computer control. It would be more difficult but nevertheless feasible to dispense with the masks and use the steerable property of an ion beam to "write" the circuit. There is also the technique of machining with ion beams, and two companies in the United States are using argon ion beams for the figuring of topical components.

The report recommends that Professor M. W. Thompson's group at the University of Sussex should remain the chief group investigating the fundamental processes of ion implantation. Equipment for implantation is comparatively expensive—typically £30,000 for a 200 keV machine, for example—and few universities have accelerators designed for ion implantation. The report recommends that the SRC should add to the equipment already available at the universities of Salford, Surrey and Sussex, which will become the chief centres, on condition that the beams will be available to other groups with particular expertise in the study of the various effects of implantation—radiative emission, production of defects and so on.

A major problem seems to be the definition of areas where the technique of ion implantation is going to prove most valuable, particularly since support is dispersed through university, government and industrial laboratories. This is where the exploratory programme recommended by the panel may help.

COMPUTERS

IBM's Handicap

DESPITE the fact that International Business Machines UK bestows many benefits on the British economy, it has constantly to overcome feather bedding by the government of British computer manufacturers. This was the impression that emerged when representatives of IBM UK met sub-committee D of the Select Committee on Science and Technology last week. Mr Edwin Nixon, the company's managing director, told the sub-committee that "the government will give an order to ICL if it possibly can. To gain an order we have to be 25 per cent better, or provide a service that ICL cannot". Mr Nixon, who declined to give the source of his information, said that he did not believe this to be just a journalistic guess. This, he said, is the guidance given by the Ministry of Technology for purchase of computers by government departments and by nationalized industry.

Nevertheless this alleged government policy does not seem to be too great a handicap to the activities of IBM UK. The sub-committee was told that the company's revenue in 1968 amounted to £125 million, of which £33 million was in exports. Although imports in that year amounted to £38 million, preliminary figures for 1969 show that the export deficit was reversed; the company exported £38 million worth of goods, and imported £35 million during that year. Mr Nixon also offered no comment on Mr Leadbitter's estimate that IBM and ICL control about 30 per cent of the UK computer market each, and the remainder is divided among about twenty other companies. He did say, however, that IBM hopes at least to retain its share of the market.

Mr Nixon also disclosed that the company's factory at Havant, Hampshire, is being almost doubled in size, but when asked by Mr Lubbock what will be built there, he said "unfortunately it is a product that we've not yet announced". Such an expansion should go a long way to ensure that the company fulfils its intention to maintain a balance between imports and exports, and IBM UK's research and development capacity will continue to be the largest of the IBM empire outside the United States.

The sub-committee was also treated to a discourse on how IBM helps the British economy. The company employs about 11,000 people, about a quarter of whom are qualified scientists and engineers, and Mr Nixon emphasized that the manufacturing plant in Greenock is situated in a technological "grey area" (unlike the plant at Havant). Besides helping the export drive and paying a lot of taxes to the exchequer, IBM UK has a large stake in computer education. Last year the company claims to have trained some 20,000 people.

Wider implications of the project should then be examined by an interdisciplinary group whose membership should be chosen according to the particular problem under discussion. Such studies, said Mr Benn, are already being considered by the Ministry of Technology for major projects. The final stage, opening up the issue to full public debate, represents the demand that the power of technology be brought under democratic control but, said Mr Benn, it would require a different attitude among members of the public. Many people feel that they are not qualified to comment on technological questions but little technological knowledge is required to suggest that some of the money devoted to space research should be spent on health research, for example.

Mr Benn pointed out that these suggestions are not new but they have not previously been heard from the Ministry of Technology. If the Ministry does change its decision-making process in this way, then perhaps issues such as Concorde, which Mr Benn firmly supports, would be opened up to public debate before a final decision is taken.

DOGS

Rabies at the Races

For the second time in five months a case of rabies has slipped through the British quarantine regulations. A mongrel that was imported from Pakistan in May, and released from quarantine in November, died of rabies at Newmarket on February 27. It had been vaccinated against rabies some eighteen months before it reached Britain. There is apparently no danger to local wildlife or to racehorses stabled in the Newmarket area, for the only animals that the mongrel bit were three dogs which have been well isolated, but the case is significant because it represents the first time since 1922, when Britain became free of rabies, that the disease has appeared more than eight months after importation. The present quarantine period was lengthened to eight months with effect from last December, presumably because it would have covered all the earlier cases.

The Ministry of Agriculture is not yet prepared to say whether the period will be extended yet further, although last year the minister, Mr Cledwyn Hughes, promised to review the quarantine arrangements at the end of 1970. He has, however, asked for an official report on the Newmarket case. Clearly there are practical limits to lengthening the quarantine period; a year's quarantine, for example, would double the demand on the space of the quarantine kennels. Even this would not guarantee against a further outbreak, because the rabies virus has sometimes incubated for more than a year (M. M. Kaplan, *Nature*, **221**, 421; 1969). Is there a case for banning the import of dogs altogether, at least from countries where rabies is established ? The trouble is that giving the quarantine regulations too savage a bite would encourage the smuggling of dogs into the country.

The Newmarket outbreak adds weight to the view that compulsory vaccination would be a poor substitute for quarantine. If the vaccine works it usually gives immunity for three years, but it seems to be only 60–80 per cent effective. It is too soon to know whether the two-day slaughter of wildlife at Camberley last October has been successful, but so far no evidence of rabies has appeared.

TECHNOLOGY

Sermon to Mancunians

Greater participation by the public in technological decision-making and more thorough analysis of the social and economic implications of technological projects were called for last week by Mr Anthony Wedgwood Benn, Minister of Technology. Speaking at a meeting of the Manchester Technology Association in London, Mr Benn said that "increasing fear that technology is being misused, that we are pursuing increased production of goods and services too single-mindedly and without regard for the general quality of life" may lead to a campaign against technology. The answer to this, he suggested, is to open up major technological decisions to public debate, and to encourage research teams to look at the social implications of their work.

Technology can be brought under democratic control in a three-stage decision-making process, said Mr Benn, and his speech was liberally sprinkled with hints that the Ministry of Technology is at present trying to find a way to incorporate such a process into its own decision-making machinery.

For the first stage of the process, Mr Benn suggested ten questions that should be put to research workers and to initiators of technological projects. To answer these questions, the whole research team, board of management or sponsoring agency would have to discuss the likely costs and benefits of the project, to assess its effects on manpower resources and on training, and to evaluate alternative projects. These "ten commandments" are clearly intended to stimulate discussion among technologists of the implications of their activities—a discussion that Mr Benn indicated does not always take place. Instead of saying, for example, love thy neighbour as thyself, Mr Benn suggests that technologists should ask themselves, "Would your project—if carried through—promise benefits to the community, and if so what are these benefits, how will they be distributed and to whom and when will they accrue ?".

SOVIET UNION

Plant for Flower Power

Heavy industry is not always the apple of a Russian planner's eye. A new branch of agriculture has recently been inaugurated in the Azerbaijan SSR—the growing of flowers for the perfumery industry. Roses, narcissi, mint, orange and lemon blossom and other ether-bearing flowers have become the raw material of the latest venture in Soviet production. The State Plan of Azerbaijan calls for the organization of state farms that are to be devoted entirely to this new crop. Processing factories are to be set up, with research laboratories and experimental centres. Present research is concerned with the active principle of saffron (obtained from the stamens of the yellow crocus); the most satisfactory achievement to date has been the isolation of an especially valuable ether oil from the scented narcissus 'Bulgarian Beauty'.

PHYSICS EXHIBITION

Computing to the Fore

SUFFICIENT of the flavour of modern physics seeped through the barrage of electronics at this year's physics exhibition at Alexandra Palace, London, last week to allay the visitor's suspicion that he may have accidentally strayed into an instruments' trade fair. The dominating role of computers in physics was one theme widely in evidence. Exhibits included the computer simulation of the neutron flux of an advanced gas cooled reactor, carried out by the Berkeley Nuclear Laboratories, and on-line monitoring of plasma dynamics experiments by the computational group of the Institute of Physics and the Physical Society.

The three lectures traditionally held at the exhibition were devoted this year to the environment. Professor A. H. Cook of Edinburgh University explained why continental drift has become such a talking point among physicists, and how variations in the Earth's magnetic and gravitational field are providing such rich sources of information about the Earth's history and interior. This was followed by talks on the physics of the oceans, by Dr G. E. R. Deacon, the director of the National Institute of Oceanography, and on buildings and noise by Mr W. E. Scholes of the Building Research Station, both of whom set out to show how physics is increasingly enlarging its traditional frontiers.

Lasers were once again strong among the exhibits. The Atomic Weapons Research Establishment at Aldermaston had on display a rotating mirror hologram camera which uses Q-switched pulses from a ruby laser to give superimposed hologram exposures. This means that the object is seen in what may be thought of as 4-dimensional space. Queen's University of Belfast had on show a new type of dye laser system which is being applied to flash spectroscopy, the optical Stark effect and studies of self-induced transparency.

Mullard's have developed an acoustic surface wave filter. The frequency selective properties of transducers are used, and the waves are launched and received by gold electrodes evaporated on a piezoceramic. Standard Telecommunication Laboratories had on display an optical fibre communication system, on which work is also being done at the Post Office Laboratories in Dollis Hill. The STL system uses a cooled GaAs laser as the light source and a glass fibre as the transmitting medium. Pulse code modulation at about 100 million bits a second is used. Fibre optical communication systems are being vigorously investigated at present as they offer the chance to transmit many hundreds of times as much information as conventional coaxial cables.

CHEMICAL INDUSTRY

No Time for Dragging Feet

A REMINDER of why the British government wishes to join the European Economic Community has been provided by the Chemicals Economic Development Committee, one of the standing committees set up to oversee critical sectors of the British economy. In a report on the chemical industry (Industrial Report by Chemicals EDC on Economic Assessment to 1972; HMSO, no charge), the committee says the chief problem has been low capital investment because of the relatively small size of the British market and the sluggish growth of the national economy. At the same time the demand for larger chemical plants is growing steadily. Ten years ago an ethylene plant would have been designed to produce 50,000 tons a year; now it must yield 500,000 tons to be a commercial success and requires a correspondingly greater capital investment. Joining the EEC would ease the problems of market size, the committee concludes, but the government could give more immediate help by reducing fuel tax, lowering the cost of electricity to large users and easing credit restrictions.

GROWTH IN CHEMICAL AND INDUSTRIAL PRODUCTION
1958–67
(Growth rate, per cent a year)

	Industrial production	Chemical production
United Kingdom	3·1	6·6
Germany	5·1	11·0
France	5·1	9·9
Italy	8·9	13·4
United States	6·0	8·3

Although the chemical industry increased its share of manufacturing output in Britain from 9·3 to 10·1 per cent between 1963 and 1968, its rate of growth has been smaller than that of other countries in the EEC. The report cites the excessive time taken to build plant in Britain as one of the factors behind the slow growth rate. EEC countries also benefit from a favourable costing system for high load electricity, which is important in the production of many chemicals, including polyvinylchloride.

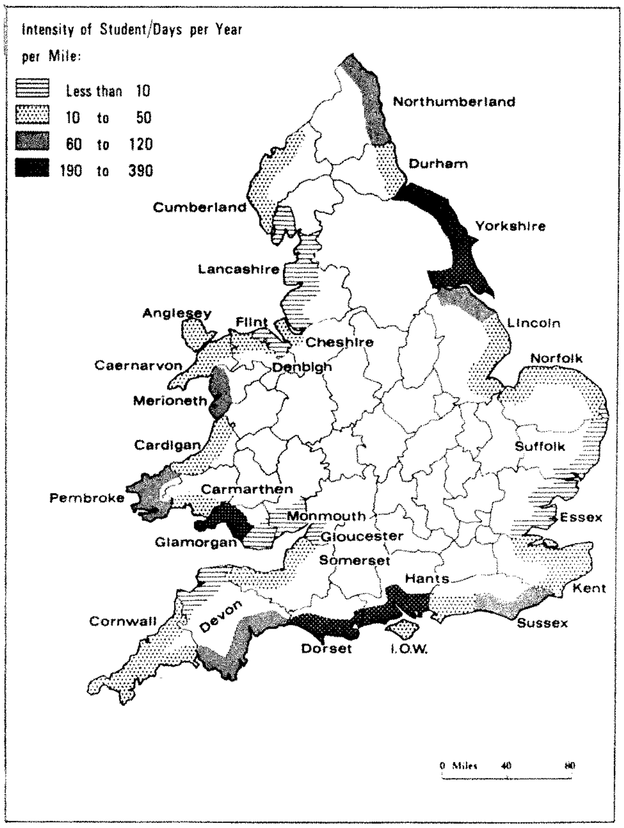
The committee estimates that about 7 per cent of the world's chemical research is done in Britain, although only 5 per cent of chemical industry is in Britain. Britain is still the third largest exporter of chemicals in the world (after West Germany and the USA), and in 1967 had a positive balance of trade of £200 million in chemicals.

COUNTRYSIDE

Safeguarding the Coast

A PLEA that policy decisions about the use of Britain's coast should be made on a national level is the burden of a new report from the Countryside Commission (*Nature Conservation at the Coast*. HMSO, £1 12*s* 6*d*) which is based on a study by the Nature Conservancy. The commission looks specifically at the 3,847 miles of coastline in England and Wales—a resource that it describes as "scarce, finite, valuable and vulnerable"—to see how the conflicting demands on the coast by housing, caravans, motor cars, defence structures, industry and so forth can be reconciled with the need to preserve the coast's unique natural features.

The committee warns that pressures on the use of the coast should not be of concern only to teachers and scientists—the richness and variety of habitat and the associated wildlife are the basis of the amenity and economic value of the coast just as much as of the scientific interest, and anything that affects these basic features will degrade the coast as a whole. A view must therefore be taken of all aspects of the coast, and all planning, management and development of it, whether at the local, regional or national level, must be based on ecological research. Here the commission believes the Nature Conservancy has a special part to play in undertaking and sponsoring research through its National Nature Reserves (of which there are 120 miles in coastal areas); the reserves should continue to be used primarily for research, wildlife conservation and education.



Results of a survey by the Nature Conservancy of the use made by students of the coastline of England and Wales.

Besides making various suggestions for safeguarding the scientific interest of the coast, the new report contains much factual information on the geology and wildlife of the British coastline and on the present administrative measures by which sites of scientific importance are conserved. The various conflicting demands on the coast are usefully tabulated in a "Chart of Human Impacts on Coastal Wildlife and Scientific Interest" which traces the incidence and effects of an activity or operation whether by industry, tourism, recreation and including the over-use of areas by scientists and students on field trips. The report also provides a classified catalogue of 371 sites of scientific importance that lie along the coast of England and Wales.

NATURAL HISTORY

Behind the Scenes

Last week the small back rooms of the British Museum (Natural History) were unlocked to two hundred or so academics and government scientists. This was the first open day at the museum, and many visitors may have been surprised to see the labyrinth of rooms and corridors in which the museum's zoologists, botanists, palaeontologists and mineralogists carry out their labours.

One of the chief duties entrusted to the museum is the cataloguing of the thousands of new animal and plant species that are described each year. To handle so much taxonomic data the museum has installed data processing machinery and is already preparing catalogues of the spider and primate collections in machine readable form.

Another useful piece of equipment is a scanning electron microscope which is revealing the microstructure of pollen grains, diatoms, sponges and mites and is also helping with the identification of mites of the order Astigmata.

Fishermen who hanker after a mention in the *Guinness Book of Records* will be glad to know that the museum has taken their problems to heart. Freshwater fish specialists are sorting out the characteristics of hybrids of the British members of the Cyprinidae, the carp family, so that they can be easily identified before hopes of a record are raised too far—hybrids are, it seems, just not good enough for therecords league table.

The botanists have been striking out in a new direction with their survey of Mull, now in its fifth and final year of field work. The object of the exercise is to produce a comprehensive flora of the area which will describe the whole range of vegetative life from flowering plants to marine algae. The variety of expertise available in the museum has made it possible to mount this project, without the need to concentrate only on flowering plants and ferns, as most writers of floras must. The team from the museum have had the services of a Royal Navy helicopter to take them to outlying islands. The first fruits of the project were on show, including news of a hitherto unknown hybrid fern.

Transition to the Seventies

A quarter of a century after the first nuclear reactor at Harwell went critical the British nuclear power industry now finds itself on the threshold of a new era. The last of the Magnox power stations conceived in the first nuclear programme will be opened this year, four of the second generation advanced gas cooled reactors are already under construction, with several more in the pipeline, and the high temperature and fast reactors are far enough along the design and testing path to keep the electricity generating authorities planning well into the nineteen eighties. But how far is British industry a prisoner of its early advances in nuclear power, and how imaginatively have the essential elements of continuity and innovation been combined in defining a reactor policy appropriate to the last two decades of the century ?

Table 1. NUCLEAR GENERATING CAPACITIES, MARCH 1969
(Excluding communist countries)

Country	MWe capacity
Britain	4,200
United States	1,981
France	1,580
W. Germany	707
Italy	597
Canada	223
Japan	168
Spain	153
Netherlands	52
Belgium	10
Sweden	9

The extent to which Britain has forged ahead in nuclear power can be seen from Table 1. By 1985 it is expected that up to a third of Britain's electricity generating capacity will be nuclear, and by the end of the century more than 100,000 MW will be nuclear generated. But an increase in the variety of reactor systems and in the number of countries embarking on nuclear power programmes has sharpened the need for a more widely international view of reactor policy—spotlighted by the continuing rumpus over the future of the steam generating heavy water reactor—and has emphasized the ease with which British industry could waste away its lead in this field through administrative or technical confusion.

The early reactors were all graphite moderated with natural uranium as the fuel. Both British and French reactors were predominantly of this design, although the French authorities have recently transferred their allegiance to light water reactors, developed principally in the United States. The two most important types of heavy water reactor are the Canadian CANDU reactor and the steam generating heavy water reactor (SGHWR), in which light water is the coolant with the steam having direct access to the turbines. Different technologies are needed for graphite and water moderated systems, which explains the somewhat anomalous role of the SGHWR in Britain's reactor programme.

The most exciting long term prospect is the fast breeder reactor. This uses plutonium as fuel, but can generate its own supply by converting uranium 238, which is non-fissile, into plutonium. Moreover, the very high energy of the neutrons—10^{11} m/s compared with 3,000 m/s in normal thermal reactors—means that fission can be induced in isotopes of plutonium that are stable to thermal neutrons, and no attempt need be made to produce fuel rich in plutonium 239. The advantages of the fast breeder reactor are compelling, both in reducing fuel requirements and core size. The prototype fast reactor at Dounreay is due to reach full power (250 MW) in 1972, but there is unlikely to be a commercial model ready for the generating boards until the end of the decade.

Table 2. MAIN NUCLEAR POWER STATIONS IN BRITAIN

Location	Type	Year of commissioning	Capacity MWe	Generating cost d/kWh
Berkeley	Magnox	1962	276	1·25
Bradwell	Magnox	1962	300	1·14
Hunterston A	Magnox	1964	320	
Hinckley A	Magnox	1965	500	1·07
Trawnsfynydd	Magnox	1965	500	0·96
Dungeness A	Magnox	1965	550	0·78
Sizewell	Magnox	1966	580	0·74
Oldbury	Magnox	1967	600	0·74
Wylfa	Magnox	1970	1,180	0·70
Dungeness B	AGR	1972	1,200	0·56
Hinckley B	AGR	1972	1,250	0·52
Hunterston B	AGR	1972	1,250	
Hartlepool	AGR	1974	1,250	0·52
(Dounreay)	PFR	1972	250	
(Winfrith)	SGHWR	1967	100	

In the intervening period two new types of gas cooled reactor will be brought into operation, namely, the advanced gas cooled reactor and the high temperature reactor, which is strongly tipped as the Central Electricity Generating Board's choice for Connah's Quay and Oldbury B. Many new concepts distinguish the AGR from the Magnox design, including a new fuel element—slightly enriched uranium—and a new type of reinforced pressure vessel which further enhances the safety of the design. This has allowed the CEGB to site its latest power station near a densely populated area at Hartlepool. The economic advantage of the AGR is also evident from Table 2.

The high temperature reactor has been developed under the auspices of the OECD in the Dragon project. It is designed to operate at around 800° C, compared with 650° C for the AGR, achieved by using helium coolant, and the core has been made homogeneous by combining the fissile and fertile components of the fuel in the moderating material. This allows the whole of the core to be removed at the end of the fuel cycle, avoiding excessive fast neutron doses and permitting higher thermal neutron densities. Another novel feature of the HTR is the use of graphite and ceramic to contain the fuel elements, eliminating the need for metal canning.

Table 3. NUCLEAR POWER STATIONS IN THE EUROPEAN ECONOMIC COMMUNITY
(January 1970)

Type	Country	MWe in service	MWe under construction
Gas-graphite	France	1,310	1,055
	Italy	200	
Boiling water	Germany	407	1,410
	Italy	150	
	Netherlands	52	
Pressurized water	Germany	283	1,780
	France/Belgium	266	
	Italy	257	
	Belgium	10	1,650
	Netherlands		450
Heavy water	Germany	50	100
	France	70	
High temperature	Germany	13	22
Na/Zr hydroxide	Germany		19
Nuclear superheat	Germany	22	

A prototype steam generating heavy water reactor is already in operation at Winfrith in Dorset, but the success of the HTR has diminished the chances of the SGHWR being adopted by the British generating boards. Table 2 shows the British nuclear power stations completed or under construction, and Table 3 gives a résumé of nuclear generating capacity throughout the European economic community. The most significant change since January 1969 is the growth in the number of pressurized water reactors under construction in the EEC, from 630 MW to 3,880 MW capacity.

Parliament in Britain

BAC 3-11

Mr Wedgwood Benn refused last week to be rushed into making a firm decision on whether to give financial support to the British Aircraft Corporation for development of the BAC 3-11 airbus. Mr John Corfield and Mr Michael McNair-Wilson both asked if any decision has been taken, and Mr Corfield suggested that delay in reaching a decision could be disastrous to the project. He also pointed out that there are very few British aircraft in the pipeline at the moment. Mr Benn denied that there has been delay in arriving at a decision. He said that discussions are still taking place between Ministry of Technology staff and the company, and a full economic analysis must be made before any decision is taken. BAC has requested a government contribution of 50 per cent of the estimated initial costs of £150 million and for some help with production. (Oral answers, February 23.)

Government Research Establishments

Mr David Howell accused the government of being on the wrong tack in the Green Paper on government research and development. He suggested that the effort spent in drumming up more work for government research establishments might be better spent in putting industrial research back in industry. Mr Benn said that the government hopes to announce its decisions on the Green Paper in the early summer, provided that no major alterations to the proposals are necessary and that the earliest possible date for establishing the proposed British Research and Development Corporation is 1972. (Oral answers, February 23.)

CS Gas

Lord Chalfont, Minister of State, Foreign and Commonwealth Office, refused to give an undertaking that the government will reconsider its decision to regard CS as being outside the Geneva Protocol. The decision, he said, was based on evidence that CS is not significantly harmful, except in exceptional circumstances, and the Geneva Protocol was formulated specifically to exclude significantly harmful agents. Lord Brockway, however, pointed out that the British government has always stood for the inclusion of lachrymatory agents within the terms of the Geneva Protocol, and he asked Lord Chalfont why there has been a change of attitude. Both Lord Brockway and Lord Ritchie-Calder also pointed out that the decision to regard CS as being outside the Geneva Protocol might affect the credibility of British intentions in relation to the Disarmament Conference. Lord Ritchie-Calder also asked for the evidence relating to the effects of the gas when it was used in Northern Ireland to be made public, to which Lord Chalfont replied that much of it is already public, and it shows that CS is harmless unless used in exceptional circumstances, such as prolonged use in confined spaces. (Oral answers, Lords, February 26.)

VTOL Aircraft

Research and development connected with vertical take off aircraft for both civil and military use has so far cost more than £110 million and a further £10 million will be spent in 1969–70. Mr Neil Carmichael, who gave this information in reply to a question from Mr Eric Lubbock, also said that £50,000 has been spent on civil market research and a further £50,000 will be spent this year. (Written answers, February 23.)

Miscellaneous Intelligence

Astronomers in the United States may grumble from time to time at their present financial straits, but times have been harsher for the profession. The prediction of today's eclipse, for example, was probably governed by regulations less draconian than the imperial Chinese prescript set forth in the *Shu Ching*: "Being before the time, the astronomers are to be killed without respite; and being behind the time, they are to be slain without reprieve". The first recorded eclipse was that of October 22, 2137 BC, but on that unhappy occasion the Chinese astronomer-royals, Hi and Ho, had drunk too much wine and neglected to scare off the dragon that was eating the Sun, an error for which they very properly lost their heads.

Like the Rector of Stiffkey, Dr James Shapiro of Harvard University seems to have acquired a more lion like reputation after leaving his profession. According to the London *Evening Standard* (February 24) he is now "one of the world's most brilliant scientists". The *Evening Standard*, of course, is in its own way equally distinguished for having produced what was perhaps the least sensible headline of 1969, "Now the Pill Contaminates London's Water" (December 23).

A vial of Moon dust was stolen this week from a charity dinner at Los Angeles where it had been put on display without official permission. With the cost of the lunar rocks being $500 million per pound, according to one estimate, and the stolen sample weighing 2·3 grams, it seems that the thief made off with $5 million. Never can so much loot have been lifted so lightly. Luckily the thief repented his crime and the stolen vial was later returned.

Mr Arthur C. Clarke, the inventor of the communications satellite, was told the following story by Mr Wedgwood Benn when the latter was Postmaster General. A parliamentary commission, convened to examine the decline in gas company shares occasioned by Edison's invention of the electric light, asked one of its witnesses if he had any comments to make on another American invention, the telephone. The witness, Sir William Preece, who was chief engineer of the Post Office, replied, "No, Sir. The Americans have need of the telephone, but we do not. We have plenty of messenger boys" (*Unesco Courier*, March 1970, p. 32). Last week Mr Benn told the same story to Terry Coleman of the *Guardian*, adding that in 1898 Preece said there was no need for dialling because girl operators were cheap, and in 1911, when he retired, Preece was called the father of the British telephone service. Mr Benn's next instalment may tell of a certain spectre recently seen stalking the GPO tower.

An imaginative way of killing two birds with one stone has been seized upon by G. D. Searle, the company that produced the world's first oral contraceptive. Its most recent product, known as Ornitrol, is a contraceptive pill with a farinaceous coating that can be scattered in the highways and byways of cities with a pigeon problem. The company appears to believe that the pill will be too large for song birds to swallow, but perhaps it should not count its linnets before they are hatched.

NEW WORLD

Downbeat at the Office of Naval Research

THE most enduring monument to the postwar growth of basic science in the United States is the Office of Naval Research, by common consent the first embodiment of the doctrine that only a national government is large enough to support scientific research effectively. The Office of Naval Research came into being immediately after the Second World War in 1946, partly because of the urging of Dr Vannevar Bush that continued support for scientific research had become a necessity and partly because of the willingness of the US Navy's managers to let some unspent money be spent on basic research. The setting up of the National Science Foundation in 1951 is a proof of how quickly the pattern established by the Office of Naval Research was accepted as a good model for sustained financial support for research projects.

It seems to be no accident that the navy should have become the service to recognize the civilian need for research support—its own operations during the war were sustained by an exceedingly distinguished group of men recruited from the universities. By all accounts, lobbying for the postwar establishment of a civilian research agency seems to have been vigorous from 1943 on, and detailed plans were made at a series of meetings within the Navy Department in the second half of 1944. In the end, the publication of the report by Dr Bush, *Science, The Endless Frontier*, seems to have persuaded the navy and the Administration that the national interest required arrangements to make sure that there would be a good supply of trained scientists in future emergencies.

The Office of Naval Research came into being with a budget of $44 million and responsibility not merely for the granting of money to university researchers but also for a laboratory of its own—the Naval Research Laboratory—and for providing advice on research as a whole to other parts of the US Navy. In its heyday, in the fifties, the Office of Naval Research was a great benefactor of all kinds of research projects. In those years, it seemed as if quite flimsy connexions with the future strength of the navy were sufficient to open the pursestrings. Thus the Office of Naval Research once explained its involvement in molecular biology by saying, possibly with its tongue in its cheek, that experiments on feeding RNA to rats may well have paved the way for a means of teaching navy pilots their jobs by a suitable choice of nucleic acid in the diet.

For the most part, however, the office's objectives were as serious as the work which it sponsored. It can now claim that it has helped the early development of masers (and therefore lasers), a great deal of behavioural research and the evolution of an understanding of the chemistry and physiology of vision as well as the mounting of a programme of rocket research which has contributed greatly to the understanding of high frequency radiation from the Sun and X-ray radiation from the galaxy as a whole. It tends to be forgotten that it was the US Navy that sponsored the disappointing Vanguard satellite project.

In the years immediately after the war, the Office of Naval Research set what was then a new pattern for the sponsorship of research by means of contracts with individual investigators for carrying out particular tasks in basic research. To begin with, the method seems to have been regarded with some suspicion by the principal universities in the United States. No doubt the success of the years since the war would not have been possible if universities such as Harvard, the California Institute of Technology and the University of California at Berkeley had not been persuaded that no damage would be done to their independence by this device.

In the fifties, some of the first successes of the Office of Naval Research stimulated other agencies to steal its thunder. Other services—the air force, for example—followed suit, although it seems to be accepted that, in the fifties and early sixties at least, the navy remained more imaginative than its competitors in its choice of projects to sponsor. Much of the success of the Office of Naval Research seems to stem from the manner in which contracts are awarded. Rear-Admiral Thomas B. Owen, the chief of Naval Research and director of the Office of Naval Research, explains that responsibility for the choice of contracts still remains with individual programme directors, and that formal advisory boards are not used in the making of decisions with the regularity with which they intervene in other organizations. No doubt the fact that ex-programme directors from the office are frequently found in important positions in the administration of other research agencies is probably closely linked with the way in which responsibility for choice tends not to be diffused through the membership of a committee.

Inevitably, with the passage of time, the pattern of work has changed and now the criteria for relevance of sponsored research are much more rigorously applied than they seem to have been ten or fifteen years ago. Admiral Owen says that with the economic stringency of the past few years, relevance has been increasingly insisted on, with the result that the Mansfield amendment forbidding the Department of Defense to sponsor basic research which has no "direct and apparent relationship" with the navy's chief function may be more a symptom than a cause of change. As things are, standing instructions of the Department of Defense require that the office should let contracts for research only when it is assured of the quality of the research proposal, its relevance to the navy's general if long term interests, the ability of the investigator, the availability of equipment and the reasonableness of the cost. Admiral Owen says that it is bound to be a subjective matter deciding when each of these criteria is satisfied and that, indeed, research sponsorship necessarily boils down to "gut feeling". Even so, the chances are that in the current climate, the point at which a programme sponsor is satisfied by a proposal will be a more exacting one.

This said, the range of the interests of the Office of Naval Research remains impressive. In the coming fiscal year, if Congress grants what has been asked of it, roughly $50 million will be spent on the three laboratories which the office maintains, two of them by contract, and a roughly equal amount will be spent in universities on research contracts. At the same time, it is likely that basic research in industry will cost $8 million in the year, that $4 million will find its way to non-profit agencies under research contracts and that between $1 and $2 million will be spent in federal contract research centres. Admiral Owen says that in the process of contraction by about 20 per cent which has been forced on the office in the past three years, care has been taken to keep support for universities and for domestic laboratories more or less in balance, so that there has been no undue concentration of effort on the places at which the office would itself be most immediately affected.

Naval Research Laboratory, Washington.

In the universities, the range of work supported is still quite substantial (and in value is roughly 3 per cent of all federal money for basic research in universities as well as about a fifth of what the National Science Foundation spends in this way). Thus the ONR has been the chief sponsor of the development of the supersonic particle accelerator at Stanford University, chiefly on the grounds that the technology of superconducting machinery is essential to its long term interests. (The National Science Foundation now shares in this development.) Naturally enough, oceanography takes a large and growing share in the office's budget—nearly a quarter of what was spent on basic science in 1969. Over the years, the ONR has been responsible for the development of submersible research vehicles, including the deep submersible Alvin which was lost in 1968 after having helped to locate the hydrogen bomb which went astray off the coast of Spain, and also the up-endable research vehicle used widely in the BOMEX programme of meteorological and oceanographic observations carried out a year ago in the eastern Atlantic.

Admiral Owen says that his office is at present particularly interested in a number of general themes which bear on the US Navy's long term interest. The development of techniques for surveillance under water and above it is understandable enough, as is the interest in techniques for command and control. The navy has its own special interest in materials technology, being as often concerned to make hollow objects which will withstand pressure of deep water as air forces are to make lightweight lifting surfaces. Energy conversion is another field of interest (responsible for some 5 per cent of the budget in the past few years). Increasing attention is being given to problems of the management of people, chiefly on the grounds that the questions of how best to get a good service out of 650,000 people (not counting the marines) have not previously been given the weight that they deserve.

The principal laboratory is the Naval Research Laboratory, with interests in thermonuclear fusion, radio astronomy and rocket astronomy as well as the more obvious functions of a naval research establishment. (The two smallish contract laboratories are the Naval Biological Laboratory at Oakland, California, which is largely concerned with aerosols, and the Arctic Laboratory in Alaska which is concerned with physiological problems.)

The part played by the Office of Naval Research in the years since the Second World War is thus not simply measured by the amount of money spent on research grants. At the same time, however, there is no doubt —this is simple arithmetic—that the scale of operations has been declining in real terms for the past three or four years, with the result that the involvement of the ONR in the direct sponsorship of basic research in the universities has necessarily become a smaller proportion of the total. In the long run, no doubt, this may be not merely inevitable but desirable—everything will depend on whether the budget of the National Science Foundation grows at such a pace as to take up the slack. But the ONR seems still to retain some of the daring that endeared it to university scientists in the years after the Second World War.

MOLECULAR BIOLOGY

Elites and Labels

THERE are now almost too many labourers in the vineyard, in the view of Dr James Watson, director of the Cold Spring Harbor Laboratory of Quantitative Biology. "Until recently all of us have thought of (the world of molecular biology) as a small group, containing most of our best friends, plus a few dissidents whom, nevertheless, we wanted to talk with if not exchange preprints." In the annual report of the laboratory Dr Watson estimates that world wide "the number of intelligent people now doing sensible, if not important, work in molecular biology" is probably at least 2,500, of whom two-fifths passed through Cold Spring Harbor last summer. The existence of the Symposium now has to be under-advertised because there is room for less than half the applicants. But despite having to turn away the crowd from his doors, Dr Watson intends to see that Cold Spring Harbor "remains an institution where graduate students are as welcome as their professors, where bad science is so labelled, and good science encouraged with every resource at our disposal".

OCEANOGRAPHY

Few Friends for NOAA

No influential supporters have been found for a proposal to set up a federal agency for oceanography and ocean engineering. This, at least, has been the experience in the past few days of the subcommittee on oceanography set up by the Senate Committee on Commerce, which has been trying to put flesh on the bones of the proposal that there should be a National Oceanic and Atmospheric Agency (NOAA). The commission, known after its chairman, Dr Julius Stratton, provided an optimistic but detailed prospectus for the exploitation of the oceans as a "national effort", and urged that an agency linking together organizations as varied as the United States Coast Guard and the US Weather Bureau would be needed to seize all the opportunities which exist. In the past year, however, interest in oceanography as such has decreased as that in the environment has grown, which is one reason why the subcommittee has found most of its witnesses lukewarm towards the concept of NOAA. At the same time, it has become known that the Ash commission set up last May to advise President Nixon on the organization of those parts of the federal government responsible for domestic affairs has the problem of organization in oceanography and for the environment very much in mind. In the circumstances, the subcommittee's proceedings have been chiefly an opportunity to know what people have been telling the Ash commission. Last week, for example, Dr L. DuBridge, the President's science adviser, said that the Ash commission's report was due to reach the President on April 15. He said that he was against the proposals of the Stratton commission because they were at once "too radical and too conservative". By this, he meant that their repercussions on government organizations would be drastic, but that even the organization called NOAA would not adequately link problems of oceanography with problems of pollution. To the assertion that "there is enough in the oceans to feed and sustain mankind more or less indefinitely, but that man is in danger of ruining this by pollution", he replied that research is necessary to test the assumptions in this view. "It has been asserted that the ocean is being polluted, but I don't believe that's true"—there is instead pollution in coastal waters which will be mitigated by the Administration's proposals for dealing with water pollution.

Dr W. D. McElroy of the National Science Foundation also opposed the setting up of NOAA in his statement to the subcommittee last week. He thought that the proposed organization would be so unwieldy that it would create more problems than it solved. He also argued that there is a logical need for organization around four functions—environmental forecasting and services (weather, for example), the development of resources, scientific research and the development of technology. He argued that the agencies now responsible for these functions should continue to look after them and he stoutly defended the interest of the National Science Foundation in oceanography through what is called the Sea Grant Program (on which the foundation spent $6 million last financial year, nearly a third of its entire support for oceanography).

The Secretary of the Interior, Mr Walter J. Hickel, also turned out to be against the proposal to set up NOAA, perhaps predictably on the grounds that the Department of the Interior could manage quite well enough with its present responsibilities for management of resources and for organizations such as the Coast Guard. At the same time, he admitted that there is much room for better coordination between the federal agencies at present responsible for various aspects of oceanography and the environment.

The extent to which the Ash commission will affect the arrangements that now exist remains to be determined. On the face of things, it would take exceedingly clever administrators to think of devising a single agency responsible for, say, "the environment"—Dr DuBridge said in his evidence that such an agency would be as hard to create as a single agency for all scientific research.

LABOUR MARKET

Bread Lines for Physicists

THE controversy whether there is actual unemployment among PhD physicists in the United States has been intensified as details have become known of the government plans for cutting back on some activities in federal laboratories. Although Dr Philip Handler has claimed that a survey carried out by the National Academy of Sciences has shown that tales of unemployment stem from "anecdotes about a few theoretical physicists" (see *Nature*, **225**, 786; 1970), the American Institute of Physics is making much of the experience of its job finding service at the Chicago meeting at the end of January this year. The institute says that the people putting down their names on the register of those wishing to move have increased over the years from 567 in 1964 to 677 in 1966, 984 in 1968, 1,285 in 1969 and 1,347 in 1970. The numbers of vacancies cannot easily be inferred from what is known about potential employers registering with the placement service, although it is held to be significant that the number of employers in 1970 was only 101, compared with 167 in 1969 and a high figure of 272 in 1967. By the same test, the numbers of vacancies registered has also fallen from 617 in 1967 to 121 in 1970, but this comparison is complicated by the way in which some employers may decide not to make publicly known details of all the jobs available. Of the physicists seeking jobs in 1970, it appears that only 70 out of 1,347 were actually unemployed, that 252 were academics and 647 were graduate students or the equivalent. More than a half of those seeking jobs were in their twenties, 439 were between 30 and 40. A further difficulty in making this comparison is that the anxiety of which physicists now speak is as much a fear of what the labour market will be like when the impending cuts in public expenditure on research take their full effect. Many of those due to leave the NASA Electronics Research Center at Cambridge, Massachusetts, have not yet resigned in the hope that something will turn up to save their jobs at the last minute, while it appears that the Atomic Energy Commission will be having to dispense with some 1,500 people from its laboratories at the beginning of the next financial year.

The American Institute of Physics is hoping that it may not be too late to influence the course of events. Dr Lewis Slack said last week that the institute was planning to carry out a survey among universities of the extent to which the new budget would make it necessary to curtail the scale of operations. He said that similar surveys were carried out among physics departments after the budget cuts of the past two years, and that the results had been found to be of some value to agencies of the federal government in their battles with Congress.

The extent to which physics typifies other scientific disciplines is not at this stage clear—given that its involvement in the new environmental programmes is less direct than that of, say, biology, it would be no surprise if physics turned out to be a particular hard luck story. Some of the features of the labour market in physics have, however, been documented in a report for the American Institute of Physics by Susanne D. Ellis (*Work Complex Study*, to be had from the American Institute of Physics, New York). On the basis of interviews with industrial physicists, employers and employees, the report points to a sharp change in the balance between industrial laboratories on the one hand, and universities and government laboratories on the other; since 1967, when the growth of university research was first halted, industrial laboratories have apparently found it easier to recruit people. At the same time, the employers interviewed seem to have been convinced that "physics education has become too specialized and graduate training, especially, is strong but narrow". A part of the problem in industrial laboratories seems to be the need to fit physicists into disciplinary teams within which communication should be easy. Mrs Ellis, in her survey, found that universities were inclined to reply with "if the universities do not train specialists, where else can one find a research atmosphere conducive to the pursuit of a narrow topic in great detail ?" The industrial employers seem also to complain, however, that those seeking jobs as physicists in research laboratories without PhD degrees tended to be too inexperienced, and that physicists were less practically minded than engineers when engaged on similar work. Mrs Ellis concludes that universities should make more effort to produce broadly trained physicists but that many potential employers were not aware of the changes in curriculum which there have been in the past few years.

Some of these issues will no doubt be raised in the study of physics that is now being carried out by the National Research Council of the National Academy of Sciences under Professor D. Allan Bromley of Yale University. The intention is to extend the work of an earlier committee under Professor George E. Pake which argued the case for continued support for university physics in a report published in 1966. On this occasion, the intention is that the committee will "necessarily consider a broader range of topics", including the relationship between physics and other branches of science in "the current national and social context". A statement by the National Research Council says that the new committee will try to discuss the criteria which should guide financial support for physics rather than attempt to suggest precisely what programmes should be followed. The committee says that it will welcome constructive advice on the task which it has undertaken. The chances are that it will find itself having to pay close attention to the character of physics education at universities.

HIGH ENERGY PHYSICS

Robbing Peter to Pay Paul

THE Joint Committee on Atomic Energy seems reluctantly to be presiding over the shrinking of high energy physics. In his evidence to the committee on Tuesday this week, Mr Paul McDaniel of the Atomic Energy Commission explained some of the consequences of closing down the Princeton–Pennsylvania accelerator, and of restricting work at the Cambridge electron accelerator to that concerned with electron beams. Between now and June 1971, he estimates, there would be a reduction of ten in the manpower involved in high energy physics in the United States. The most spectacular decrease would be associated with the Princeton–Pennsylvania accelerator where the work force consists at present of 180 scientists, but more than sixty people would also leave the Cambridge operation. At the same time, he said, there has been a reduction in all the contracts let to the operators of the accelerators which will continue working.

One of the ironies of the situation that has developed is that nobody is quite clear what will now happen to the Princeton–Pennsylvania accelerator, the facilities at which are worth $39 million. By all accounts, the fixed equipment now belongs to the universities collaborating in the venture, and Professor D. H. White, director of the laboratory, told the Joint Committee that he is hoping to raise enough money to keep the machine in operation either from the National Science Foundation, private foundations or even the universities themselves. Dr White said afterwards that the position of many research students engaged on work at the accelerator is very much in doubt, and that many of them will no doubt be "ruined". He reckons that as little as a million dollars a year might be enough to keep the machine in being for two or three years, in the hope that by then the climate will have improved a little. Dr McDaniel agreed that "with the Princeton–Pennsylvania accelerator, we've cut too deeply—one can't turn on and off scientific activities like these". The new 200 GeV machine in Illinois is by contrast pushing ahead, although it seems now to be clear that the machine that eventually delivers the first beam of protons in 1972 will be as spartan as any machine could be. This year, the AEC was apparently hoping to persuade the Administration to let it spend $112 million on the machine, but it was given authority for only $65 million. The result is that equipment for using the beam is being deferred.

If high energy physics has taken the brunt of the Administration's economies in the Atomic Energy Commission's parish, however, two parts of the research programme will prosper. First, the Los Alamos meson production facility seems to have raised everybody's hopes that the negative pi meson will be exceedingly useful in radiotherapy. At the same time, the control thermonuclear research teams have been so heartened by the progress of the Russian Tokamak device that they are proposing to spend $5·5 million, roughly half as much again as in the present year, on new experimental devices which are frankly intended "to go into this field in a big way". Plainly the Joint Committee, one of the most avuncular in congress, will still have plenty to be avuncular about even if there was only the thinnest logic in one member's suggestion that gravitational waves should also be within its purview.

NEWS AND VIEWS

Mysterious Satellites

ANY biologist told that 10 to 12 per cent of the total DNA genome of an animal is sequestered in a chemically distinct fraction would find it hard to escape the conclusion that such DNA has some crucial cellular function. That explains why the so-called satellite DNAs are exciting so much interest and why the reports in this issue of *Nature* by Jones (page 912) and Hennig and Walker (page 915) will be widely welcomed.

Satellite DNAs were discovered some six years ago when several groups independently, and more or less simultaneously, found that the sheared DNA of higher organisms can be fractionated on the basis of its buoyant density. During density gradient centrifugation of the total cell DNA, satellite DNA is resolved as a distinct band with a different buoyant density from the bulk of the DNA of the main band. This difference in buoyant densities means, of course, that the nucleotide base composition of satellite DNA is quite distinct from that of main band DNA. Moreover, when the two strands of a satellite DNA are separated and then allowed to reassociate, they do so very much faster than does the main band DNA. Satellite DNA must therefore contain many copies of very few base sequences which means its potential as a repository for information specifying the structure of proteins is severely limited. This restriction of base sequences usually, but not inevitably, results in satellite DNA having a different overall base composition and therefore buoyant density from the rest of the DNA.

What are the other salient properties of satellite DNA and what possible function can it serve ? First, a glance at Hennig and Walker's article shows that the amount of satellite DNA varies widely between even closely related species. Twelve per cent of the DNA of mouse cells is satellite, enough for four mouse chromosomes, while another rodent, *Microtus agrestis*, has less than 2 per cent satellite DNA, and *M. arvalis* has 6 per cent satellite DNA. Second, as Hennig and Walker and others have shown, the kinetics of the renaturation of satellite DNAs are consistent with the idea that they are made up of tandem repeats of identical sequences about 150–300 base pairs long. Sequence analyses still in progress in Walker's laboratory apparently suggest that this is an overestimate of the length of satellite sequences and that they may be families of sequences only about ten or fewer base pairs long. Third, the overall base compositions of satellite DNAs from different species differ as widely as the relative proportions of satellite DNA present. Finally, the attempts reliably to detect RNAs complementary to satellite DNA have all failed. It seems that satellite DNA plays no part in coding for proteins or RNAs.

Jones (page 912) and Gall's group in the United States (*Nature*, **225**, 414; 1970) have exploited the technique of intracellular nucleic acid hybridization, which they have developed recently, in order to localize satellite DNA in interphase and mitotic nuclei. As Jones's autoradiograms show, satellite DNA seems to be located in the condensed chromatin of interphase nuclei. This is not surprising because current theory holds that condensed chromatin is not active as a template for RNA synthesis and satellite DNA is not transcribed as far as anyone knows. Localization of satellite DNA in the centromere regions of mitotic chromosomes, however, is most interesting.

It is early days yet, and Jones says that he cannot be certain that every chromosome contains satellite DNA in the centromere region, though if that proves to be the case it may explain both the function and chemistry of satellite DNAs. Their restricted and highly reiterated base sequences might be the molecular basis of chromosome pairing between both homologous and non-homologous chromosomes. Moreover, the apparent association of satellite DNA with nucleoli begins to make sense because cytogeneticists have often commented on the association of centromeres and nucleoli.

A host of experiments and speculations leap to mind. Perhaps satellite DNA plays some part in the assembly of the mitotic spindle, for example, by influencing polymerization of spindle protein or the attachment of chromosomes to the spindle. Hybrid cells might be useful in studying the specificity of a putative interaction between satellite DNA and components of the mitotic spindle. And the chromosomes of organisms with diffuse centromeres might be useful for further testing the relationship between satellite DNA and centromeres.

The localization of satellite DNA in centromere regions may suggest explanations of some of its bizarre properties, but many questions remain. What is the quantitative distribution of satellite DNA in any chromosome set, why do some species have five or six times as much satellite DNA as other species, and how does satellite DNA evolve ? One possible explanation is that it arises by the duplication or amplification of a short sequence of base pairs followed by, or concomitant with, the translocation of some of these duplicates to every chromosome in the cell. Once several million copies of the sequence had become established, and assuming some sequences have selective advantages over others, it might well take long times, even on an evolutionary time scale, to change radically the overall composition of satellite DNA. During speciation from a common ancestor perhaps different short sequences are selected for amplification from the ancestoral sequence pool, so that two closely related species end up with very different satellite DNAs. It is becoming increasingly clear that gene amplification is not all that uncommon, and Gibson and Hewitt (*Nature*, **225**, 67; 1970) in their work on the DNAs of geographically separated populations of grasshoppers may have found an example of the evolution of something very similar to satellite DNA.

MINERALS

Extraction, not Destruction

THE extraction of minerals in Britain is an economic necessity, but conservationists need not despair because dereliction on the scale left by nineteenth century industry is avoidable. And, according to speakers at a symposium on mineral extraction and the countryside held in London on March 3, it is not even a very expensive job.

Each year 480 million tons of minerals are produced in Britain and, as Dr K. C. Dunham (Institute of Geological Sciences, London) implied, there is scope for expansion in terms of available reserves. In Cornwall, for example, there are still valuable veins of tin, some stretching out under the sea, which are expected to contribute to a doubling of the Cornish output of this mineral. And although there is a tendency to import high grade iron ore there may still be a need for the considerable British reserves of a lower quality. Dunham predicted increasing extraction of fluospar and barites (CaF and $BaSO_4$) in the Pennines and further discoveries of metalliferous minerals in the north of Scotland. The potassium salts to be extracted from north-east Yorkshire represent the largest discovery of minerals made under land in Britain this century.

But all this does not mean that the countryside need suffer, for it is now possible to cover up the traces of mining by filling up holes, smoothing out the land and replanting it with vegetation. The story is not of course that simple, and Mr J. Taylor (Blue Circle Group and Confederation of British Industry Minerals Committee) explained some of the reasons why. Local authorities, he said, are unwilling to give planning permission on a time scale sufficiently long to allow extractors to plan for restoration work. Transport costs often increase the price of filling in holes, and Taylor suggested that there might be more enthusiasm on the part of local authorities to use abandoned mineral sites as deposits for domestic and industrial refuse. Local authorities, he implied, could also do more to cope with sites that are already derelict. In 1969 the British Government provided £5,000,000 in grants for reclamation, but only fifty-eight local authorities applied for help, and most of the money was unused.

The local authorities were defended by Mr D. J. Davison (National Coal Board Open Cast Executive), who pointed out that even with a 95 per cent grant impoverished councils cannot afford the burden on the rates that reclamation would require. A new organization is needed, he said, to formulate a national programme to eliminate dereliction. The money is available and the technical problems involved are not enormous. The size of the problem and some of the efforts made to tackle it are illustrated in a small exhibition on mineral extraction and the countryside which was opened on March 3 at the Geological Museum, London, under the auspices of the Institute of Geological Sciences and the Geological Section of the Nature Conservancy.

SOLID STATE

Trends in Diffusion

from a Correspondent

ALTHOUGH measurements of substitutional diffusion in metals are well documented, diffusion in ceramics and semiconductors, and even interstitial diffusion in metals, is far less clear. Several new techniques aimed at these more difficult systems were described at a conference on trends in diffusion sponsored by the Institute of Physics and the Physical Society in collaboration with the Institute of Metals and the National Physical Laboratory at Teddington on February 25 and 26. The most novel of the new techniques was probably the use of centrifuge methods to study the diffusion of noble metals in the alkali metals. Dr L. W. Barr (Atomic Energy Research Establishment, Harwell) described experiments confirming the interstitial nature of the process for gold in sodium and potassium. Studies of oxygen diffusion in TiO_2 were described by Dr D. G. Lees (University of Manchester), who told how the α-particle yield from the diffusing ^{18}O was measured as a function of the depth at which the energy of the incident proton beam is attenuated to the resonance energy of 1·78 MeV.

Present interest in thin-film electron microscopy techniques was well represented by contributions dealing with annealing studies of secondary defects. Apart from their relative experimental simplicity, these techniques have the advantage that measurements can be made at much lower temperatures than with conventional radioactive tracer methods, so that information can be obtained about the curvature of the Arrhenius plot. Professor R. E. Smallman (University of Birmingham) made it clear that these experiments have the merit that the process can be observed dynamically while the diffusion data are obtained. This is a valuable feature in aiding interpretation, as shown by the work of Dr R. N. Cornell (Berkeley Nuclear Laboratories) on the growth of fission gas bubbles in irradiated uranium dioxide.

In spite of the lost dimension, surface diffusion studies pose many problems in interpretation. Dr G. E. Rhead (University of Paris) pointed out that when the temperature is normalized to that of melting, the surface diffusion coefficients for clean metal surfaces lie on the same curve, and can be related to solid state diffusion. For surfaces containing adsorbed impurity layers the melting point of the two dimensional adsorbed compound was shown to be important, the high diffusion coefficients obtained being interpreted in terms of diffusion in a two dimensional liquid. A record value of 1 $cm^2 s^{-1}$ was claimed for the diffusion coefficient in the Pb/Cu system.

The application of diffusion in metallurgical processes such as diffusion creep is largely concerned with the efficiency of interfaces as vacancy sources or sinks. This was clearly shown to be related to the effect of surface films and solute absorption at grain boundaries. Although interfaces are usually assumed to be both high diffusivity paths and vacancy sources or sinks, Dr J. E. Harris (Berkeley Nuclear Laboratories) pointed out that experimental evidence suggests otherwise. Clearly interface phenomena are becoming increasingly important and are likely to be a centre of attention in the future.

BAND STRUCTURE

Copper Leads the Way

by our Solid State Physics Correspondent

The complicated band structure of the transition metals may at last be within reach of a solution if a new way of treating the *d* bands of copper proves to be as general as it seems. C. Y. Fong and M. L. Cohen (*Phys. Rev. Lett.*, **24**, 306; 1970) have replaced the tight binding approximation for the *d* bands by a non-local pseudopotential with an angular quantum number of 2, a technique first vented on the simpler case of potassium. By introducing parameters to respond to well known energy gaps in the zone they have obtained encouraging agreement with experiment and with other more fundamental calculations. Fong and Cohen urge that the more intractable transition metals should now be analysed.

Empirical pseudopotentials became fashionable in the wake of Abarenkov and Heine's work in 1964, which established the value of relaxing the pseudopotential formalism in favour of physically sensible model potentials. It was seen as a means of capitalizing on the weakness of the pseudopotential method, namely, the non-uniqueness of the potential due to the pseudo-wave-functions forming an overcomplete set. It soon became clear that a parametrized model could describe alkali metals with fair precision, as might be expected, but was not suitable for the transition metals, where the interaction between the *s* and *d* bands is strong. Attempts to use the tight binding approximation for the *d* bands and a pseudopotential for the *s* and *p* bands have proved of limited value, and so Fong and Cohen decided to dispense completely with the tight binding approximation in copper.

The pseudopotential they use was a square well with a simple damping term. The bands were constrained to fit experimental values at important symmetry points in the zone, and the band structure and the corresponding density of states were computed. Although only limited experimental results are available, the agreement produced by the model was good enough to make Fong and Cohen raise their sights to what may be achieved with other noble metals, and with the transition metals and their compounds, where the richer prizes lie.

There may be room, however, for an improved form of empirical pseudopotential for copper, based on the same approach to the *d* bands. Fong and Cohen could not use their model to reproduce some important details of the density of states curve, in particular the heights of the peaks, and although other calculations seem to have shown similar discrepancies there is no reason to suppose that such an unsophisticated potential should be the optimum form. But it is encouraging that this new representation of the *d* bands produced the sort of agreement that was needed to justify work on the transition metals.

VARIABLE STARS

Fast Pulses from White Dwarf

from our Cosmology Correspondent

Following the discovery by A. U. Landolt that the dwarf star Haro-Luyten Taurus 76 has a rapid variability with a period of about 12 minutes (*Astrophys. J.*, **153**, 151; 1968), B. Warner and R. E. Nather have observed this object over the 1969 observing season, in an attempt to determine the cause of its variability. Their observations seem clearly to favour a pulsational rather than an eclipsing model for HL Tau-76, for the light curves which they have obtained greatly resemble those of dwarf novae of the SS Cygni type, although HL Tau-76 varies on a remarkably short time scale when compared with those of the accepted dwarf novae. Typical quasi-periods for dwarf novae are in the range 20–100 days (*Mon. Not. Roy. Astron. Soc.*, **147**, 21; 1970).

Several important features are clear from the observations of Warner and Nather, notably that although the amplitude variations of the light curves are quasi-periodic with a period of 12·44 minutes, the size of different peaks varies so much that occasionally odd peaks seem to be absent. The identification of this variation with that of dwarf novae must be tentative, if only because the period is so short. Warner and Nather point out that although the usual period–amplitude relation for these novae does not fit HL Tau-76 this is hardly surprising in view of the extrapolation required, which is more than three orders of magnitude. The most important question raised by this discovery must be that of a possible evolutionary sequence from models with periods of about 50 days to those with periods of a few minutes. Observational effects naturally favour the discovery of the longer period variations, but there will now be some incentive to look for variable stars with shorter periods.

HEARING

Auditory Illusions

from our Experimental Psychology Correspondent

Optical illusions have fascinated psychologists for many years, not just as mere curiosities, but because when the visual system fails to interpret a stimulus correctly, this gives valuable clues as to the nature of perceptual mechanisms. Illusions and confusions of an auditory kind are very much rarer. But R. M. Warren has reported recently (*Science*, **167**, 329; 1970) that noises such as coughs can adequately replace speech sounds, with the hearer unaware that any speech sound is missing, and with the median subject in a group of twenty unable to locate the position of the cough to within five phonemes. (A phoneme is the smallest unit of speech that distinguishes one utterance from another.)

Warren's experiment involved erasing from magnetic tape 120 ms of speech sound, thus removing a complete phoneme from a word together with portions of the adjacent phonemes that might give transitional cues to the missing sound. Control subjects who were played the recording of a sentence with 120 ms of silence where the phoneme had been were easily able to notice that there was a sound missing, and correctly indicate on a written version of the sentence which part has been cut out. But nineteen experimental subjects hearing the sentence with a cough replacing the speech sound reported that all speech sounds were present. One subject reported a sound missing but chose the wrong one.

This is the third rather striking example of an auditory illusion discovered by Warren. With Gregory he reported the phenomenon of verbal transformation (reviewed by Warren, *Psychol. Bull.*, **70**, 261; 1968) in which repetition of a single word on a tape loop gave the hearer the impression that the word altered its apparent sound. Throughout a series of a few hundred repetitions the heard sound was reported to change successively into different words. A typical series of transformations heard by a subject listening to the word "tress" repeated continually for 3 min (with the subject reporting whenever a change in apparent sound occurred) was "stress, dress, stress, dress, Jewish, Joyce, dress, Jewess, Jewish, dress, floris, florist, Joyce, dress, stress, dress, purse". An explanation for this is that unaided by context and possibly encouraged by neural adaptation, perceptions break away from the sounds usually associated with a particular physical stimulus.

The second of Warren's illusions (*Science*, **164**, 586; 1969) should more properly be called a confusion. It turns out to be impossible to assign a correct ordering to four sounds, a high tone (1,000 Hz), a hiss, a low tone (796 Hz), and a buzz, each lasting for 200 ms and played repeatedly in the same order. Four spoken digits repeated at the same rate can easily be ordered even when all transitional cues such as usually occur between fluent speech sounds are absent. When listening to the cycle of sounds there is no difficulty in identifying each sound; it is the ordering that is impossible; a subject understands speech sounds which have an average duration of 70 ms and music can be repeated by musical subjects with notes occurring as fast as 20/s.

These three demonstrations indicate a surprising flexibility of the mechanisms of auditory perception. Powerful reconstructive processes may partly account for the ability to understand speech even in the midst of other distracting noises, and for tolerance of the very different accents and sounds produced by different speakers. Warren has shown that speech perception is not a matter of guessing what might have been said. The reconstructive process gives some information about the timing of irrelevant sounds and, aided by context, yields direct impressions of coherent speech.

LAND MANAGEMENT

Conservation on the Farm

from a Correspondent

A MEETING held at Monks Wood Experimental Station on February 19 and 20 should have forged contacts which will prevent future instances of two government bodies, both concerned with the countryside, giving contrary advice. The topic was land management for agriculture and conservation, and it brought together members of the Nature Conservancy and the Agricultural Land Service (ALS) of the Ministry of Agriculture, Fisheries and Food, as well as representatives of the Forestry and Countryside Commissions.

The ALS is the body which can most affect the farming pattern of England and Wales. Its officers advise farmers on all problems of estate management. Equally important they are closely concerned with the administration of the various grant and subsidy schemes which greatly influence the way farming is done, particularly in the less productive areas of Britain. The ALS is sometimes blamed by conservationists for many allegedly undesirable farming practices, including the destruction of hedgerows, factory farming of livestock and the massive use of fertilizers which pollute inland waters. Farmers, of course, complain that conservationists pay too little attention to the economics of agriculture.

The principal task facing the participants was to discover whether efficient farming need harm Britain's native flora and fauna. Because nature reserves only cover a fraction of 1 per cent of the area of lowland England, most wild plants and animals, if they are not to become extinct, must continue to be found on farm land.

There was much common ground, partly no doubt because so many members of the ALS are essentially countrymen. It had to be agreed that in many lowland areas productivity must continue to have priority, and that changes such as the removal of many—possibly most—hedgerows were inevitable. Only when farmers are keen game preservers will they retain all the cover the conservationists would desire. Mr P. J. Huguet (ALS) and Dr M. Hooper (Monks Wood Experimental Station) agreed that nevertheless even on the most intensive farms there are areas which may be set aside for the benefit of wildlife if suitable advice on their location is available. Mr J. B. Rundle (ALS) pointed out that in mountain and upland Britain farming is partly maintained for social reasons, for the subsidies might be spent more profitably (in terms of food production) in the lowlands. Here the conservationists are quite as keen as the agriculturalists that the present farming pattern should continue. Mr I. Nicholson (Nature Conservancy, Scotland) explained that controlled grazing often improves the wildlife interest.

Not all differences of approach can be resolved easily. Water pollution or eutrophication from farm wastes which cannot be economically used as manure will continue to be a problem, and so will the chemical fertilizers in the run-off from arable land, as Mr K. B. C. Jones (ALS) pointed out. Here the ALS and the National Agricultural Advisory Service may still have to give advice which they know may not be in the best interests of conservation. The only solution, said Dr K. Mellanby (Monks Wood Experimental Station), would be a change in government policy to support the use of organic manures with subsidies, something which may happen if present practices are shown to cause the deterioration in British soils which is alleged to occur in parts of North America.

The meeting revealed that clearly the ALS and the Nature Conservancy can often have an agreed policy. Where this is impossible, close collaboration can often prevent much of the damage which would otherwise occur.

ANTIBIOTICS

Sense and Sensitivity

from our Molecular Biology Correspondent

A NEW group of articles concerned with the mode of action of antibiotics of different kinds in blocking protein synthesis follows hard on the work I discussed last week. New light on the site of streptomycin action comes from Strigini and Gorini (*J. Mol. Biol.*, **47**, 517; 1970), in an article which does not yield up its treasures easily.

The burden of the authors' argument is as follows: the agents that suppress nonsense mutations are known to be tRNA species with anticodons that make sense of the nonsense. Mutations of *E. coli* and T4 bacteriophage at streptomycin loci not only vitiate the proper function of the suppressors, but also affect the extent to which translation can occur by misreading. Now the ribosomal protein associated with streptomycin sensitivity resides in the 30S particle, and has been identified by Traub and Nomura. It therefore seems that the well known manifestation of misreading, which the binding of streptomycin at this site engenders, can be simulated by a structural aberration in the same protein. By working with a set of different suppressors containing identical anticodons, Strigini and Gorini have established that the failure of the suppressor is not related to the nature of the anticodon. They have likewise shown that the identity of the aminoacyl group is not involved in the mechanism. The inference is that the ability of the aminoacyl-tRNA to bind productively to the ribosome is determined by the streptomycin-sensitive protein, which therefore evidently plays a central part in polypeptide chain propagation.

Returning now to the mechanism of antibiotic action on the ribosome, Monro and Vazquez and their collaborators have continued their studies by applying an assay related to the so-called fragment reaction (Celma *et al.*, *FEBS Letters*, **6**, 273; 1970). This takes advantage of the strong evidence that it is only the aminoacyl end of the tRNA chain that actually becomes involved with the peptidyl transferase on the 50S ribosome. By restricting the assay system to an aminoacylpentanucleotide fragment and 50S subunits, it is thus possible to evaluate the effects of added antibiotics in terms explicitly of whether or not they molest the peptidyl transferase. The fragment–ribosome interaction requires the presence of considerable concentrations of ethanol, without which this anthropomorphic enzyme will not function.

The fragment reaction itself is simply the transfer of the amino-acid from the fragment to puromycin, sitting in the so-called A site (normally associated with the attachment of the incoming aminoacyl-tRNA) on the 50S particle. This reaction is known to be strongly inhibited, for example, by the antibiotic, streptogramin *A*, which, it is also found, will effectively chase off the aminoacylpentanucleotide in the binding assay. It follows that the primary binding of the fragment is functional, occurring at the peptidyl transferase site. In a range of twelve antibiotics, three strongly and one rather weakly inhibited the binding of the fragment, and all the rest, including chloramphenicol, actually caused varying degrees of stimulation. If, as seems likely from earlier work, chloramphenicol operates at the A site, it seems that the fragment assay pertains to effects at the P site at which the growing peptidyl-tRNA chain resides. Evidence regarding whether the interactions involve direct competition or binding at a linked site is still equivocal.

The activity of antibiotics on eukaryotic protein synthesis is a relatively unexplored field, which Neth *et al.* (*ibid.*, 198) have now approached by application of the fragment reaction to ribosomes from nothing less than human tonsils, and also from yeast. The experimental conditions for amino-acid transfer to puromycin are similar to those with *E. coli* ribosomes. Three antibiotics inhibit the reaction in systems from all three species of ribosome, but others are highly selective. Cycloheximide, long known as an inhibitor of eukaryotic protein synthesis, has no effect on the fragment reaction, and evidently therefore does not attack the peptidyl transferase. Anisomycin is an antibiotic that has no effect on *E. coli* ribosomes, but is an especially deadly inhibitor of the fragment reaction in the eukaryotic species. The authors suggest that the search for antibiotics with narrowly defined cell specificities might produce all manner of rewards.

PROTEIN SYNTHESIS

Making a Start

from our Cell Biology Correspondent

How are the different initiation sequences that signal the start of cistrons in bacterial and phage messenger RNAs distinguished by bacterial ribosomes, which are presumed to be identical? This has become a question of great interest, and work in several laboratories indicates that the F3 initiation factors will prove to have a key role in providing the specificity required for initiation of a protein chain. The transitory association of an F3 factor may temporarily confer on a ribosome the capacity to distinguish one species of initiation sequence from all others.

Much less is known, of course, about the initiation of protein synthesis in eukaryotes, but it is likely that the mechanism will prove to be basically similar to that in bacteria. There have, for example, been several reports of more or less compelling evidence, chiefly from kinetic studies, which suggest that at the end of each round of translation the eukaryote ribosome, like the bacterial ribosome, dissociates into free subunits ready for the initiation of a new cycle of synthesis. In the current *Journal of Molecular Biology* (**47**, 335; 1970) Vesco and Colombo, for example, report that sodium fluoride inhibits protein synthesis in HeLa cells by preventing the dissociation of 80S ribosomes. Once the pool of free subunits is exhausted protein synthesis stops, and after removal of the fluoride the restart of synthesis is preceded by dissociation of the accumulated ribosomes. Apparently the two subunits produced by the dissociation of 80S ribosomes have a greater chance of recycling than entering the pool of free subunits.

A decision about the nature and precise role of initiation factors and the requirements for the formation of initiation complexes in eukaryotes has been hampered by lack of well characterized mRNAs. Nonetheless, it seems that different species of initiation factor(s), each specific for one or more species of mRNA, probably exist in eukaryotes. Recently Heywood (*Nature*, **225**, 696; 1970) claimed that, in addition to tRNAs and GTP, initiation factors washed from chick muscle cell ribosomes are required for the formation of a 70S initiation complex between 40S ribosome subunits and a 26S RNA fraction containing myosin mRNA. Chick reticulocyte ribosomes will also form an initiation complex with myosin mRNA but only in the presence of muscle cell initiation factors. Also recently, Hertzberg *et al.* (*Europ. J.*

Biochem., **11**, 148; 1969) have reported what may prove to be specific initiation factors in rabbit reticulocytes.

RNA virus RNAs are, of course, far more readily characterized than cellular mRNAs, and Baltimore and Huang have described recently (*J. Mol. Biol.*, **47**, 263, 275; 1970) the fate of polio virus RNA made in HeLa cells. Apparently progeny RNA molecules do not associate with ribosomes until they have left the replication complex but the RNA is bound non-specifically to a heterogeneous collection of cell protein. This RNP has a buoyant density of 1·40 g/cm^3 and it passes sequentially through forms with densities of 1·44 and 1·47 which are precursors to polyribosomes. According to Baltimore and Huang these two forms may well be respectively polio RNP associated with a 40S subunit and an 80S ribosome.

Unequivocal rather than suggestive analysis of eukaryote protein synthesis, however, depends on the future exploitation of cell free systems such as that described by Smith *et al.* (*Nature*, **225**, 184; 1970). With such a system it should be possible, for example, to test critically the claim (Tiboni *et al.*, *J. Mol. Biol.*, **47**, 467; 1970) that the G and probably T chain elongation factors from eukaryotes are specific for 80S ribosomes while the factors from prokaryotes and plastids are specific for 70S ribosomes.

AMPHIBIA

Origins of the Frog

from our Vertebrate Palaeontology Correspondent

SOME newly described fossil material from Oklahoma may help to settle the puzzle of the origin of the Amphibia. The common frog is one of the most aberrant vertebrates ever evolved. Most notably the whole skeleton is profoundly modified for jumping, but there are many other curious anatomical and physiological features. Prominent among these is the use of the whole surface of the skin for respiration. This latter character is not unique to the Anura, the group comprising the frogs and the toads, but is shared with the Urodela, or newts and salamanders, which have a shape more like a conventional primitive tetrapod. The anurans and urodeles together with the rare worm-like Apoda (caecilians) comprise the living representatives of the class Amphibia.

The record of fossil Amphibia is very full, but there is little to connect them with the living groups. The first fossil frog is a Triassic form, the first urodeles occur much later and there are no known fossil apodans. The other members of the class Amphibia are fossil forms ranging from the Devonian–Carboniferous boundary to the top of the Triassic. Two groups were present, the labyrinthodonts and the lepospondyls, but neither is obviously related to the living forms.

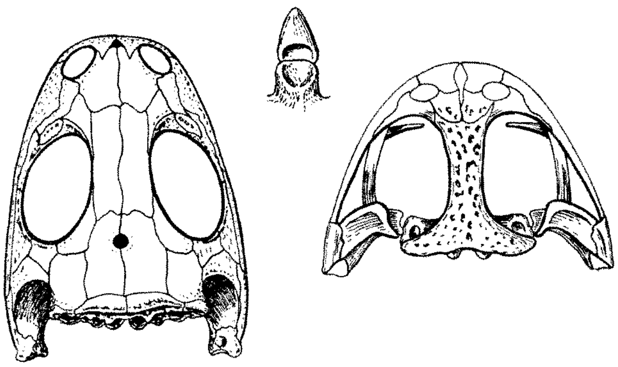
Attempts to relate the living Amphibia to labyrinthodonts or lepospondyls have been numerous and generally unconvincing. D. M. S. Watson in 1941 suggested that several small Upper Carboniferous labyrinthodonts had the reduction in the number of bones of the skull roof and in the number and nature of the vertebrae which would be expected in a frog ancestor. But the urodeles and the apodans were left without putative forefathers. The balance was restored by Romer in 1945 when he assigned the urodeles to the lepospondyls.

The Swedish tradition has been to give frogs on one hand and newts on the other an even longer separate ancestry. In the 1930s Holmgren and Säve-Söderbergh derived the urodeles from the Dipnoi or lungfish, and more recently Jarvik has developed the idea that the Anura and Urodela are derived from separate groups within the Devonian rhipidistian fishes. Unfortunately the Swedish philosophy does not require the tracing of any lineage of intermediate forms to bridge the 350 million year gap. Also later work by Gregory showed that the apparent frog-like character of the skulls of Watson's postulated anuran ancestor was largely due to the misinterpretation of difficult material.

In the past decade interest in the origin of living Amphibia has revived, largely because of the work of Parsons and Williams. In 1962 they cited a unique and unifying character of the three living orders in the structure of their teeth and in the following year discussed the characters to be expected in an ancestor for all three.

Recent speculation has thus tended to be on the ancestry of the Lissamphibia, an old term revived by Parsons and Williams to embrace all living forms. Cox has argued for the lepospondyl ancestry of Lissamphibia, largely because the latter do not use costal respiration to ventilate their lungs, whereas the labyrinthodonts, with well developed ribs, almost certainly did. It seems probable, however, that his favoured ancestors among the lepospondyls also used their ribs to breathe.

Bolt (*Science*, **166**, 888; 1969) has recently proffered the most likely Lissamphibian ancestor yet. He describes a small labyrinthodont from the Lower Permian of Oklahoma which has Parsons and Williams's tooth character. Instead of the characteristic (and diagnostic) labyrinthodont teeth *Doleserpeton*, as the animal is called, has pedicellate teeth (see figure) with a bicuspid crown separate from the root portion by connective tissue. The vertebrae also are unusual for the group of labyrinthodonts to which *Doleserpeton* belongs, and show a possible pre-Lissamphibian condition.



On the left is the skull of *Doleserpeton* (redrawn, after Bolt); in the middle, a pedicellate tooth of *Doleserpeton* (highly magnified, after Bolt). On the right is the skull of the earlier frog-like form, *Triadobatrachus* (redrawn, after Watson).

Thus *Doleserpeton* could be a proto-Lissamphibian anatomically while stratigraphically it appears at about the right geological horizon. Ironically, it is a member of the same family of labyrinthodonts as Watson's original frog ancestors.

The Chemical Physics of Ice

N. H. FLETCHER

A lot has been learned about ice in the last 20 years. The structures of several of the ten allotropes have been elucidated; the freezing process has been intensively studied; the growth and structure of crystals have been investigated, and from a practical point of view, the mechanical properties of ice, so important in climatic areas where ice is a building material, are now much better understood.

Modern theories of quantum mechanics and the solid state have led to this growth of knowledge, and this book is a case study in how to apply such formal principles to explain the structure of a relatively simple material. Professor Fletcher has collected material from many sources for this excellent monograph, which will interest pure scientists and glaciologists, meteorologists and workers in cloud physics. £4 *net*

Random Variables and Probability Distributions

Third Edition

H. CRAMÉR

First published in 1937, this tract develops the purely mathematical side of probability theory.
CONTENTS: 1 Introduction. 2 Axioms, Preliminary Theorems. *Distributions in* R_1: 3 General Properties, Mean Values. 4 Characteristic Functions. 5 Addition of Independent Variables. 6 Normal Distribution, the Central Limit Problem. 7 Error Estimation, Asymptotic Expansions. 8 A Class of Stochastic Processes. *Distributions in* R_k: 9 General Properties. 10 The Normal Distribution. 35*s. net*

Elements of Functional Analysis

I. J. MADDOX

For undergraduates who have completed basic courses on real and complex variable theory.
CONTENTS: 1 Basic Set Theory and Analysis. 2 Metric and Topological Spaces. 3 Linear and Linear Metric Spaces. 4 Normed Linear Spaces. 5 Banach Algebras. 6 Hilbert Space. 7 Matrix Transformations in Sequence Spaces. 50*s. net*

A Second Course in Mathematical Analysis

J. C. and H. BURKILL

Aimed at third year undergraduates, this book presents analysis in the abstract setting of metric spaces, providing a link with topology.
CONTENTS: 1 Sets and Functions. 2 Metric Spaces. 3 Continuous Functions on Metric Spaces. 4 Units in the Spaces R_1 and Z 5 Uniform Convergence. 6 Integration. 7 Functions from R_m to R_n. 8 Integrals in R_n. 9 Fourier Series. 10 Complex Function Theory. 11 Complex Integrals, Cauchy's Theorem. 12 Expansions, Singularities, Residues. 13 General Theorems, Analytic Functions. 14 Applications to Special Functions. £4 *net*

High-energy Gamma-ray Astronomy

by
G. G. FAZIO
Smithsonian Astrophysical Observatory,
and Harvard College Observatory,
Cambridge, Massachusetts

Gamma-ray astronomy above 10 MeV is difficult from the experimental point of view, but promising data are beginning to appear, as this survey progress report shows.

In the late 1950s the detection of cosmic photons with energy greater than 10 MeV seemed to be a most promising new branch of astronomy and a means of obtaining fresh information about the structure of the universe[1]. This was true even though the direct radiation could only be measured above the Earth's atmosphere. There were several reasons for enthusiasm. Theoretical calculations indicated that many known cosmic radio sources contained high-energy protons that could interact to produce detectable γ-ray fluxes. Another fascinating source of γ-rays was matter–antimatter annihilation in a steady state cosmology; the proposal that the radio source Cygnus A could be matter–antimatter galaxies in collision acted as a spur to the experimentalist. In addition, γ-ray photons are very penetrating, and travel in a straight path from the source so that they can be detected from sources at cosmological distances and from sources invisible in other regions of the spectrum. Gamma rays could also penetrate the upper atmosphere just enough to be detected at balloon altitudes. Apparatus for measuring the predicted fluxes already existed in laboratories with high-energy particle accelerators; it needed only to be made rugged and sufficiently compact to be carried by high-altitude balloons and satellites.

Many cosmic ray and nuclear physicists were attracted to this new field, and the search for sources began. Almost ten years of frustration and hard work followed. Scintillation counters, nuclear emulsions, and spark chambers in balloons and satellites were used and a few reports of sources were never substantiated. Only upper limits were published for the most likely radio sources. These did produce some significant facts about sources but hardly had the impact of a direct flux measurement. Finally, in 1968 the most conclusive evidence for a diffuse high-energy γ-ray flux from the galactic plane was published. The experiment, conducted by Clark, Garmire, and Kraushaar[2], consisted of a complex scintillation-Čerenkov detector on the third Orbiting Solar Observatory (OSO 3). In 1969, scientists at Case Western Reserve University and at the University of Melbourne cooperated in joint high-altitude balloon experiments and reported evidence for a point γ-ray source in Sagittarius[3].

Morrison[4] pointed out (with hindsight) that, in general, the cosmic electromagnetic spectrum exhibits a monotonic decline in intensity per unit frequency as a function of frequency, and so experimenters should first investigate the lowest energy photons beyond the visible that can be transmitted through a given galactic region. On this basis, X-rays (~1,000 eV) would disclose the first important results in high-energy astronomy, which indeed was the case. The discovery of cosmic X-rays by Giacconi, Gursky, Paolini and Rossi[5] in 1962, several years after γ-ray astronomy became active, has led to a rich field of research in high energy astronomy. In the short-wavelength region of the spectrum, isotropic diffuse radiation has been detected over the energy range from 0·2 keV–6 MeV, and discrete sources (for example, the Crab Nebula, Cygnus XR-1, and M 87) have been detected to energies of the order of 500 keV. An information gap appears in the spectrum from 1–50 MeV and above 1 GeV (10^9 eV).

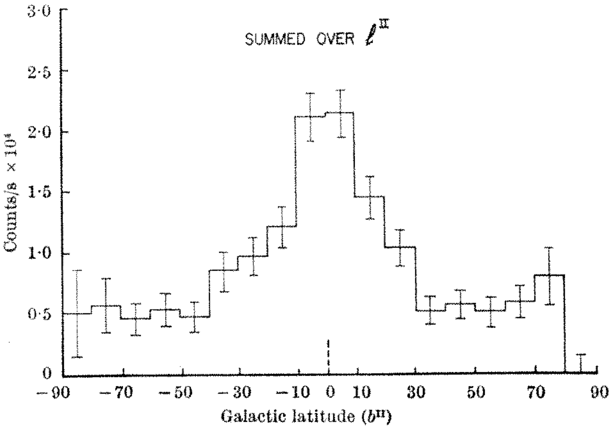

Fig. 1. OSO 3 data showing the dependence of γ-ray intensity on galactic latitude, summed over all galactic longitudes.

Energy Region 10 MeV–1 GeV

The existence of high-energy γ-rays (> 100 MeV) from the galactic plane and particularly from the galactic centre is rather definite. The OSO 3 (refs. 2 and 6) measurements of the directional properties of this radiation are most convincing (Figs. 1 and 2). As the resolution of the detector is ±15°, the angular distribution of the photons is consistent with a line source along the galactic plane, with strongest emission from the galactic centre. The distribution in longitude, however, is much broader than the distribution expected for a point source at the galactic centre. Significant peaks of lesser intensity along the galactic equator are also apparent in the data. The average line intensity in regions more than 60° from the galactic centre is about 0·25 of the line intensity near the centre. What is still in doubt is the absolute intensity that is quoted to be 3×10^{-4} photon cm^{-2} s^{-1} rad^{-1} from a region encompassing the galactic centre. There is still a discrepancy between measurements of the Earth albedo flux from OSO 3 and the albedo measurements of Explorer 11 and high-altitude balloons. The OSO 3 results are a factor of four higher than those of Explorer 11, and a factor of three higher than the results of Fichtel, Kniffen and Ögelman[7]. Several groups[3,7–10] using high altitude balloons have reported supporting evidence for the OSO 3 results but at a marginal statistical level. Recent results of the OGO 5 spacecraft experiment of the University of Southampton[11] have also indicated a maximum γ-ray intensity in the direction of the galactic plane. Table 1 compares the results of two such groups with the OSO data in the region of the galactic centre. Of particular importance are the recent results of Frye *et al.*[3], who can only reconcile their data with OSO 3 if the line source has a half-width of 15° and an intensity less by at least a factor of four. These discrepancies are being investigated by recalibration of the satellite and balloon detectors and by additional balloon flights from Australia.

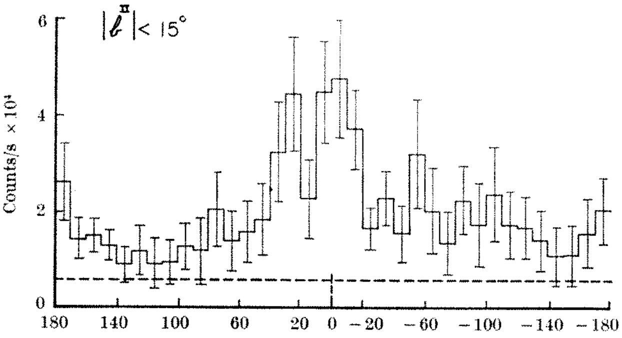

Fig. 2. OSO 3 data showing the dependence of γ-ray intensity on galactic longitudes near the disk. The dotted line shows the average rate at high galactic latitudes.

There is also evidence from the OSO data for an isotropic component of cosmic γ-rays with a background intensity of $(1{\cdot}1 \pm 0{\cdot}2) \times 10^{-4}$ photon cm^{-2} s^{-1} sr^{-1}, but it is difficult to measure and is not so convincing as the galactic flux. It is interesting to note that, within the errors discussed, this flux is in rough agreement with the value predicted by a power-law extrapolation of the isotropic X-ray flux to higher energies. The photon intensity per unit energy interval can be approximated by a spectrum of the form dE/E^2, implying equal amounts of energy per decade of photon energy.

The spectrum measurements, although of rather poor resolution, indicate that γ radiation from the galactic plane is on average more energetic than radiation from the isotropic component at high galactic latitudes.

Above 1 GeV, only upper limits exist for the isotropic γ-ray flux, which have been determined primarily by nuclear emulsion experiments in balloons[12–15]. Large air-shower experiments, based on the detection of showers with a low number of μ-mesons, have given upper limits of 10^{-13} photon cm^{-2} s^{-1} sr^{-1} to the intensity of isotropic γ-rays in the energy region 10^{14}–10^{16} eV (refs. 16 and 17). Recent evidence[18], however, has indicated that these showers were not caused by cosmic γ-rays.

In the energy region from 50 MeV–1 GeV, two important conclusions can be drawn from the upper limit measurements of the isotropic γ-ray flux. (*a*) If matter is being created, as required by steady state cosmology, matter and antimatter cannot be created in the metagalaxy in comparable amounts in the same region. The Explorer 11 and OSO 3 experiments indicate that the density ratio of antiprotons to protons is less than 10^{-6}. Steigman[19] has shown that if a charge-symmetric steady state cosmology is to survive, matter and antimatter must be created in separate regions, or, as Hoyle[20] has proposed, antimatter must be created in dense regions, such as galactic nuclei, where the annihilation γ-rays would be absorbed and never detected. (*b*) These same experiments indicate that the high-energy intergalactic electron density is less than the galactic density by at least a factor of ten. This conclusion is based on the flux predicted by Compton scattering of high-energy electrons on photons of visible light.

Table 1. GAMMA-RAY LINE INTENSITIES MEASURED NEAR THE GALACTIC CENTRE

Experiment	Energy region (MeV)	γ-Ray line intensity (10^{-4} cm^{-2} s^{-1} rad^{-1}) for given galactic latitude interval		Galatic longitude l^{II}
		$b^{II} = \pm 15°$	$b^{II} = \pm 3°$	
Clark, Garmire and Kraushaar[6] (OSO 3 satellite)	> 100	3	—	−30° to +30°
Fichtel, Kniffen and Ögelman[7] (balloon)	30 to 100	$0{\cdot}9 {+2{\cdot}2 \atop -0{\cdot}9}$	—	−10° to +25°
	> 100	2·4 ± 2·4	2·2 ± 1·1	
Frye, Staib, Zych, Hopper, Rawlinson and Thomas[3] (balloon)	> 50	≤0·7*	≤0·3*†	−30° to +30°

* Upper limits are at 95 per cent confidence level.

† $b^{II} = \pm 2{\cdot}3°$.

The evidence for the detection of cosmic γ-radiation above 50 MeV from a discrete source in Sagittarius[3] is not so strong as the evidence for the galactic component. The measured intensity of the source, designated Sgr γ-1, is $(3 \pm 1) \times 10^{-5}$ photon cm^{-2} s^{-1} and its preliminary position is $\alpha = 288° \pm 3°$ and $\delta = -35° \pm 2°$ ($l^{II} = 3°$, $b^{II} = -20°$). There is marginal evidence for the source in each of two high-altitude balloon flights from Australia, performed 21 days apart in February 1969. Two different multiplate spark-chamber detectors of similar design were used on the two flights, and the data were analysed separately, thus eliminating systematic errors.

The detection of a source above atmospheric background is based on two facts. First, in angular resolution bins of equal solid angle, $\Delta\alpha = 4°$, $\Delta \sin \delta = 0{\cdot}08$, the maximum number of events occurred in the same bin on the first flight for pair tracks as well as for single tracks. A γ-ray photon, interacting in the plates of a spark chamber to form an electron–positron pair, leaves visible tracks in the form of an inverted V. At higher energies this pair may not be resolved and a single track, originating in the chamber, results. Second, the maximum signal of the second flight occurred at the same values of right ascension and declination as the maximum signal on the first flight to within one angular resolution bin. The data are summarized in Table 2. The evidence for a source in each flight separately is not significant, but when the two flights are taken together, the effect is seen.

There are in the literature several examples of the possible detection of discrete γ-ray sources above 50 MeV (notably the Cygnus source[21] found in 1966).

These sources were observed on only one flight. In examining these experiments, which were performed by competent groups, no obvious error appears in the data. One explanation, which has never been invoked because it was the easiest way out of the dilemma, is time-variable sources. In view of the recent examples of the sudden appearance of new X-ray sources, the idea of time-dependent γ-ray sources should be considered anew. After a successful balloon flight, usually at least 4–6 months elapse before the results become known to other groups. If a new source is discovered, several more months elapse before another group can verify the results. If the half-life of a source is of the order of 1 month (as with some X-ray stars), then few sources will be verified. The only solution is the long exposure times of satellite-borne detectors.

Table 2. SPARK-CHAMBER DATA FROM FRYE *et al.*[3] ON THE γ-RAY SOURCE IN SAGITTARIUS

	Number of events (pair + single tracks) per equal solid angle bin Source	Background	Poisson probability
Flight I (February 5–6, 1969)	57	36·7 ± 1·0	0·2
Flight II (February 26–27, 1969)	54	33·4 ± 1·0	0·1
Combined	111	70·1 ± 1·4	8×10^{-4}

Astronomy above 10^{11} eV

At photon energies above 10^{11} eV, cosmic γ-rays, interacting within the atmosphere, generate a cascade of high-energy particles and visible Čerenkov light, both of which can be detected with ground-based instruments. Although the expected photon intensity in this energy range is considerably below that expected for the 100-MeV region, the simplicity and relatively low cost of instrumentation encourage experimentation. Again, theoretical predictions, based on Compton-scattering modes in radio sources, have indicated detectable fluxes.

Since 1960, several research groups[22-26] have developed this ground-based technique to search for discrete sources of cosmic γ-rays, particularly from intense radio sources. More recently the emphasis has been on pulsars, because the detection of radiation of this energy would certainly give credence to the theory that pulsars are the source of cosmic rays. Although several indications of positive results have been published[23,26-29] of both continuous and pulsed radiation, they have never been verified[30,31]. Recent upper limits to the flux from the Crab Nebula at 10^{11} eV found by the group at the Smithsonian Astrophysical Observatory[32] are a factor of fifteen below the theoretical predictions[33,34].

Again these negative results have been valuable in interpreting processes, particularly in the Crab Nebula. They have shown that (1) the high-energy electrons in the Crab Nebula could not have been the result of secondary interactions of protons, but must have been accelerated from lower energies[22,35,36], and (2) on the assumption that the continuous radiation, from radio to visible, is synchrotron radiation, the average magnetic field in the Crab Nebula must be greater than $1{\cdot}5 \times 10^{-4}$ G (ref. 37).

Status of Theoretical Calculations

There are two basic ways by which high-energy γ-rays can be produced. First, by particle interactions that convert kinetic energy to photon energy, and second, by matter–antimatter annihilation. In the first process the particular electro-magnetic interactions are bremsstrahlung and Compton scattering by high-energy electrons; the strong interaction is neutral π-meson production in high-energy proton collisions. In the second process protons and antiprotons annihilate into charged and neutral π-mesons. The neutral π-meson decays into two γ-ray photons. A summary of the properties of these interactions is given in Table 3.

Table 3. SUMMARY OF INTERACTIONS THAT PRODUCE HIGH-ENERGY γ-RAYS*

Interaction	Intensity proportional to the product	Characteristic γ-ray energy	Differential γ-ray spectrum
Bremsstrahlung	$(I_e)(\varrho_g)$	E_e	$E_\gamma^{-\Gamma_e}$
Compton scattering	$(I_e)(\varrho_{ph})$	$\gamma_e^2\varepsilon$; $\gamma_e\varepsilon \ll m_ec^2$	$E_\gamma^{-(\Gamma_e+1)/2}$
Neutral π-meson decay	$(I_p)(\varrho_g)$	70 MeV	Peak at 70 MeV; $E_\gamma^{-4(\Gamma_p-1/2)/3}$ for $E_\gamma \gg 70$ MeV
Matter–antimatter annihilation	$(\varrho_p)(\varrho_{\bar{p}})$	70 MeV	Sharp peak at 70 MeV

* Here, $I_e = K_eE_e^{-\Gamma_e}$ and $I_p = K_pE_p^{-\Gamma_p}$ are the differential intensity spectra of electrons and protons, respectively; ε is the low-energy photon energy and m_ec^2 is the rest energy of the electron; ϱ_i is the density of gas (g), low-energy photons (ph), protons (p) or antiprotons ($\bar{p}$), $\gamma_e = E_e/m_eC^2$.

Theoretical activity at present is devoted primarily to explaining the 100-MeV γ-ray flux from the galactic centre and plane. Before the discovery of this radiation, the most optimistic and reliable calculations of a galactic γ-ray flux were based on neutral π-meson production in cosmic-ray proton collisions with the interstellar gas. If the proton flux were assumed the same everywhere in the galactic disk, the γ-ray flux would be proportional to the integrated interstellar hydrogen-gas density subtended by the field of view of the detector. The cosmic-ray proton intensity was assumed to be the same as that measured at the Earth, and the gas density was obtained from 21-cm radio measurements. The present OSO 3 flux is a factor of ten higher than the predicted value and exhibits a greater dependence on galactic longitude than the calculated value. The discrepancy in intensity could be due to (1) a large amount of cool or molecular hydrogen[38] or (2) higher cosmic-ray proton intensity in the galactic disk. The difference would also be reduced by a factor of three or four if the flux measurements were too high, as previously indicated. The theoretical intensity, based on the usual assumptions about gas density and cosmic-ray intensity, could be increased by a factor of two, but not much more. Even if the flux intensity is explained, the distribution in galactic longitude is difficult to explain with present models of π-meson production.

Bremsstrahlung by cosmic-ray electrons in the interstellar gas, under assumptions similar to those used in the proton calculations, gives a flux a hundred times smaller than the OSO 3 results.

Compton scattering[39,40] (inverse Compton effect) by cosmic-ray electrons on known optical stellar photons or the microwave (2·7 K) blackbody radiation cannot explain the flux. But Cowsik and Pal[41] and Shen[42] have shown that Compton scattering on the infrared (8 K) blackbody radiation, reported by Shivanandan, Houck and Harwit[43], can give γ-ray flux values of the measured intensity and angular distribution in the galactic plane. The flux at the galactic centre can only be explained by assuming an additional intense infrared source at the centre or the galactic centre to be a strong cosmic-ray source. The existence of universal or even galactic infrared radiation at such a temperature and density is still in doubt.

It is interesting to note that the measured flux is similar in galactic longitude distribution to the nonthermal radio noise[6] at 1·5 m and to the cumulative flux from discrete X-ray sources within 15° of the plane. Using this latter fact, Ögelman[44] obtains agreement with the γ-ray flux by extrapolating X-ray spectra to 100 MeV (three decades) assuming a power-law spectrum of index two. Although a meaningful extrapolation is doubtful, the idea that the flux arises from a group of unresolved discrete sources (whatever their nature) in the galactic plane is interesting and very probable[2,45].

A review of these theoretical calculations is given by Clark and colleagues[6].

Theoretical explanations of the isotropic and presumably metagalactic γ-ray flux are based on experimental data from the one OSO 3 measurement at 100 MeV and a power-law extrapolation to 100 MeV of the X-ray data at 100 keV–1 MeV. The most popular explanation is Compton scattering by relativistic metagalactic electrons on the universal microwave (2·7 K) radiation[46]. The greatest uncertainty in these calculations is the intensity of relativistic electrons, which are assumed to come from radio galaxies. There have been several attempts to place the source of this radiation at early epochs (redshifts of $z \geq 2$) to ease energy requirements and to match the observed spectrum. Stecker[47] has shown that the radiation above 1 MeV may be due to neutral π-meson decay at $z = 100$. The isotropic γ-ray flux may well be a remnant of an early phase of the universe.

Again, assuming the presence of the universal infrared radiation, which has an energy density more than fifty times greater than the microwave radiation, the isotropic γ-ray flux can be explained by Compton scattering of cosmic ray electrons in the galactic halo. O'Connell and Verma[48] have shown that this same interaction also produces the X-ray background flux. If galactic in origin, however, this X-ray flux will not be isotropic outside the galactic disk, in contradiction to the measured isotropy of ~ 10 per cent. Although the predicted values of background flux seem reasonable in these models, many other consequences of the universal infrared radiation cast doubt on its existence.

Recently Longair and Sunyaev[49] have suggested that the hard X-ray portion of the isotropic radiation is produced by Compton scattering on the infrared photons in the nuclei of galaxies (Seyfert galaxies, for example).

Above γ-ray energies of 100 MeV, neutral π-meson production may become the important source of the isotropic radiation because the electrons needed to produce γ-rays by Compton scattering very rapidly lose energy by radiation.

The isotropic γ-ray spectrum is not expected to continue beyond 10^{14} eV, because of interactions with the universal microwave radiation[50,51]. The photon–photon interaction at these energies results in the production of an electron–positron pair.

The real origins of both the galactic and the metagalactic γ-ray flux still remain a mystery, and at this stage the success of theoretical activity depends on the quality and quantity of the experimental data.

Recent calculations of the γ-ray flux expected from strong radio sources[33,34] are based on Compton scattering by relativistic electrons on their own synchrotron radiation. From the measured synchrotron spectrum (radio to X-ray), and an assumed average magnetic field intensity, the relativistic electron intensity and spectrum as well as the photon density can be calculated. Comparison with experimental data permits the mean value of the magnetic field to be determined. These discrete-source flux predictions are also most useful in designing new detectors.

Apparao[52] has also considered Compton scattering by relativistic electrons in radio sources on the 2·7 K universal radiation. This effect is important in expanded sources, whereas the Compton-synchrotron effect dominates in compact sources.

Greisen (unpublished) has pointed out that in contrast to the difficulty of finding adequate mechanisms to account for the diffuse γ radiation, which has been detected, there are numerous means of producing γ-rays from discrete sources as yet undetected.

Detailed discussions of the theoretical aspects of γ-ray astronomy are given in review articles by Ginzburg and Syrovatskii[53], Garmire and Kraushaar[54], Hayakawa and Matsuoka[55], Gould and Burbidge[36], Fazio[56], and Lüst and Pinkau[57].

Gamma-ray Detectors

In the 100-MeV region a γ-ray photon can be detected only when it interacts with matter, producing an electron and positron. The particle pair branches in the direction of the initial γ-ray photon with an opening angle of the order of $m_e c^2/E_\gamma$, where E_γ is the photon energy. The γ-ray energy and direction can be determined from the kinematics of the pair. Unless the converting material is very thin, the electron and positron undergo considerable multiple scattering. Thus a typical detector has an angular resolution only of the order of 1°. Energy measurements, determined from multiple-scattering measurements or by total absorption of the pair, have only fair resolution (10–50 per cent). The minimum detectable flux, I_m, from a discrete source in the presence of a background flux, B, is given by

$$I_m \propto \left(\frac{B\Omega}{\varepsilon A T}\right)^{1/2}$$

where Ω is the solid angle of the resolution cone of the detector, A the sensitive area, ε the conversion efficiency, and T the observing time.

Table 4. MINIMUM DETECTABLE FLUX OF γ-RAYS FROM THE CRAB NEBULA (UNPUBLISHED WORK OF GREISEN)

γ-Ray energy threshold	Upper limit to the integral flux (photon cm^{-2} s^{-1})	Extrapolated integral flux (photon cm^{-2} s^{-1})
10 MeV	4×10^{-3}	$1·9 \times 10^{-4}$
50 MeV	$1·7 \times 10^{-5}$	
100 MeV	$3·1 \times 10^{-5}$	$1·5 \times 10^{-5}$
500 MeV	5×10^{-6}	
1 GeV	12×10^{-8}	$1·2 \times 10^{-6}$
2 TeV	1×10^{-10}	
10^3 TeV	3×10^{-15}	

The present minimum detectable flux levels, as functions of energy, for a discrete source such as the Crab Nebula are given in Table 4. The fluxes are already quite small (the optical flux from Polaris is ~100 photons cm^{-2} s^{-1}) and the values of I_m must be made considerably smaller if other sources are to be found. The values of B, Ω and ε are relatively fixed. The γ-ray background flux at balloon altitudes is of the order of 10^{-3} photon cm^{-2} s^{-1} sr^{-1}, and in space, 10^{-4} photon cm^{-2} s^{-1} sr^{-1}. These detectors must also discriminate a background flux of charged particles more than 1,000 times as intense as the γ radiation. The value of Ω (for 1°) is 10^{-3} sr, and ε is about 0·2. The only parameters that can change by orders of magnitude are area and time. The ultimate experiment is therefore a large-area detector in a satellite or on the Moon.

Three basic types of detectors have been used so far: scintillation-Čerenkov counters, nuclear emulsions, and spark chambers. Detailed descriptions of these detectors have been given in review articles by Greisen[58] and Kraushaar[59]. The scintillation-Čerenkov counter telescope was the principal detector used in the early days of γ-ray astronomy. A typical area was 100 cm² with an angular resolution of ±15°. These detectors reached their most sophisticated development in the satellite experiments of Explorer 11 and OSO 3 (Fig. 3). Although they offered high conversion efficiency and sufficient sensitive area, they had poor angular resolution and poor discrimination against background radiation. Nuclear emulsions offered high angular and energy resolution, low energy threshold (~20 MeV), and simplicity, but had the disadvantage of continuous sensitivity and long and tedious data reduction (in a sense that they contained too much information).

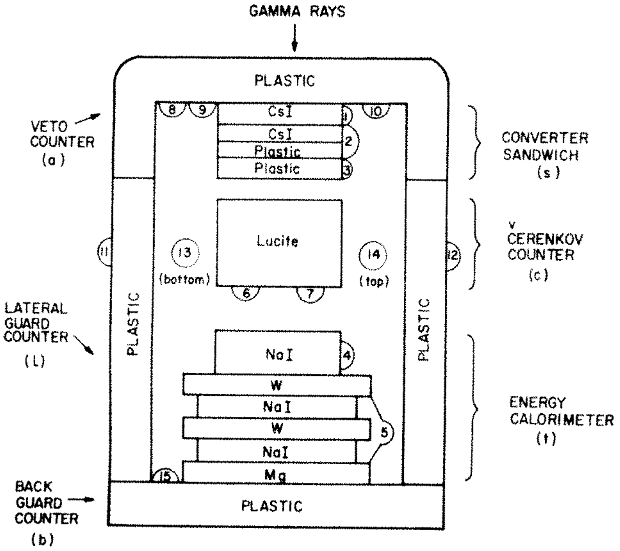

Fig. 3. Schematic diagram of the γ-ray detector flown aboard OSO 3 in 1967.

In the mid-1960s the spark chamber became the primary detector. It is essentially a device for making visible the electron–positron tracks by means of a spark discharge along the paths of the ionized particles. The tracks can be recorded by film, by a vidicon camera, by sonic pickups, or digitally by wire grids connected to a magnetic memory. The advantage of the spark chamber is that it is a visual device with selective sensitivity, so that unwanted background events are low or can be identified. The chamber has a relatively large sensitive area (10^2–10^4 cm²) and a large acceptance angle (±30°) with angular resolution of the order of ±1°, which make it an ideal survey instrument. The spark chamber has already provided γ-ray astronomy with a significant increase in sensitivity; the next major advance will occur in 1971 when the group at the Goddard Space Flight Center, led by C. Fichtel, will fly a large ($6\cdot5\times10^2$ cm²) digital spark chamber (Fig. 4) in the Small Astronomy Satellite (SAS-B). In 1972 a joint European group (University of Milan; Centre d'Etudes Nucléaires de Saclay, France; Max-Planck-Institut für Extraterrestrische Physik, Munich) will launch a vidicon spark chamber (132 cm²) in the ESRO satellite TD-1.

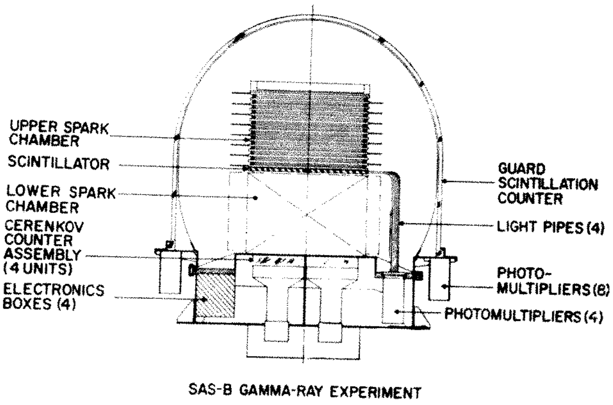

Fig. 4. Schematic diagram of the digital spark chamber to be flown on the Small Astronomy Satellite (SAS-B) in 1971 by the Goddard Space Flight Center.

Emulsion spark-chamber combinations are also being used, with the promise of greater angular resolution and lower threshold energy. In this detector the spark chamber is used to locate the γ-ray conversion point in the emulsion. Groups at Washington University (St Louis), University of Minnesota, and the Naval Research Laboratory are now using this technique.

Fig. 5 shows the minimum detectable flux at 100 MeV that could be measured by γ-ray detectors over the past ten years and the expected sensitivity of future detectors. Note that the minimum detectable flux has decreased by an order of magnitude every 2·3 years and should continue at that rate, reaching sensitivities of $10^{-6}-10^{-7}$ photon cm^{-2} s^{-1} within the next two years.

An attempt to increase significantly the area of detectors has brought about the development of the gas-Čerenkov detector by a joint Cornell University–Smithsonian Astrophysical Observatory–Naval Research Laboratory group. The single detector has an area of 5×10^4 cm² with an angular resolution of ±1°, an acceptance angle of ±3°, and (expected) excellent background rejection. The first balloon flight of the instrument is expected in 1970, and it should be able to measure sources as weak as 5×10^{-7} photon cm^{-2} s^{-1} in six hours. The detector is also being proposed for a large spacecraft mission. A smaller version of this detector ($1\cdot9\times10^3$ cm²) has been designed[60] for the energy region from 10 to 100 MeV.

Although the most sensitive experiments will be performed in satellites, much work can still be done by high-altitude balloons, particularly as balloons become larger and more reliable. For example, with a spark chamber it should be possible to confirm definitely the galactic γ-ray flux measurements of OSO 3. These experiments are now being performed by groups at the Goddard Space Flight Center, the Case Western Reserve University and the University of Southampton, and the results will be known soon. Balloon experiments at present compete with satellite experiments as regards sensitivity in the search for discrete sources. Because of atmospheric

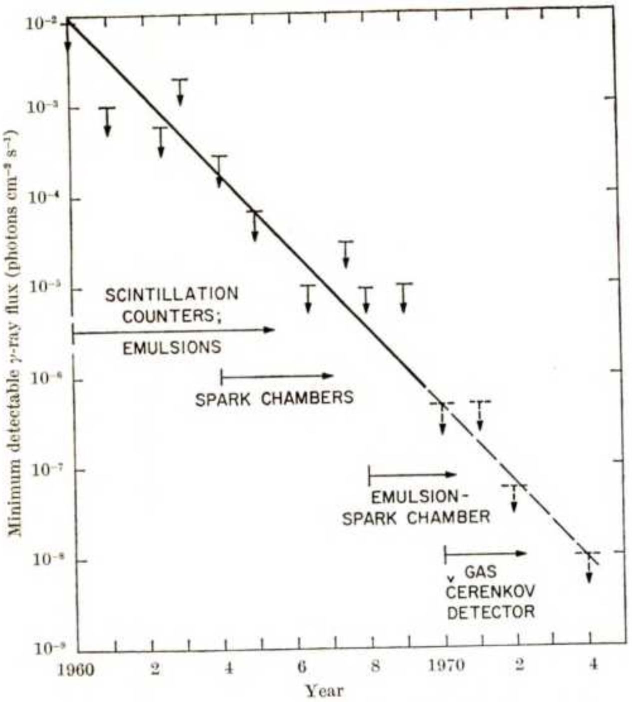

Fig. 5. Decrease in the minimum detectable γ-ray flux levels at 100 MeV over the years.

background radiation, the isotropic γ-ray flux will be best measured in satellite experiments. A continued balloon programme is also needed to develop and test new detectors.

I have mentioned that γ-ray astronomy above energies of 10^{11} eV is performed with ground-based detectors. A cosmic γ-ray of these energies interacts with air molecules and generates a cascade of high-energy electrons, positrons and secondary γ-rays. This cascade, called an air shower, is highly directional and proceeds with relativistic velocity in the direction of the initial γ-ray photon. The relativistic charged particles in the air shower generate a cone of Čerenkov light of about 2° total opening angle in the direction of the shower axis. The light, which is primarily in the blue and ultraviolet region of the visible spectrum, occurs as a burst lasting about 10^{-8} s, and covers a ground area of 10^8 cm². The detection of this light at the lowest possible γ-ray energies requires a dark site, a cloudless, moonless night, and a sensitive light collector. Unfortunately, high-energy cosmic ray particles, primarily protons, also generate air showers and bursts of Čerenkov light in the atmosphere, resulting in a uniform distribution of this light over the sky (approximately 10^{-4} of the total light of the night sky). Gamma rays can be distinguished at present only by increased numbers of light pulses coming from the direction of possible sources. A typical experiment therefore consists of positioning a mirror and phototube detector ahead of a suspected source and recording the rate of observed light pulses as the Earth's rotation carries the source across the field of view. Such a telescope can detect γ-rays over an area of 10^8 cm² with an angular resolution of about 1°. Jelley has written a review on this technique[61].

A typical detector used in this energy region consists of a cluster of searchlight mirrors, 1–1·5 m in diameter, mounted on a steerable frame. Such a detector, developed by the Atomic Energy Research Establishment, Harwell, and University College, Dublin, and now being used in Malta, is shown in Fig. 6. The Smithsonian Astrophysical Observatory has in operation, in Arizona, a fully steerable 10-m reflector consisting of a mosaic of 248 small hexagonal mirrors (Fig. 7).

Although no sources have been detected definitely in this energy region, the search continues, with longer exposure times and in an all-sky survey. Pulsars may be sources of 10^{16} eV particles and considerable effort, by all groups, is being devoted to a search for γ-rays from these objects.

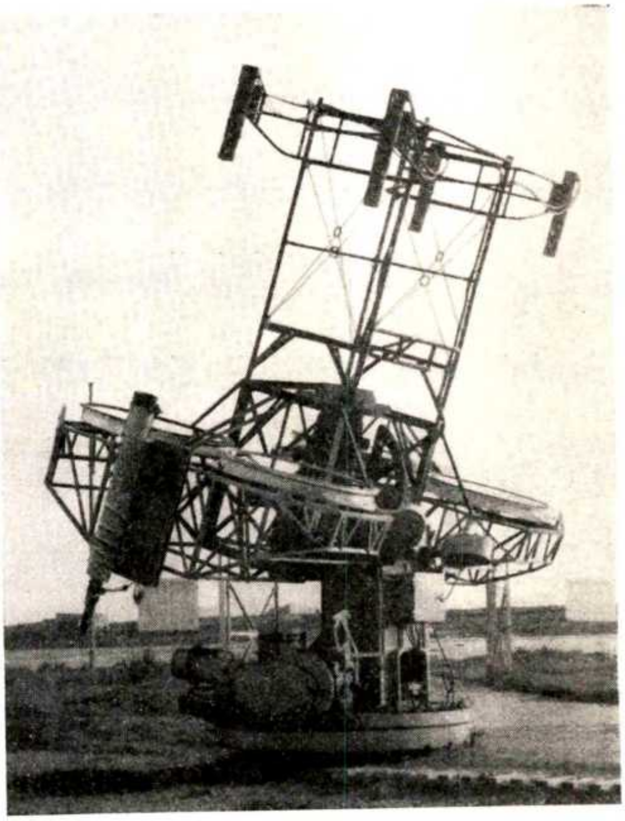

Fig. 6. The Čerenkov γ-ray installation operated jointly by the Atomic Energy Research Establishment, Harwell, and University College, Dublin. This installation consists of four 90 cm diameter f/2 mirrors and is sited at Qrendi, Malta.

It is very difficult to lower the threshold γ-ray energy by a significant amount; however, a considerable increase in sensitivity, perhaps a factor of 30, could be obtained if showers induced by γ-rays could be distinguished from proton-induced showers.

It is interesting to note that all major atmospheric Čerenkov light detectors are located in the northern hemisphere and almost no research has been carried out south of the equator.

Future Progress

Progress depends greatly on new experimental data. The origin of the galactic γ-ray flux remains a major mystery. Is it diffuse and generated by interactions of high-energy particles in the interstellar medium, or is it composed of discrete, unresolved sources ? Further theoretical work cannot proceed without more data. Another question is how many discrete sources, "γ-ray stars", exist ? Are they a transient phenomenon ? Are they galactic in origin ? A systematic all-sky survey is needed to answer these questions. Are pulsars γ-ray

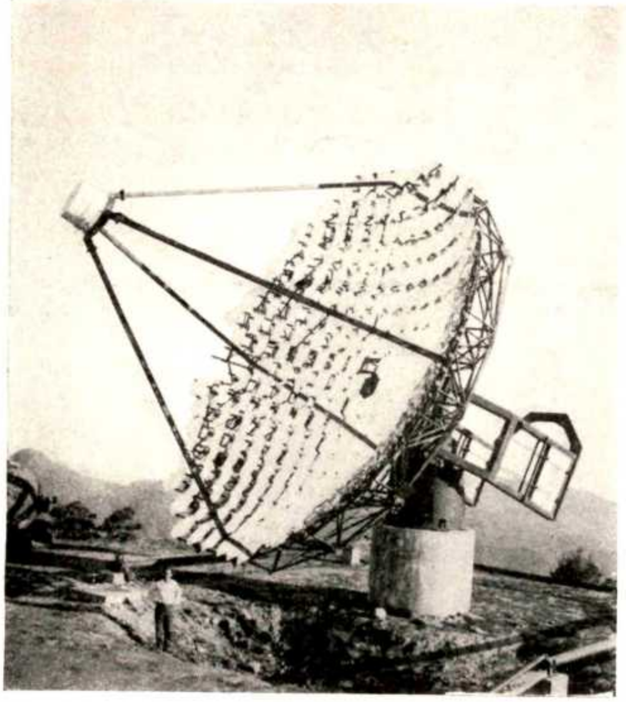

Fig. 7. The 10-m optical reflector at Mt Hopkins, Arizona, used by the Smithsonian Astrophysical Observatory to search for cosmic γ-rays at 10^{11} eV.

sources ? Detection of such radiation would provide very strong evidence that pulsars are the sources of cosmic rays. Of more cosmological significance is the origin of the diffuse γ radiation. Is it a remnant of an early stage of development of the universe ?

The experimental data necessary to answer these important questions may be slow in coming. The next major satellite detector, the digital spark chamber on the SAS-B satellite, will not be launched until 1971. Larger detectors in manned space stations will not be launched before 1974. Recent balloon experiments from Australia should yield more information on the γ-ray flux from the galactic centre, particularly its intensity and angular distribution; however, satellites are needed to investigate the galactic plane and the isotropic radiation.

New ideas in detector development are needed. For significant increases in sensitivity, $\sim 10^{-7}$ photon cm^{-2} s^{-1} at 100 MeV, there seems no alternative to the increase in the area-time product. The gas-Čerenkov detector or clusters of spark chambers may be a solution. With the use of large space stations or the Moon, there seems to be no serious limit to the sensitive area that can be obtained. Energy resolution must be increased to distinguish between mechanisms of γ-ray sources; this is particularly important in the 10–100 MeV region. Although difficult to achieve, higher angular resolution is also needed at all energies. A lunar-based detector, using the horizon as an occulting edge, could achieve resolutions of minutes of arc.

Questions about the distribution and density of high-energy particles, matter, and photons in the universe may be answered only by the future results of γ-ray astronomy. Compared with optical and radio astronomy, the field is relatively young and experiments are still difficult to perform. Exciting results are just now being produced, and the future should be even more promising.

Chromosomal and Nuclear Location of Mouse Satellite DNA in Individual Cells

by
K. W. JONES
MRC Epigenetics Research Group,
Institute of Animal Genetics,
University of Edinburgh

Single strands of mouse satellite DNA were annealed to nuclei and chromosomes in mouse cells. From the location of autoradiographic grains, it is suggested that there is a concentration of satellite DNA sequences close to the centromeres of the chromosomes.

THE DNA from many eukaryotes may be fractionated on CsCl gradients into a main component, usually referred to as the major DNA band, and minor components called satellites. With one or two exceptions[1,2] the precise location of these minor components is unknown and their biological significance is obscure in all but one case[3]. Satellite DNA from the mouse, one of the most extensively studied, and comprising 9–10 per cent of the total DNA[4], consists of short sequences of nucleotides repeated end to end to form molecules with a molecular weight of several million daltons[5]. The complementary strands have been shown to differ in base composition[6] and may be separated from each other by virtue of their difference in buoyant density on alkaline CsCl gradients[7]. Cell fractionation has shown that satellite sequences are enriched in isolated nucleoli[8] and in dense chromatin fractions[9]. Chromosome fractionation[10] has provided evidence of the distribution of sequences throughout the chromosome set.

Methods for specifically annealing nucleic acids to chromosomes and nuclei which allow the localization of the annealed or hybridized molecules by autoradiography have recently been developed[11], and I now describe the results of the application of these methods to the problem of the location of mouse satellite DNA. Purified single strands of mouse satellite DNA were annealed to mouse and to rabbit nuclei and chromosomes.

Primary embryonic mouse cell cultures from a local strain of inbred mice were grown in 250 ml. flasks (Falcon Plastics) in Eagle's minimal essential medium which contained 10 per cent calf serum and 100 units of penicillin and streptomycin per ml. Rabbit kidney cells were obtained as an established cell line from Flow Laboratories and were maintained in the same manner as the mouse cells. The cell cultures were maintained in an incubator at 37° C gassed with 5 per cent CO$_2$ in air.

Labelling and Isolation of DNA

Approximately 50 µCi of tritiated thymidine ('TRK 120', Amersham) with a specific activity of 20·2 Ci/mmole was added to each flask of mouse cells previously grown to half confluence. After 2 days of incubation, the medium was changed and fresh medium containing the same amount of tracer was added. Incubation was contained for a further 2 days. The cultures were then washed several times with Dulbecco saline, trypsinized away from the flasks and harvested by pelleting in a bench centrifuge. The pellets were resuspended in a very small volume of saline and then lysed by addition of $2 \times$ SSC (SSC = 0·15 M NaCl–0·015 M sodium citrate) in 1 per cent in sodium lauryl sulphate and containing 200 µg/ml. protease (Sigma) predigested at 37° C for 20 min. The lysate was incubated for 2 h at 37° C, cooled to room temperature, mixed with CsCl (1·26 g/ml.), overlayered with paraffin oil and centrifuged at 42,000 r.p.m. in an MSE centrifuge rotor No. 2410 for 40 h at 20° C. The tubes were pierced and 0·5 g fractions were collected. The absorbance at 260 nm of the fractions was determined in a 'Unicam *SP* 800' spectrophotometer. Samples were spotted on Whatman No. 1 filter disks, which were washed twice with 5 per cent trichloroacetic acid, followed by ice cold ethanol and ether (three washes each). Radioactivity was determined by scintillation counting in toluene based scintillation fluid using a Nuclear Chicago 'Unilux' counter. The coincident peaks of absorbance at 260 nm and radioactivity were then pooled and the DNA was recovered by pelleting, after suitable dilution, in an MSE 2418 rotor at 30,000 r.p.m. at 4° C for 18 h. The pellets were resuspended in $0{\cdot}1 \times$ SSC. 4 ml. of the dissolved pellet containing 100 µg of DNA was then mixed with 5·02 g of CsCl overlayered with paraffin oil and were centrifuged for 40 h at 42,000 r.p.m. 0·2 g

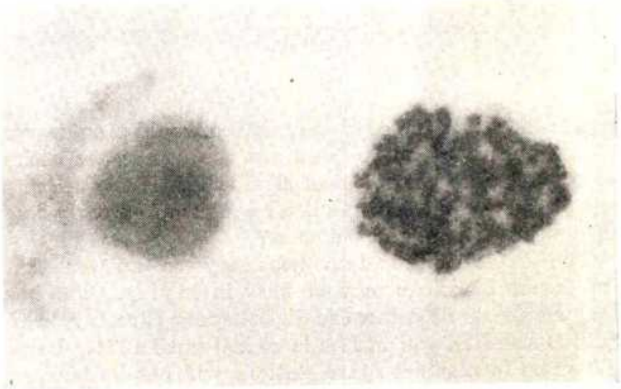

Fig. 1. Rabbit interphase and metaphase nuclei after annealing to mouse satellite. Note absence of grains.

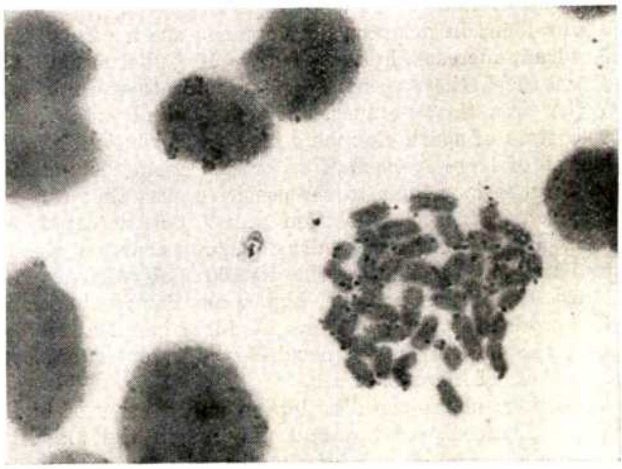

Fig. 2. Mouse interphase and metaphase nuclei after annealing to mouse satellite. Note absence of autoradiographic background and grains above both kinds of nuclei with localization in groups over dense chromatin at interphase and over chromosomes at metaphase. Focused at level of grains.

fractions were collected and their absorbance at 260 nm was determined as before. The light satellite fractions were collected and pooled. The pooled material was recycled on CsCl gradients and was then fractionated on alkaline CsCl gradients[12]. The peak fractions of the light strand of the satellite DNA were pooled and the buoyant density of a small sample of this material was determined in a Spinco model *E* analytical ultracentrifuge, using a marker of denatured *Pseudomonas aeruginosa* DNA (buoyant density, 1·736 g/cm^3). A value of 1·700 was obtained and the DNA was observed to migrate as a single symmetrical band. An aliquot of this material was taken for the determination of its specific radioactivity which was estimated to be approximately $2{\cdot}2 \times 10^6$ d.p.m./μg by scintillation counting in a toluene based scintillator using a counter with an efficiency (unchecked) of about 10 per cent. The remaining single stranded material was then diluted with 0·1 × SSC brought to *p*H 7·4 and recovered by pelleting at 30,000 r.p.m. as previously described.

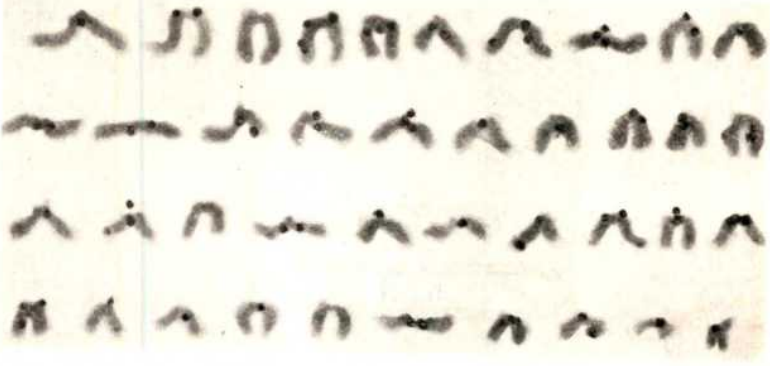

Fig. 4. Chromosomes from Fig. 3 arranged roughly in order of size, to show relative distribution of grains.

Chromosome preparations were obtained from cell cultures after treatment with colcemid (0·4 μg/ml. for 6 h). The cells were trypsinized away from culture flasks, pelleted gently, resuspended in hypotonic saline for 15 min, repelleted and fixed in ice cold ethanol–acetic acid (3 : 1). The fixed cells were resuspended in 45 per cent acetic acid and drops of the cell suspension were air dried onto coverglasses, and then stored at 4° C *in vacuo* until required.

Annealing in Rabbit and Mouse Cells.

Before annealing, the cell preparations were either dipped into 0·1 × SSC at 100° C and then quenched in 0·1 × SSC at 0° C, or alternatively treated with 0·07 M NaOH for 5 min at room temperature[14] to denature the DNA *in situ*. Denatured preparations were then dehydrated through 70 per cent, 90 per cent and absolute alcohol, and then dried *in vacuo*. The dry preparations were inverted over a 1 μl. drop of single stranded satellite DNA at a concentration of 0·6 μg/μl. on a siliconized slide, sealed to the slide with rubber solution and then incubated at 60° C for 2 h. The coverslips with cells were then detached and washed three times in 2 × SSC at room temperature to remove excess unbound radioactive DNA and then further incubated in a stirred waterbath containing 2 × SSC at 55° C for a further 2 h, to remove non-specifically trapped radioactive DNA. The preparations were rinsed twice again in 2 × SSC at room temperature and were then dehydrated in the usual way. Dehydrated preparations were mounted on slides and were dipped in Ilford 'L4' emulsion diluted 1 : 1 with water, and stored in lightproof boxes at 4° C. After 10 days exposure the autoradiographs were developed in Kodak 'D19b' developer, stained in 0·02 per cent toluidine blue at *p*H 6·0, and were photographed on Ilford '*R*40' plates using a Zeiss 'Ultraphot II' photomicroscope equipped with an interference filter.

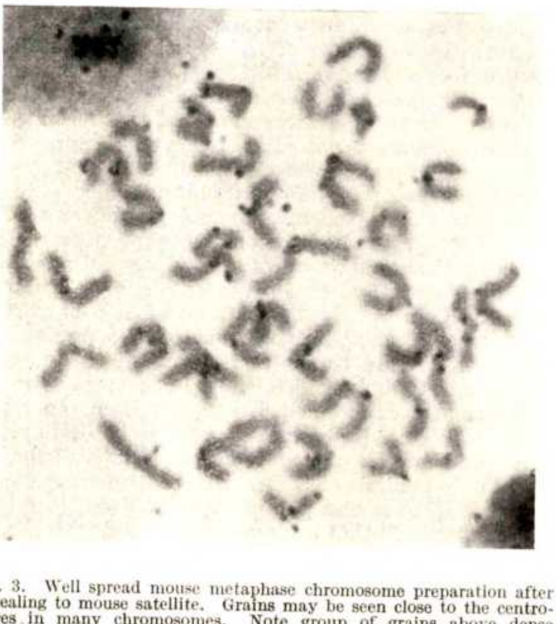

Fig. 3. Well spread mouse metaphase chromosome preparation after annealing to mouse satellite. Grains may be seen close to the centromeres in many chromosomes. Note group of grains above dense chromatin in nucleus at upper left.

The rabbit cells showed no significant grains located over any cellular structure after annealing with mouse light satellite radioactive DNA, and further autoradiographic exposure, beyond that used in the experimental group, failed to reveal any significant label. This control was therefore taken to be negative, indicating no tendency for the radioactive DNA to become non-specifically trapped by heterologous cell structures or by non-cellular materials in the preparations. An example of these preparations is shown in Fig. 1. They are compared with mouse cells in Figs. 2–4.

Autoradiographic grains were located over both interphase nuclei and chromosomes in the mouse cells. The cytoplasmic and non-cellular backgrounds were similar to that observed in rabbit cells. Grains were located over most of the chromosomes in any given group (Figs. 2 and 3), and there were few background grains. To see if the grains were polarized in favour of the centromeric regions, each chromosome was divided into three regions, proximal (*A*), median (*B*) and distal (*C*), with respect to the centromere, and grains were counted over each region. The counts on five well spread metaphase preparations were averaged and are shown as a histogram in Fig. 5. It is clear that there is a marked skewing of the grain distribution in favour of the centromeric regions. The pattern of grains over the centric regions of daughter chromosomes was often strikingly symmetrical, indicating that the annealing is to homologous sites and it is very likely that annealing occurs at an available site. That some chromosomes were unlabelled is potentially significant. The unlabelled chromosomes were therefore recorded into size classes designated small, medium and large (Table 1). The numbers of labelled and unlabelled chromosomes in five well spread metaphase plates are recorded in Fig. 5. Unlabelled chromosomes do not seem to belong exclusively to a particular size class, but most of the unlabelled chromosomes found were classified as medium sized. This is probably not significant, however, because medium sized chromosomes predominate in the mouse. Because the number of grains per chromosome is low, a class of chromosome without label would be expected by chance and from trivial causes such as self

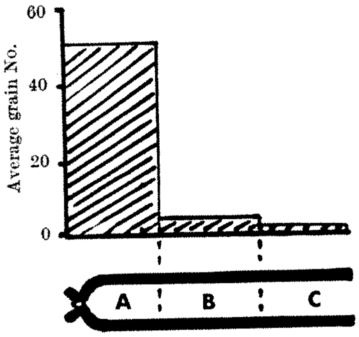

Fig. 5. Histogram based on average grain count from five well spread metaphase plates of mouse chromosomes showing distribution of grains relative to the centromere.

absorption of radioactivity; further experiments may, however, reveal truly unlabelled chromosomes.

In interphase nuclei, grains were largely associated with the dense chromatin and nucleoli. In nuclei without dense regions the grains were more scattered and this shows that the binding of radioactive DNA occurs to both diffuse and concentrated arrangements of the available specific annealing sites and is not merely an artefact of binding to lumps of chromatin. The absence of binding to rabbit nuclei, which present ostensibly similar targets for non-specific binding, confirms this. Differences in the intensity of labelling were noted in nuclei of similar size and conformation lying in the same regions of the preparation. It is not known whether these appearances reflect real differences in the availability of annealing sites or are the results of some more fortuitous aspect of the technique. In occasional nuclei, prematurely condensed individual chromosomes were present within the mass of uncondensed chromatin, and it was sometimes possible to see the polarized distribution of the associated label similar to that noted in chromosomes at metaphase.

It has previously been shown[11] that it is possible to anneal RNA molecules to complex structures such as chromosomes and nuclei. Molecular hybrids thus formed have been re-isolated and characterized by biophysical methods. There is clear evidence of the specificity of the molecular interactions and similar results have been obtained independently[13–15]. The results of the experiments reported here show clearly that DNA annealing to cytological preparations is possible and they constitute the first demonstration of the location of a chemically defined class of DNA on mammalian chromosomes. Specificity similar to that obtained using RNA[11] is found as can be seen from the failure of heterologous nuclear structures to bind radioactivity. The species specificity of mouse satellite has been previously shown *in vitro* using the DNA from a wide variety of different organisms[16]. In this experiment advantage has been taken of the facility of obtaining pure single strands of satellite DNA in order to promote annealing to the specimen by overcoming the rapid self-annealing which would otherwise be expected. It has been shown[17] that the $C_0t_{1/2}$ of mouse satellite DNA is about 10^{-3} and it is the second fastest renaturing DNA that has yet been isolated. In the conditions of our experiments the efficiency of annealing may be calculated as follows: specific activity of the input single stranded DNA is approximately 2×10^6 d.p.m./µg; assuming 10 per cent autoradiographic efficiency[18] 2×10^5 grains/µg/min or 0·2 grains/pg/min can be expected; if it is assumed that there are 7 pg DNA/nucleus, then each nucleus has 0·7 pg/satellite, which represents 0·35 pg of DNA available for annealing. With 100 per cent efficiency of annealing, $0{\cdot}2 \times 0{\cdot}35$ grains/nucleus/min or 0·07 grains can therefore be expected; with 10 days exposure, 100 per cent annealing would produce approximately 1,000 grains/nucleus. A maximum of about eighty grains per nucleus was in fact observed: this represents an efficiency of about 8 per cent.

Table 1. NUMBERS OF LABELLED AND UNLABELLED CHROMOSOMES IN FIVE METAPHASE PLATES INDICATING RELATIVE SIZE DISTRIBUTION OF UNLABELLED CHROMOSOMES

	Chromosomes				
	Unlabelled				Labelled
Cell No.	Large	Medium	Small	Total	Total
1	0	4	1	5	35
2	0	4	0	4	36
3	1	1	1	3	37
4	1	3	0	4	36
5	1	1	1	3	37
Total	3	13	3	19	181

Location of Satellite Sequences

The location of the bound radioactivity is not general, but is restricted to definite regions in both nuclei and chromosomes. This localized binding is similar in homologous daughter chromosomes in many instances, as can be seen from the matched pattern of grains, and reflects underlying homology of chromosomal structure. The discontinuity in labelling pattern is not necessarily related to the concentration of complementary satellite sequences, but could equally well reflect local differences in accessibility to the incoming radioactive molecules. Chromatin fractionation[8] indicates, however, that nucleoli are enriched three to four-fold in satellite sequences compared with DNA from whole nuclei and provides independent evidence of discontinuity in satellite distribution. This has been confirmed in our work which reveals a preferential localization of grains over nucleoli and dense chromatin. It is therefore logical to interpret the chromosomal pattern on similar lines and to conclude that a concentration of satellite DNA sequences exists close to the centromeres in most, if not all, of the chromosomes of the mouse. A similar distribution of reiterated DNA sequences has been found in *Drosophila melanogaster* in studies of the hybridization pattern of c-RNA with salivary chromosomes (K. W. J. and F. W. Robertson, in preparation). The distribution of satellite sequences among most or all of the chromosomes in the mouse has been previously inferred from analyses of gradient fractionated chromosome preparations[10].

Significance of DNA Annealing

One of the potentially significant aspects of this approach is that it can discover the location of defined DNA sequences on the chromosomes and relate this to their functional distribution at interphase. Thus it seems clear, from the evidence of the enriched satellite DNA content of nucleoli and of centric regions of chromosomes, that these become associated in interphase. The respective functions of centromeres and satellite DNA in this phenomenon are not clear, but a mechanism which obviously coordinates the physical, and perhaps the functional, aspects of different chromosomes may rely to some extent on the chemical homology of the associated satellite DNA. Non-homologous association particularly of telocentric chromosomes occurs widely in vertebrates and can be extensive and persistent in certain circumstances[19]. Centromeric association of non-homologous chromosomes in the rainbow trout (*Salmo irredeus*) has been shown to lead to the appearance of tissue specific chromosomal polymorphism[20]. The concentration of satellite sequences at nucleoli has also been reported in human and vole (*Microtus agrestis*) cells[8] implying a general tendency for aggregative or associative behaviour of these unique kinds of DNA. The centric concentration of satellite DNA is also potentially significant in relation to the suggestion[21] that it may be connected with chromosome pairing.

It is obvious that satellite DNA is concentrated close to regions which are usually referred to as heterochromatin. The term heterochromatin is used, however, in reference to a wide assortment of chromosomal phenomena whose common denominator is that they are present as characteristically staining regions. For this reason, it would not yet be wise to identify satellite DNA too closely with heterochromatin in all its aspects. Nevertheless, properties of satellite DNA which may serve to explain some aspects of certain kinds of heterochromatin require mention. For example, the recent report[22] that mouse satellite DNA replication is differentially repressed by sulphur mustard may impart new significance to the classical finding that these chemicals preferentially produce aberrations in heterochromatin[23]. This is especially relevant in view of the finding[24] that DNA synthesis in late *S* is localized to the proximal chromosomal regions in mouse—that is, those nearest the centromeres. Much of the heterochromatin is also localized in these regions[25].

The encouraging precision of the technique of DNA annealing to cytological preparations should also allow the identification of chromosomes and nuclei of mouse in situations in which these are intimately mixed with those of another species. This is interesting in relation to studies on interspecific cell hybrids and heterokaryons. The application of the method to other species combinations will become possible as more DNA sequences with similar properties to the mouse satellite become available. The technique should also find applications in studies of mixed cell populations such as in connexion with tissue immunology and radiation chimaeras.

I thank Professor Waddington for his support and for reading this manuscript; also Dr Max Birnstiel and P. M. B. Walker for helpful discussions. I am indebted to Mr J. Speirs for the buoyant density analysis, and to Mrs K. Hall, Miss B. Geddes and Miss M. Smith for expert technical assistance. This work was supported by the Science Research Council and the Muscular Dystrophy Research Group of Great Britain.

Variations in the DNA from Two Rodent Families (Cricetidae and Muridae)

by
W. HENNIG*
P. M. B. WALKER
MRC Research Group on the Mammalian Genome,
Department of Zoology,
University of Edinburgh,
Edinburgh 9

Even within a closely related family, the banding profiles in CsCl and reassociation rates of the DNA exhibit considerable differences.

THE DNA of higher organisms has been shown to contain easily distinguishable fractions by following the rate of reassociation after denaturation[1–4]. Because the reassociation follows second order kinetics it must be dependent on the concentration of those single-stranded molecules which are able to reform stable duplex molecules. Consistent with this is the finding of a linear relationship between the rate of reassociation and the complexity or size of the genome over a wide range of organisms[2,3]. Higher organisms, however, contain a proportion of nuclear DNA which reassociates more rapidly than expected, indicating that such fractions have multiple nucleotide sequences with some degree of similarity. In certain higher organisms some of these sequences are distinguished by their uniformity, and, if their base compositions are sufficiently different from that of the bulk DNA, they can be isolated by centrifugation in CsCl to give so-called "satellite" DNA[5]. Mouse "satellite" DNA is one species which has been extensively studied[6–10].

Some of the difficulties raised by the evolution and function of these related sequences have been discussed elsewhere[11] together with preliminary comparisons of the DNA from different organisms[12]. We report here studies on sixteen different species, subspecies and geographically separated populations within two rodent families, the Cricetidae and the Muridae. *Microtus*, *Clethrionomys* and *Arvicola* all belong to the tribe Microtini within the family Cricetidae, while *Rattus*, *Mus*, *Acomys* and *Apodemus* are members of the sub-family Murinae of the family Muridae. They represent therefore both of the great families comprising the super-family Muroidea, sub-order Myomorpha. From reassociation kinetics and CsCl centrifugation of the DNA, we conclude that the proportion of these sequences varies even within this closely related group of animals.

Differences in Banding Properties in CsCl

The banding properties in CsCl after centrifuging to equilibrium in an analytical centrifuge show that the average buoyant density—and therefore the average content of C+G—is nearly the same for the bulk DNA in all species investigated, but some exhibit a minor component distinct from the main DNA band, while in others a similar component is visible within it (Fig. 1). The latter are not likely to be artefacts because centrifuging in alkaline CsCl, which denatures the DNA, reveals a banding profile which is very like that found in the neutral conditions (Fig. 2). We have also fractionated some of these DNA samples on a preparative neutral CsCl gradient, before banding the separated fractions in the analytical centrifuge (Fig. 3). The minor component is present and enriched in the fraction corresponding to its average base composition. We conclude from this that, like guinea-pig DNA[14,15], several other rodent DNAs have minor components analogous to the "satellite" components found in the mouse. From the banding pattern in alkaline CsCl (Fig. 2) it also seems—in confirmation of earlier studies on *Apodemus sylvaticus*[11]—that strand separation, which is so characteristic of mouse[7], guinea-pig[14,15] and human[16] minor components, is not a general property of such fractions.

---

* Present address: Max Planck Institut für Biologie, Abt. Beermann, Tübingen.

The proportion of the DNA found in these minor components seems to vary between about 2 and 10 per cent, but fractions like that from human DNA[16], which is less than 2 per cent of the total, would not be detected in our experiments. The banding position in CsCl of the minor component, indicative of its average C+G content, varies considerably between the species investigated. Even the satellites of the closely related *Apodemus flavicollis*, *sylvaticus* and *agrarius* species display (Fig. 4) small differences in density of the order of 0·001 g/cm³, and differences in relative amounts. These three species, together with *A. mystacinus* (Fig. 1), thus show a remarkable variation within a single genus.

The most important factor affecting measurements of the relative proportion of these components is molecular weight, because there is evidence from studies on the mouse[10] that these sequences are covalently linked to main band DNA. Band sedimentation studies indicate that the molecular weight of our DNA preparation is about 3×10^7 daltons. Mechanical shearing of the DNA

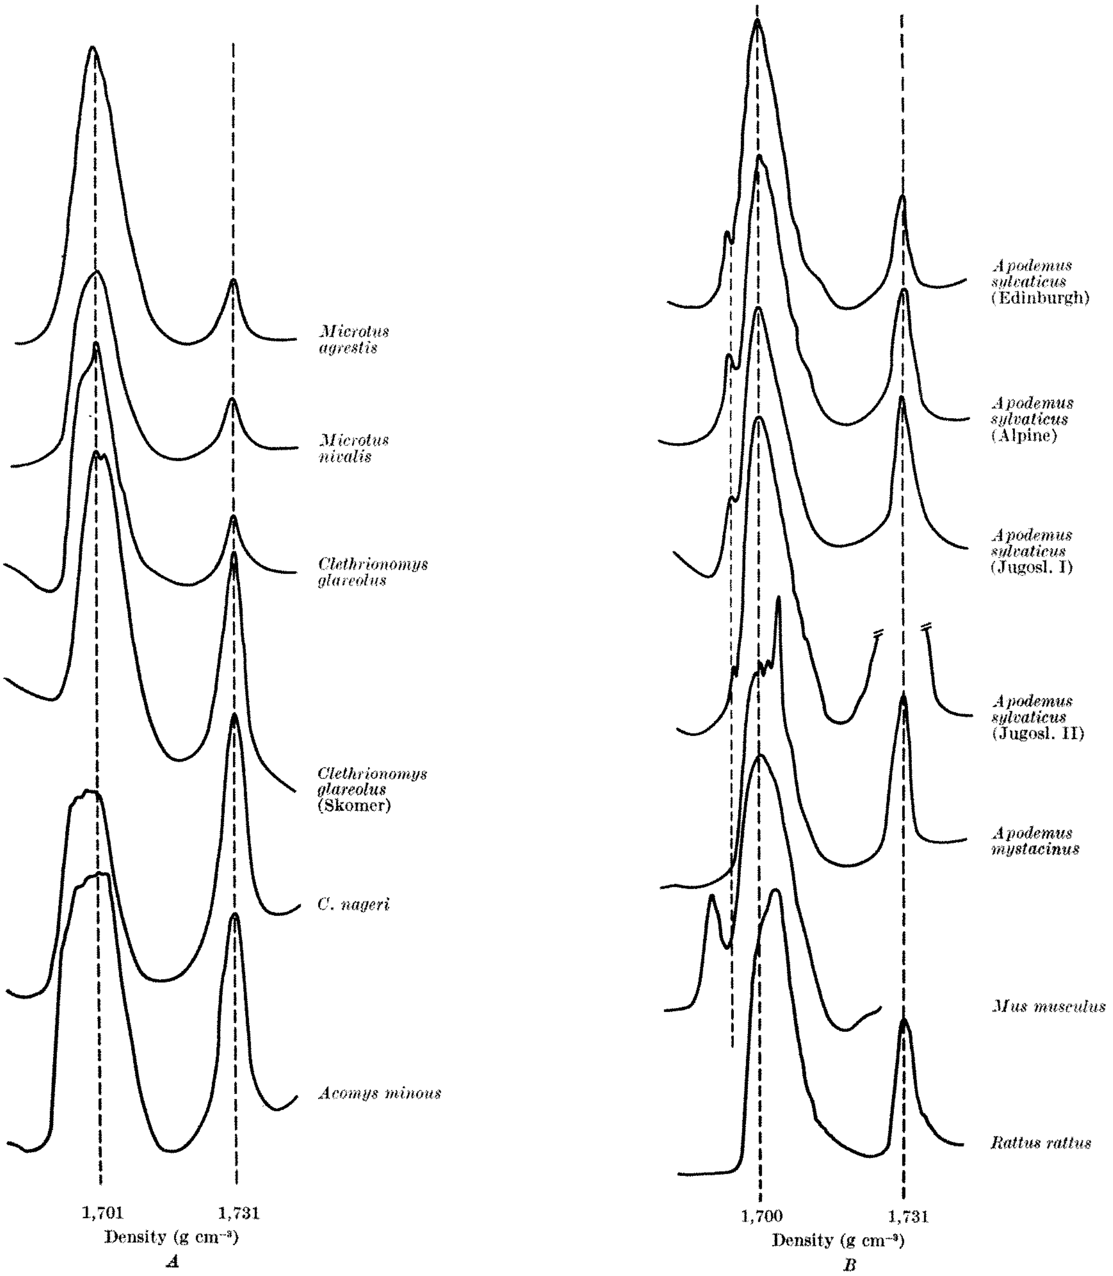

Fig. 1. Analytical centrifugation of different rodent DNAs in neutral CsCl (Harshaw, optical grade). Approximately 3 μg of DNA from liver nuclei and 1–3 μg DNA from *Micrococcus lysodeikticus* (density 1·731 g cm⁻³) were dissolved in 0·01 M Tris (*p*H 8) and mixed with CsCl to an initial density of 1·715 to 1·720 g cm⁻³. Centrifugation was carried out at 44,700 r.p.m. and 25° C in an MSE analytical centrifuge for 22 to 28 h using bromine and chlorine gas filters and Kodak film. Liver nuclei were prepared by homogenization and centrifugation through nearly isopycnic sucrose[13].

(at about 4×10^6 daltons) before centrifugation does not affect the proportion of minor components recovered.

Kinetics of Reassociation

In the mouse and the guinea-pig, minor satellite fractions have been isolated and their rates of reassociation determined[10,15]. These are very rapid and indicate that those sequences which are responsible for the reformation of stable duplexes must recur, in the mouse for example, once every 150–300 nucleotides. On the other hand, both the melting behaviour of the reassociated DNA[6,7] and the more precise technique of pyrimidine tract analysis[17] indicate that the 150–300 nucleotide sequences are similar but not identical (E. Southern and A. Carr-Brown, manuscript in preparation). For mouse and guinea-pig DNA, therefore, the fast reassociating fractions are homogeneous in base composition, and after CsCl centrifugation occur as narrow bands either superimposed on or separable from the main band DNA.

It is convenient[18] to distinguish between these "fast" reassociating fractions and those which reassociate at an intermediate rate: that is, intermediate between the fast fraction and a principal component of the DNA which reassociates at the much slower rate predicted[2,3] for sequences having only a single copy in each genome. These intermediate and slowly reassociating DNAs occur in the main band which contains sequences with a wide range of different base compositions. Intermediate fractions have been found in all the higher organisms so far studied[2]. They have rates of reassociation indicative of many different "families of repeated sequences". Each family can be defined by a degree of repetitivity, bearing in mind again that repetitivity denotes similarity but not necessarily identity. One of the difficulties in measuring the size of families is that the degree of similarity, or goodness of fit, between complementary chains is highly dependent on the conditions during reassociation of the polynucleotide chains[18]. Relaxed conditions, such as low temperature and high Na$^+$ concentration in the incubation mixture, will allow less specific interactions to be measured and the family

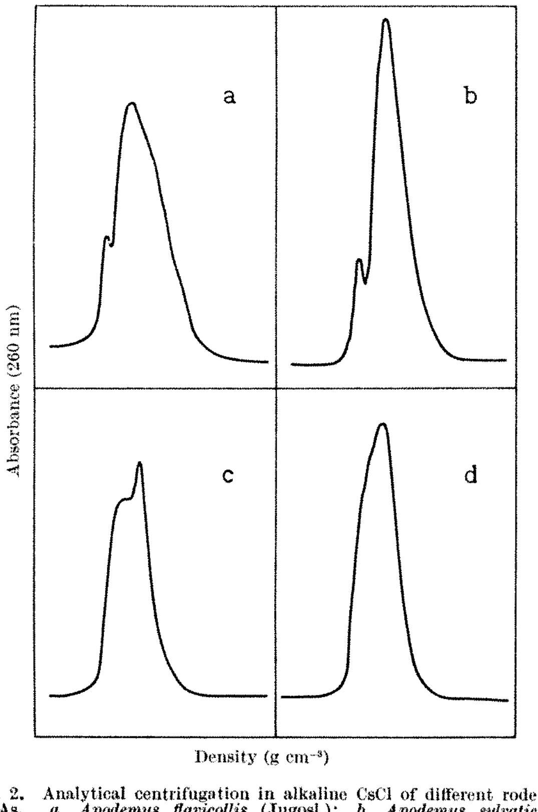

Fig. 2. Analytical centrifugation in alkaline CsCl of different rodent DNAs. *a*, *Apodemus flavicollis* (Jugosl.); *b*, *Apodemus sylvaticus* (Alpine); *c*, *Rattus rattus* (Jugosl.); *d*, *Acomys minous*. 3 μg of DNA was dissolved in 0·58 ml. of 0·01 M Tris (pH 8), denatured with 0·1 ml. 0·2 M NaOH and adjusted with 0·93 g CsCl to an initial density of 1·740 to 1·750 g cm^{-3}. Centrifugation was carried out as in Fig. 1.

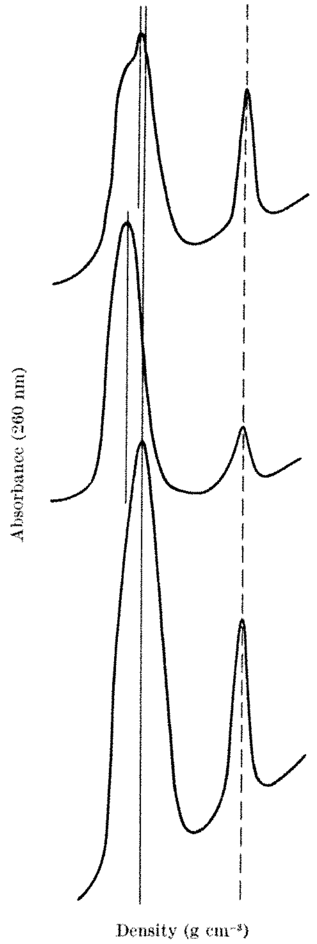

Fig. 3. Analytical centrifugation of DNA from liver nuclei of *Arvicola amphibius* (female) after prefractionation on a preparative ultracentrifuge. *a*, Total DNA; *b*, light fraction of the preparative run; *c*, heavy fraction of the preparative run. The distributions in *c* are non-Gaussian and therefore indicate further heterogeneity in the heavy fraction. Centrifugation was carried out as in Fig. 1.

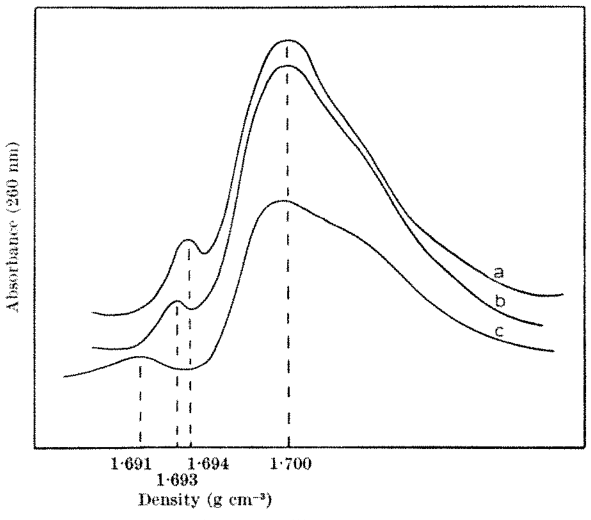

Fig. 4. Comparison of the satellites of different *Apodemus* species. Whole liver DNA was centrifuged as described in Fig. 1 and the traces aligned as shown. The densities were obtained with reference to the marker DNA peak not shown at this magnification. *a*, *Apodemus sylvaticus* (Edinburgh); *b*, *Apodemus flavicollis* (Hereford); *c*, *Apodemus agrarius* (Bohemia).

size will be larger. Nevertheless, just as the fast minor components vary in size in different species, so does the size of the intermediate fraction. Britten has reported[2] a variation from 20 to 80 per cent in the intermediate fraction, using standardized conditions of reassociation.

For our comparisons of reassociation rates between different rodent DNAs we have measured ultraviolet hypochromicity in relatively stringent conditions; the reassociation temperature was 60° C in 0·12 M Na^+ which defines a T_m for the native DNA of about 85° C (ref. 19). Second order rate plots similar to those of Wetmur and Davidson[3] have been used to compare the kinetics of reassociation. The reciprocal of the fraction unreassociated is plotted against time, and in simple DNAs such as those from T4 or bacteria this gives a straight line. For higher organisms, a number of more or less straight lines of different slopes are found (Fig. 5). Extrapolating to zero time gives a crude estimate of the proportion of each component in test systems with mixtures of T4 and *E. coli* DNA (unpublished data of M. L. Birnstiel and W. H.). Calculated in this way, the proportion of rodent DNA sequences reassociating at an intermediate rate varies between 4 and 13 per cent. The proportion of fast reassociating sequences has an even greater variation, between 0 and 12 per cent: in *Microtus agrestis* and *Clethrionomys glareolus* fast fractions cannot be detected by the method, which, like CsCl centrifugation, does not immediately reveal the presence of small minor components.

The Biological Significance of Repetitive DNA

The evidence for any biological function for fast reassociating fractions like the mouse satellite is small, although mouse satellite is probably not transcribed[10]. The hypothesis that highly repetitive DNA has a "chromosomal housekeeping" function[12] is supported by recent findings that the DNA which remains in chromosomes after salt extraction[9], and also condensed chromatin (ref. 20 and personal communication from B. J. McCarthy), are enriched in satellite DNA. In addition, similar proportions of satellite sequences have been found in isolated chromosomes of different size classes[9]. More recently, Smith[8] has shown that mouse satellite is the first DNA fraction to be replicated after polyoma infection, and Jones[8a] has used the technique of *in situ* hybridization to indicate that a high proportion of satellite sequences are localized near the centromeres of each mouse chromosome. These findings should not be interpreted to indicate that heterochromatin, which is only definable by cytological and genetic observations, is exclusively composed of highly repetitive DNA. Indeed, our experiments contradict this because *Microtus agrestis*, in which about 20 per cent of the genome is contained in the giant heterochromatic sex chromosomes[21], has no large satellite (Fig. 1) nor any fast reassociating component (Fig. 5). No other correlation between karyotype and the occurrence of multiple sequences is evident from our data (Table 1). Nor is there any precise information on the DNA content

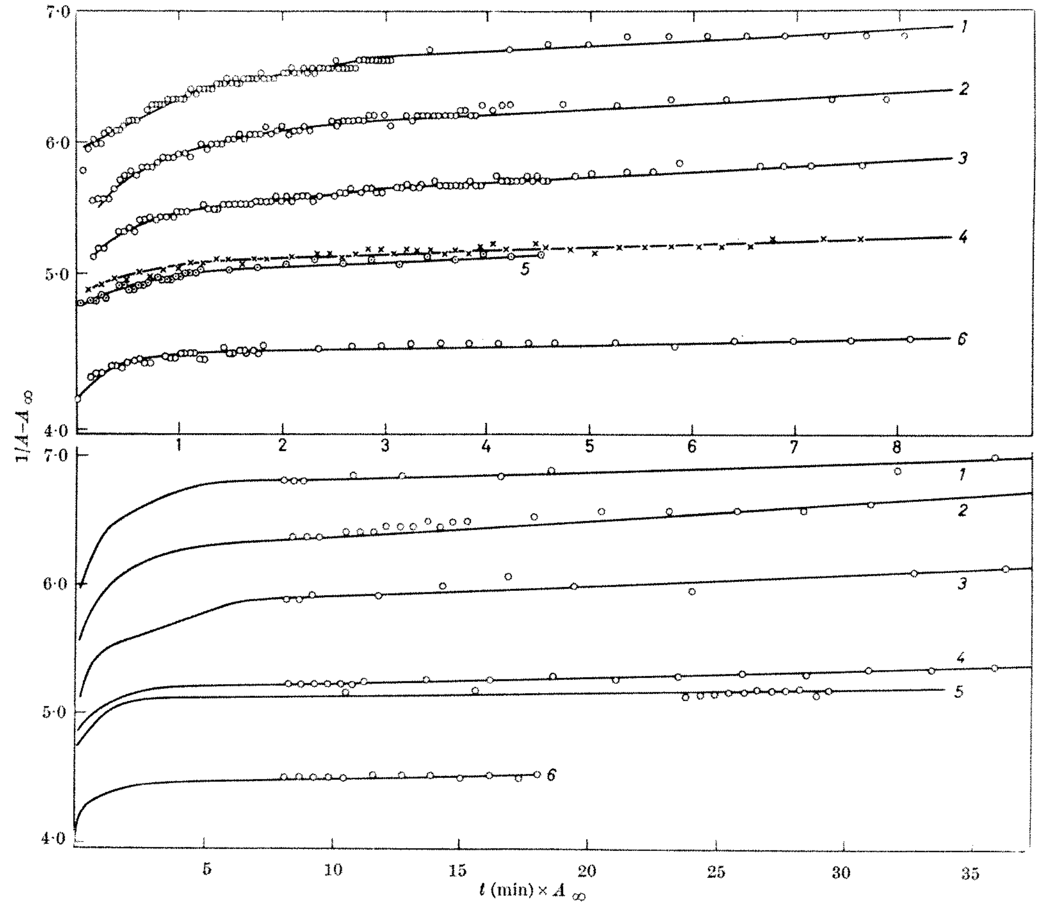

Fig. 5. Renaturation behaviour of some rodent DNAs. 1, *Microtus arvalis* (Orcadensis); 2, *Apodemus sylvaticus*; 3, *Apodemus flavicollis*; 4, *Microtus agrestis*; 5, *Clethrionomys glareolus*; 6, *Apodemus mystacinus*. Sonicated DNA (average size 500–1,000 nucleotides according to molecular weight determinations by boundary centrifugation) at a concentration of 10 to 20 μg/ml. was denatured at 100° C in 0·08 M phosphate buffer (pH 6·8) and quickly injected into a 1 cm or a 5 cm cuvette of a Zeiss spectrophotometer 'PMQ II'. The cuvettes were kept at 60° C as measured by a platinum resistance thermometer and bridge circuit (Rosemount Engineering). The renaturation temperature reached 60° C after 10 to 20 s. The changes in absorbance were then recorded at (initially) 3 s intervals with a 'Unilog' digital print-out (Joyce, Loebl). Usually the reaction was followed for about 48 h and the initial hyperchromicity was checked by an additional melting of the duplexes at the end of the run. The data were plotted according to Wetmur and Davidson[3]. A_∞, Absorbance (260 nm) of the native DNA; A, absorbance at time t. To facilitate comparison ($t \times A_\infty$) is plotted on the abscissa. The lower half of the figure consists of the data at longer times of renaturation, together (< 8) with the curves from the upper figure after an appropriate scale correction.

of these species, which could allow a comparison between the proportion of multiple sequences and the genome size.

A much canvassed possibility is that repetitive DNA is associated with the presence of multiple copies of genes as suggested by the chromosome models of Callan[22], Beermann[23] and Whitehouse[24]. It is well established that the DNA sequences specifying ribosomal[25] and 5S RNA[26] are present in multiple copies. Recently[27] a tissue specific RNA has been localized in the *Drosophila hydei* genome and correlated with distinct functions in sperm histogenesis. The conditions of this experiment were such that the DNA complementary to this RNA must have been highly reiterated. This provides direct evidence that these repeated sequences are not fortuitously similar but are functionally related.

Table 1

Species	2 N	Per cent of the genome "Fast"	"Interm."	Total Repetitive
Microtus arvalis (orcadensis)	46	6	8	14
Microtus agrestis	50	—	7	7
Microtus nivalis	56	5	5	10
Clethrionomys glareolus britannicus	56	—	11	11
C. glareolus skomerensis	56	7	8	15
C. nageri	56 ?	7	8	15
Arvicola amphibius	36	5	5	10
Rattus rattus	42	10	4	15
Mus musculus	40	12	8	20
Acomys minous	?	5	7	13
Apodemus mystacinus	?	5	5	10
Apodemus flavicollis	48	7	13	20
Apodemus sylvaticus (Edinburgh)	48	11	9	19
Apodemus sylvaticus (Yug. I)	48	11	9	19
Apodemus sylvaticus (Yug. II)	48	11	9	19
Apodemus sylvaticus (Alpine)	48	9	9	18

Chromosome numbers (2 N) are given in the first column. Percentages of the genome are obtained by extrapolating the different parts of the reaction curves to zero time and calculating the corresponding $A\infty$ (see text for an empirical justification). The column "fast" refers to the initial rapid phase of the reaction curve and "intermediate" to all other components except the final slow reaction which occurs at values greater than 10 for $t \times A\infty$ in Fig. 5. In *Microtus agrestis* it is not possible to distinguish between "fast" and "intermediate" within the small amount of repetitive DNA and in one *Clethrionomys* nearly all the repetitive DNA renatures at an intermediate rate. The amounts of the "fast" component will not necessarily be the same as that in satellite DNAs defined by CsCl centrifugation.

On the other hand, about 80 per cent of the genome of the rodents studied in this work reassociates at the rate characteristic of sequences having only a single copy on each genome. Such measurements, however, cannot exclude the presence, of, for example, two copies of each gene, but they appear to exclude a chromosomal model based on the general large-scale multiplication of all genes. The hypothesis of "masters" and "slaves" could be rescued if it were confined to cistrons specifying proteins and if these were confined to the intermediate fraction of DNA. The number of such cistrons would be relatively small, however, because the rate of reassociation of the intermediate fraction is consistent with the presence of about 10,000 copies of each cistron, on average, while the size of the fraction (20 per cent intermediate DNA) limits the number of such copied cistrons to about 100. Even if each of these families of copied cistrons specified several related proteins, it would still seem to be essential to involve the unique sequences in a protein-specifying role. It should also be remembered that the quality of reassociated DNA from the intermediate fractions indicates that the "copies" are far from perfect.

Further, even such a homogeneous repetitive fraction as the mouse satellite discussed earlier is not composed of identical copies (E. Southern and A. Carr-Brown, manuscript in preparation), and except perhaps for the cistrons transcribing 5S RNA[28,29], and possibly the ribosomal DNA in *Xenopus*[25], there is no evidence that other repeated DNA sequences are identical.

If repetitive DNA in higher organisms is not largely associated with multiple gene copies, can it be explained in other ways ? Any explanation has to account for the wide variations in the amount of DNA which reassociates at fast and intermediate rates (Table 1): it seems as if the genomes of these rodents are in a state of continuous and large scale fluctuation.

Earlier[12], one of us (P. M. B. W.) considered the possibility that there are frequent base substitutions at non-critical positions in the DNA. Thus interchange between synonymous codons might be selectively more nearly neutral—even more than substitutions resulting in conservative[31] amino-acid replacements. A random selection of available synonyms may destroy the ability of two cistrons coding for similar proteins to reassociate and form stable duplexes[18], so that if all "single-copy" DNA specified proteins, the size of the intermediate fraction may be altered in different species by varying degrees of bias in the selection of the available synonyms. Even if "single-copy" DNA is largely untranslated, this explanation may still hold, because it is likely that base substitutions could also occur in non-protein specifying regions of the DNA without damaging their function.

The gross differences which we have revealed in one rodent family, and which seem to involve up to 500 million base pairs (10 per cent of the genome), must surely reflect the operation of significant molecular mechanisms in higher organisms. They need to be accounted for in any theory of genome organization or, indeed, any theory of satellite DNA function. Moreover, we need to know to what extent these differences are caused by the evolutionary amplification of DNA sequences—which has certainly occurred—and how much by the rapid substitution of bases at less critical but nevertheless not neutral positions in the genome.

Rattus rattus, *Apodemus mystacinus* and some *A. sylvaticus* were collected by Mr T. Day in Yugoslavia with the help of the Weir Fund of the University of Edinburgh. *A. flavicollis* was collected by Mr H. Jones from Herefordshire. Mr T. Warwick collected or arranged for the collection of the *Microtus* spp., some of the *A. sylvaticus* and *Arvicola amphibius*. *Clethrionomys* spp. were obtained from the laboratory populations of Dr J. Godfrey, who also collected the alpine individuals of *A. sylvaticus*. *Acomys minous* was a gift from the London Zoo. We thank those who have assisted and also acknowledge the support of a research grant from the Medical Research Council and by the Max-Planck-Gesellschaft and the Deutsche Forschungsgemeinschaft for W. H.

Position of the Initiator and Peptidyl Sites in the *E. coli* Ribosome

by
ERNST KUECHLER*
ALEXANDER RICH
Department of Biology,
Massachusetts Institute of Technology,
Cambridge, Massachusetts

If an initiation complex is formed with *E. coli* ribosomes, viral messenger RNA and formylmethionyl-tRNA and the unprotected messenger RNA is then digested with ribonuclease, the ribosome is still able to synthesize a pentapeptide fragment. The point of entry for messenger RNA on the ribosome therefore seems to be four codons removed from the initiator site. The same distance was found for the peptidyl site.

THE function of the ribosome is more fully understood than the details of its structure. There are two subunits with a combined diameter in the electron microscope of approximately 200 Å. It is usually believed that the addition of amino-acids takes place in the interior of the ribosome, but there is very little information about the site of this process. The fact[1] that proteolytic enzymes acting on the growing polypeptide chains in reticulocyte ribosomes are unable to digest the thirty to thirty-five amino-acids proximal to the transfer RNA suggests that a portion of the nascent chain is buried within the ribosome. Experiments[2,3] involving both synthetic and natural messenger RNAs have shown that the fragment of messenger RNA bound to the ribosome is also resistant to ribonuclease digestion.

We have extended this kind of study by binding *Escherichia coli* ribosomes to the initiator site of R17 viral RNA in the presence of labelled formylmethionyl-transfer RNA[4], subjecting this initiation complex to extensive ribonuclease treatment and then allowing it to incorporate amino-acids. The product was found to be the N-terminal pentapeptide fragment of the coat protein, which was attached to the ribosomal structure through transfer RNA. We interpret these experiments to indicate that the initiator site is four codon units away from the position where ribonuclease can act at the ribosomal site of entry for messenger RNA. A similar interpretation is also suggested by experiments in which the sequence was determined of viral RNA segments protected by ribosomes attached to initiator sites[5,6]; and further by an experiment in which an amber codon in the viral RNA is brought into the ribosome before ribonuclease digestion. When the amber is four codon units removed from the peptidyl site, ribonuclease digestion of the messenger RNA does not affect its normal function in bringing about termination and release of the peptide chain. These experiments also show that ribonuclease digested ribosomes are able to carry out the normal steps of polypeptide chain elongation and termination.

The single stranded messenger RNA extracted from the R17 bacteriophage virus[7] was added to purified *E. coli* ribosomes in the presence of ^{35}S-labelled formylmethionine transfer RNA, the initiator of protein synthesis[4], to give the initiation complex shown in Fig. 1*a*. The complex was exposed to pancreatic ribonuclease (10 μg/ml.) and incubated for 1 or 2 h at 0° C, resulting in an almost complete digestion of the R17 messenger RNA and considerable digestion of the ribosomal RNA. In these conditions, however, the formylmethionyl-tRNA remains intact (E. K. and A. R., manuscript in preparation). The nuclease digested ribosomes were retrieved by centrifugation through sucrose and placed in a complete system for amino-acid incorporation. The oligopeptide obtained was characterized by thin layer electrophoresis.

Another variant of this experiment was carried out by using a mutant of R17 virus, amB$_2$ (ref. 8), which has an amber codon in the seventh position of the coat protein gene. When this RNA is used in an amino-acid incorporating system a free hexapeptide is produced, fMet-Ala-Ser-Asn-Phe-Thr, corresponding to the N-terminus of the *in vitro* synthesized R17 virus coat protein[9]. The initiation complex is again formed with the amB$_2$ RNA using ^{35}S-labelled formylmethionyl-tRNA and ribosomes (Fig. 1*b*). A limited addition of amino-acids was carried out using an *in vitro* incorporation system deficient in asparagine, the fourth amino-acid[10]. This incorporation results in the formation of tripeptide which is still attached to the tRNA in the ribosome. In this complex the amber codon is four codons away from the peptidyl site which is occupied by the tRNA containing the tripeptide. When ribonuclease digestion was carried out and the ribosomes used in an *in vitro* system in the presence of all amino-acids, the hexapeptide fragment of the coat protein was released into the supernatant.

Oligopeptides were identified using thin layer electrophoresis at *p*H 4·8 (ref. 11), which gave a good separation of all of the peptides (Fig. 2). The mobility of the N-terminal oligopeptides is plotted relative to the mobility of formylmethionine as a function of molecular weight. In the absence of side effects, mobility should be inversely related to molecular weight: the observed points in fact fall very close to the solid line in Fig. 2. For electrophoresis, *p*H 4·8 was chosen because it is far enough from the *pK* value of the carboxyl groups to minimize individual differences between carboxy terminal amino-acids.

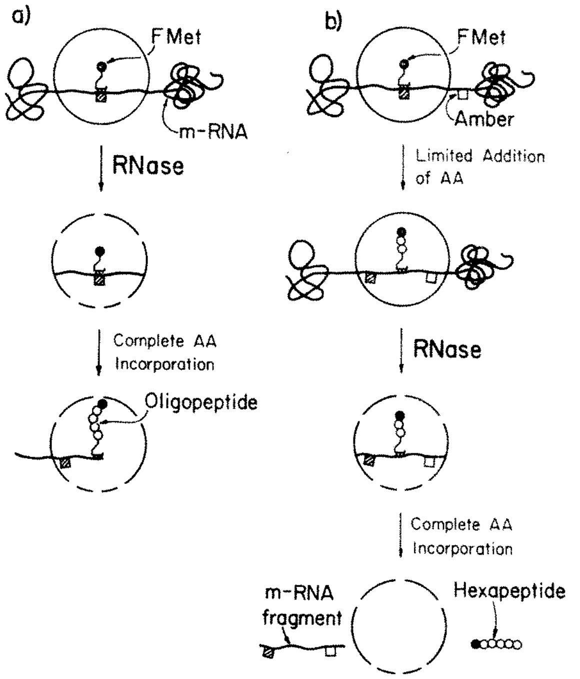

Fig. 1. Schematic diagram of the experiments: (*a*) Formation of the initiation complex with wild type R17 RNA as messenger, followed by ribonuclease digestion and incorporation in a complete *in vitro* protein synthesizing system. The cross-hatched square represents the initiation triplets; the hook is tRNA and the large circle is a ribosome. (*b*) Formation of the initiation complex with amB$_2$ RNA. The open square represents the amber triplet. A limited addition of two amino-acids is followed by ribonuclease digestion and complete amino-acid incorporation results in released hexapeptide.

---

* Present address: Institut für Biochemie, University of Vienna, Vienna 9.

The ribosome is able to carry out normal peptide synthesis after treatment with ribonuclease. The N-terminal peptides of the coat protein, fMet-Ala and fMet-Ala-Ser, are formed sequentially in an incorporation system which is deprived of asparagine[10], the fourth amino-acid in the polypeptide chain (Fig. 3). After ribonuclease treatment of the initiation complex, ribosomes were incubated at 15° C in the presence of alanyl and seryl-RNA plus supernatant. At various times, aliquots were analysed by thin layer electrophoresis. There is a rapid disappearance of formylmethionine with a corresponding sharp rise in the amount of radioactive fMet-Ala which reaches a peak approximately 10 s after the onset of incubation and then falls slowly. Concurrently there is a gradual rise in the radioactivity of the tripeptide fMet-Ala-Ser which continues for the entire 5 min incubation period. These kinetic curves would be expected in a system in which fMet-Ala is an intermediate in the synthesis of the fMet-Ala-Ser tripeptide. The rapid appearance of the dipeptide fMet-Ala results from a fast initial transpeptidation step; the somewhat slower appearance of the tripeptide fMet-Ala-Ser may reflect a limiting amount of a supernatant factor[12]—tripeptide formation is known to require all the factors for polypeptide chain elongation[13,14]. Similar results are obtained with ribosomes which have not been subjected to ribonuclease treatment, so that functions essential for protein synthesis are unimpaired and it implies that the degraded ribosomes are capable of synthesizing longer peptides.

Identification of Peptide Sequences

The initiation complex (Fig. 1) containing ^{35}S-labelled formylmethionyl-tRNA was isolated and then incubated with a complete amino-acid mixture and supernatant. After various times, aliquots of the incubation mixture were precipitated with 5 per cent trichloroacetic acid (TCA) and the precipitate was hydrolysed with alkali to release the nascent peptides from the tRNA. At zero time of incubation it can be seen that, where no ribonuclease treatment took place, all of the radioactivity is associated with formylmethionine. At 5 and 10 min of incubation there are a series of radioactive products which migrate to positions both above and below the position of the marker compounds of radioactive N-terminal penta and hexapeptides of the coat protein. The more slowly migrating oligopeptides present after both 5 and 10 min of incubation include nona and decapeptides; no larger peptides are found because of the method of isolation. Following incubation with alkali to release the oligopeptides bound to tRNA, peptides containing more than ten amino-acids were precipitated with 5 per cent TCA, so accounting for the fairly sharp discontinuity in the longer peptides. In the absence of R17 RNA in the incubation mixture, there is no appreciable accumulation of peptides, which suggests that there is only a very small background of endogenous messenger RNA present in the ribosome preparation.

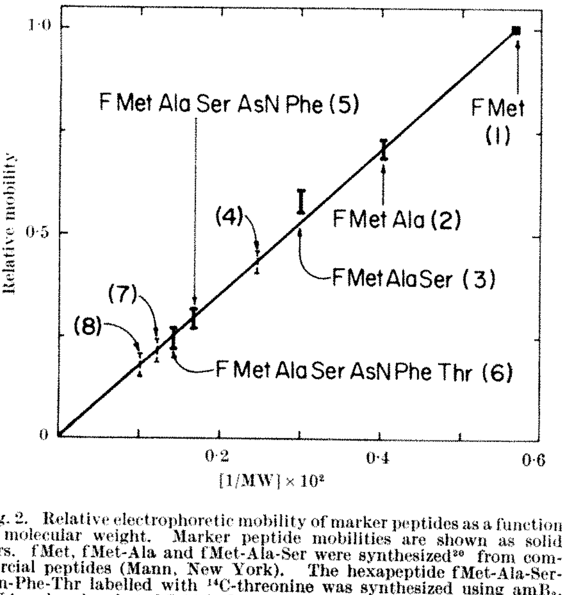

Fig. 2. Relative electrophoretic mobility of marker peptides as a function of molecular weight. Marker peptide mobilities are shown as solid bars. fMet, fMet-Ala and fMet-Ala-Ser were synthesized[20] from commercial peptides (Mann, New York). The hexapeptide fMet-Ala-Ser-Asn-Phe-Thr labelled with ^{14}C-threonine was synthesized using amB$_2$, RNA and preincubated S-30 (ref. 10). The pentapeptide fMet-Ala-Ser-Asn-Phe labelled with ^{14}C-phenylalanine was obtained from the hexapeptide containing ^{14}C-phenylalanine by incubation with 50 μg/ml. of chymotrypsin (Worthington) in 0·1 M Tris (*p*H 8) and 0·005 M CaCl$_2$ at 37° C for 1 h. The dashed bars indicate the positions of radioactive peptides formed *in vitro* cell free synthesis. Their electrophoretic mobilities characterize them as the N-terminal tetra, hepta and octapeptide of the R17 coat protein. The length of the bars characterizes the range of relative electrophoretic mobilities obtained. Electrophoresis was carried out at 4° C on 20 × 20 cm cellulose thin layer glass plates (Merck, Germany) at *p*H 4·8 (12·5 ml. acetic acid, 14 ml. pyridine per l. buffer) using 38 V/cm (ref. 11). Electrophoresis times were either 105 min or 210 min. To correct for the endosmotic effect, ^{14}C-uridine was used as a marker for the origin.

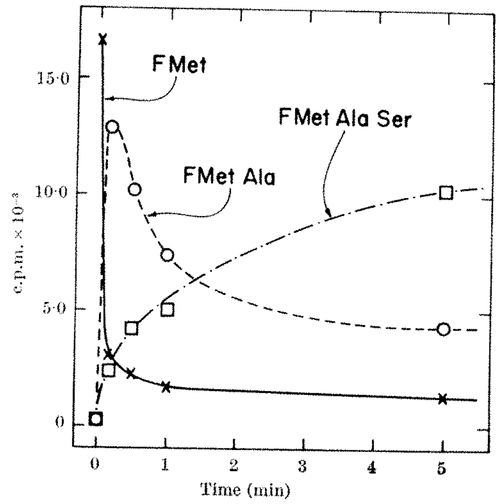

Fig. 3. Kinetics of the sequential formation of the N-terminal peptides fMet-Ala and fMet-Ala-Ser on ribonuclease treated ribosomes. *E. coli* Q13 ribosomes containing about 70 per cent native subunits were used throughout[19]. The ribosomes were preincubated for 30 min at 37° C in the presence of 3 mM ATP, 0·2 mM GTP and 5 mM PEP; 20 μg of PEP kinase and 100 μg of N^5-formyltetrahydrofolic acid were added per ml. The ribosomes were purified by centrifugation through 6 ml. 1 M sucrose containing 0·03 M NH$_4$Cl, 0·05 M Tris (*p*H 7·6), 0·01 M magnesium acetate, 0·001 M EDTA, 0·001 M Cleland's reagent for 14 h at 60,000 r.p.m. in a Spinco 65 rotor. ^{35}S-fMet-*t*RNA was freed from aminoacyl-tRNA by treatment with 10 mM CuSO$_4$ at *p*H 5·5 (refs. 21, 22). The mixture for the formation of the initiation complex (2 ml.) contained per ml.: 2·7 mg *E. coli* ribosomes, 0·75 mg R17 RNA, 2·3 μmoles GTP, 5 μmoles magnesium acetate, 1·8 × 10^6 c.p.m. ^{35}S-fMet-tRNA (2 × 10^5 c.p.m. per $A_{260\text{ nm}}$ unit), 50 μmoles KCl, 10 μmoles NH$_4$Cl, 100 μmoles Tris (*p*H 7·2) and 6 μmoles mercaptoethanol. After 10 min at 37° C and subsequent cooling to 0° C the Mg^{2+} concentration was raised to 10 mM and the solution was incubated for 1 min at 37° C. 10 μg/ml. of pancreatic ribonuclease was added at 0° C and the digestion continued for 1 h at 0° C. All subsequent operations were carried out at 0–4° C. The solution was layered on 6 ml. of 1 M sucrose-containing NH$_4^+$-Tris-Mg^{2+} buffer; 0·03 M NH$_4$Cl, 0·05 M Tris (*p*H 7·6), 0·012 M magnesium acetate and 0·001 M Cleland's reagent. It was then centrifuged for 5 h at 60,000 r.p.m. at 2° C in a Spinco 65 rotor. The pellet was washed and resuspended in a 1·6 ml. NH$_4^+$-Tris-Mg^{2+} buffer. Part of this suspension (0·3 ml.) was used to make a 1 ml. final solution. The final solution for limited amino-acid addition contained per ml.: 800 μg tRNA ("stripped" in 0·5 M Tris, *p*H 9, at 30° for 45 min and purified on 'Sephadex *G*-25'), 3 μmoles ATP, 0·2 μmoles GTP, 5 μmoles PEP, 20 μg PEP kinase, 40 nmoles each of alanine and serine, S-100 (purified by ribonuclease treatment and phosphocellulose chromatography)[10] containing 1 mg protein, 30 μmoles NH$_4$Cl, 50 μmoles Tris (*p*H 7·6), 12 μmoles magnesium acetate and 1 μmole Cleland's reagent. The mixture was preincubated for 10 min at 37° and cooled to 0° before the addition of the ribosome suspension. Incubations were carried out at 15° C and stopped by freezing in solid CO$_2$–alcohol. TCA was added to 5 per cent and the sample was centrifuged at 1,000*g* for 5 min. The precipitate was treated with 0·1 M NaOH for 1 h at 0° C. TCA was again added to 5 per cent and the sample was centrifuged. The supernatant was extracted with cresol–ethyl acetate and the product purified according to the technique of Capecchi[11]. The eluate from the 'Dowex 50' column (0·5 × 2·5 cm) was lyophilized and redissolved in 25 μl. H$_2$O. 10 μg each of synthetic fMet, fMet-Ala and fMet-Ala-Ser were added. Electrophoresis was for 105 min as described in Fig. 2. The peptides were detected by spraying with platinic iodide reagent[11] and by autoradiography. Spots were removed from the plate and collected in scintillation vials; 0·5 ml. H$_2$O and 20 ml. of Bray's solution were added and the samples were counted in a liquid scintillation counter.

Fig. 4*b* shows the peptide fragments synthesized by ribosomes which had been subjected to 1 h of ribonuclease action. No products are formed at 0 min incubation, but after both 5 and 10 min of incubation there are peptides smaller than the hexapeptide. Most of the radioactivity released by alkali is found in a very intense spot which has the same electrophoretic mobility as the synthetic pentapeptide fMet-Ala-Ser-Asn-Phe of the viral coat protein. Smaller amounts of the intermediates fMet-Ala, fMet-Ala-Ser and fMet-Ala-Ser-Asn are also found. The pentapeptide product is absent when R17 RNA is not added to the incubation mixture. If the initiation complex is formed using RNA from the mutant amB$_2$ virus and treated analogously, the results are identical to those with wild type R17 RNA. In the electrophoretogram of Fig. 4 there is only a small separation between the penta and hexapeptide. Experiments using paper electrophoresis for longer time periods demonstrated that the oligopeptide product had the same electrophoretic mobility as the tritiated pentapeptide marker fMet-Ala-Ser-Asn-^{3}H-Phe and was clearly separated from the hexapeptide marker. The identity of the product in Fig. 4*b* with the synthetic pentapeptides was confirmed by co-electrophoresis after acid deformylation (E. K. and A. R., manuscript in preparation). Fig. 4*c* illustrates the experiment carried out with ribosomes subjected to 2 h of digestion with ribonuclease. After 10 min incubation the pentapeptide is still the chief product. Corresponding supernatants from the experiments in Fig. 4 were also analysed by thin layer electrophoresis and autoradiography. There was some release of the N-terminal di and tripeptide, which occurred equally in the ribonuclease and non-ribonuclease treated ribosomes, but no appreciable release of pentapeptide. Apparently when this product is formed on the ribonuclease digested messenger RNA it is securely held to the ribosome and released only by incubation with alkali which hydrolyses RNA.

In the amB$_2$ virus, the amber is the seventh codon in the coat protein gene. The amB$_2$ RNA was used as outlined in Fig. 1*b*. After limited incorporation of amino-acids in an asparagine-deprived system, the major product is the tripeptide fMet-Ala-Ser (Fig. 5*a*), which is not found in the absence of added amB$_2$ RNA. Following ribonuclease digestion, the ribosomes were incubated with a complete mixture of amino-acids and the radioactive peptides found in the supernatant and in the TCA precipitate were separated. The supernatant product (Fig. 5*b*) consists exclusively of the N-terminal hexapeptide of the coat protein, as indicated by co-electrophoresis with synthetic fMet-Ala-Ser-Asn-Phe-Thr. It is absent when no RNA from the amber mutant bacteriophage is added. The TCA precipitated ribosomes were treated with alkali to release nascent polypeptide chains, and autoradiography of the products (Fig. 5*c*) reveals a small amount of hexapeptide bound to the ribosome; quantitative analysis showed that 94 per cent of the hexapeptide is released. Thus, by contrast with the experiment of Fig. 4 in which the pentapeptide remains bound to the ribosome, the addition of three amino-acids before ribonuclease treatment resulted in the protection of the amber codon against ribonuclease and release of hexapeptide into the supernatant on *in vitro* incubation.

We have also used wild type R17 RNA in the experiment in which a tripeptidyl-tRNA-ribosome complex is formed before ribonuclease digestion. In this case the precipitate contained largely heptapeptide (Fig. 5*d*) which was identified by its mobility (Fig. 2). A quantitative analysis showed that 80 per cent of the heptapeptide was in the precipitate. This is in accord with the first experiment where formylmethionine was on the initiator site (the position occupied by fMet-tRNA, in the presence of GTP and initiation factors), indicating that four additional amino-acids can be added following ribonuclease digestion. But the tripeptidyl-tRNA occupies the peptidyl site on the ribosome, so that the initiator site seems to be identical to the peptidyl site on the ribosome within the resolution of this experiment—the length of one codon.

Significance of the Protected Region

The ribosome is able to carry out many of its normal functions following extensive exposure to ribonuclease. In experiments with polyuridylic acid directed polyphenylalanine synthesis, it has been shown that *E. coli* ribosomes are able to form polyphenylalanine even after

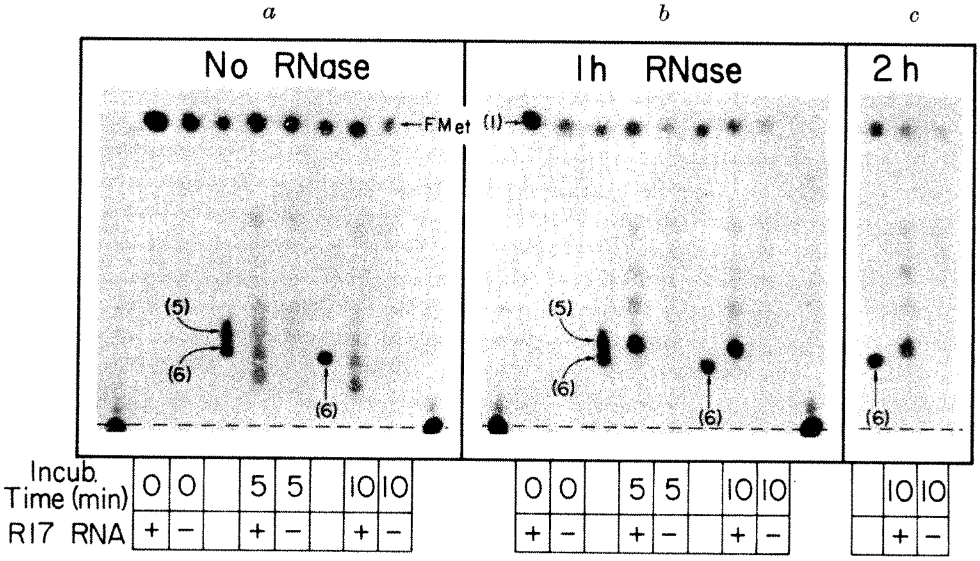

Fig. 4. Oligopeptide synthesis using the untreated and ribonuclease treated initiation complex containing ^{35}S fMet-tRNA, ribosomes and wild type R17 RNA. The initiation complex (2 ml.) was formed as described in Fig. 3; $3 \cdot 4 \times 10^6$ c.p.m. of ^{35}S-fMet-tRNA was used ($3 \cdot 7 \times 10^5$ c.p.m. per $A_{260\ \mathrm{nm}}$ unit) per ml. After the incubation and adjustment of the Mg^{2+} concentration to 10 mM, the mixture was split into three equal parts: *a* was not treated further; *b* and *c* were incubated with 10 μg/ml. of pancreatic ribonuclease at 0° C for 1 h and 2 h, respectively. Centrifugation and resuspension of the ribosomes were as described above. The *in vitro* protein synthesizing system was the same as in Fig. 3, except for the following components: 800 μg tRNA was precharged with all twenty amino-acids; 100 μg N^5-formyltetrahydrofolic acid and 100 nmoles of all amino-acids were present per ml. of incubation mixture. In addition a crude *E. coli* B S-100 was used at a concentration of 1·5 mg protein/ml. After incubation for 0, 5 and 10 min at 15° C, the reaction products were isolated from the TCA precipitate as described above. The electrophoresis was run for 2 h. The numbers (5) and (6) refer respectively to synthetic fMet-Ala-Ser-Asn-^{14}C-Phe and fMet-Ala-Ser-Asn-Phe-^{14}C-Thr. Radioactive uridine was added as a marker to show the position of the origin corrected for endosmotic migration (the dashed line at the bottom of the autoradiograph which passes between two uridine markers at either side). The plates were exposed to X-ray film for 6 days.

the 50S ribosomal subunit has been digested with ribonuclease to the point where there is no remaining intact 23S ribosomal RNA[15]. In those experiments it was necessary to increase the concentration of divalent ions above that used in a normal incubation. Now it has been shown that optimum incorporation of amino-acids occurs with a divalent ion concentration of 12 mM Mg^{2+}, by contrast with the optimum of 7–10 mM Mg^{2+} which is normally used with natural messenger RNA[9,10,16]. Our experiments show that the digested ribosomes (whose characterization will be described elsewhere) not only elongate polypetide chains but also release them when directed by an amber codon.

The R17 bacteriophage RNA codes for three proteins: maturation protein, coat and RNA synthetase protein. We are considering primarily the coat protein. Most of the binding of formylmethionyl-tRNA is on the coat protein initiation site if the viral RNA is intact[17]. In addition, however, we are using Capecchi's procedure of assaying the supernatant and the ribosome bound peptides[11,16] which involves an extraction of uncharged peptides into a cresol–ethyl acetate phase followed by chromatography on 'Dowex 50' and yields only N-blocked peptides which do not contain basic amino-acids. The N-terminal peptides of both the maturation and synthetase protein contain arginine and lysine[17]. Our analytical procedure would thus preferentially select for coat protein fragments and, because the amber mutation is in the coat protein, the substantial release of hexapeptide in the experiment described in Fig. 5 shows that we are primarily analysing peptides directed by the coat protein gene.

In experiments with synthetic oligonucleotide messenger RNA, it has been shown that ribosomes are capable of reading to the end of a complete codon in the oligonucleotide[18]. If a codon is incomplete—does not contain three nucleotides—the ribosome does not add another amino-acid. In assessing the results of the experiment which yielded the pentapeptide fMet-Ala-Ser-Asn-Phe, we therefore conclude that the pancreatic ribonuclease cleaves at least beyond the fifteenth nucleotide of the coat protein gene. The ribonuclease could have cleaved through the codon which specifies threonine in the sixth position, but it is unlikely that the ribonuclease left any appreciable amount of the threonine codon intact because no hexapeptide was detected attached to the ribosome (Fig. 4). The presence of the N-terminal heptapeptide (Fig. 5*d*) reinforces this interpretation. These results are in agreement with experiments in which the portion of the messenger RNA protected by the ribosome was isolated and sequenced and which indicated that ribonuclease cleavage occurs immediately after the fifteenth residue in the polynucleotide chain[5]. Similar results have also been obtained with Qβ virus[6]. The results of these and the amino-acid incorporation experiments therefore indicate that the initiator site is removed from the ribosomal entrance for messenger RNA by four codons, or a total of fifteen nucleotides if we include the initiator codon. Formation of a heptapeptide when the peptidyl site is occupied by tripeptidyl-tRNA suggests that that site is similarly removed some fifteen nucleotides from the ribosomal point of entry for messenger RNA, although the same result would be obtained if the peptidyl site were sixteen or seventeen nucleotides removed.

If we assume that the ribonuclease is able to act at the periphery of the ribosome and that the messenger RNA has its bases stacked with a separation of 3·4 Å per nucleotide, a distance of approximately 50 Å from the initiator or peptidyl sites to the periphery is suggested. But the polynucleotide chain can also be extended to an internucleotide spacing near 7 Å per base, so that the maximum distance could be as great as 100 Å, or approximately half the ribosomal diameter. It is of interest that proteolytic digestion of the nascent polypeptide chain on the ribosome[1] also indicated that the site for amino-acid addition is a similar distance from the point at which the proteolytic enzymes can act. Thus it is likely that the enzymatic functions of the ribosome occur deep within the ribosomal structure.

This research was supported by grants from the US National Institutes of Health and the National Science Foundation. We thank Dr M. Capecchi for supplying us

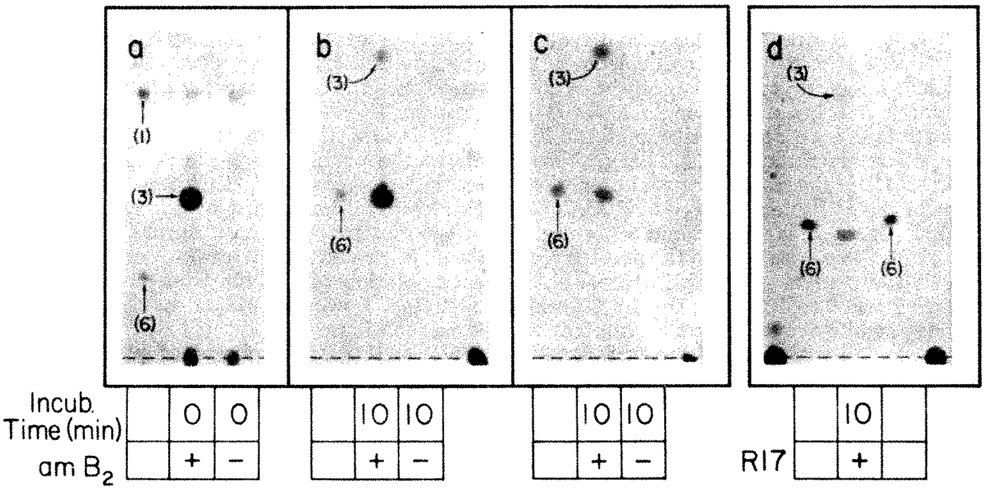

Fig. 5. Experiments using RNA from the virus mutant amB_2. The tripeptidyl-tRNA–ribosome–mRNA complex was formed in a purified *in vitro* system (2 ml.) by limited addition of alanine and serine as described in Fig. 3 except that 0·75 mg amB_2 RNA, 2·7 mg *E. coli* ribosomes and $1·9 \times 10^6$ c.p.m. ^{35}S-fMet-tRNA ($3·3 \times 10^5$ c.p.m. per $A_{260 \text{ nm}}$ unit) were added per ml. The incubation was carried out at 7 mM Mg^{2+} for 10 min at 37° C. After increasing the Mg^{2+} concentration to 10 mM, the mixture was again incubated for 1 min at 37° C and rapidly chilled. Ribonuclease digestion was carried out at 0° for 1 h at 10 μg/ml. Following centrifugation and resuspension of the ribosomes, a complete amino-acid incorporation system identical to that in Fig. 4 was used. The oligopeptides were isolated from the 5 per cent TCA precipitate after hydrolysis at 0° C in 0·1 M NaOH[10]. *a*, The tripeptide fMet-Ala-Ser isolated from the TCA precipitate before amino-acid incorporation in the complete *in vitro* system; *b*, hexapeptide released into the supernatant; *c*, the peptides which remain bound to tRNA. Electrophoresis was for 105 min in *a* and 210 min in *b* and *c*. The plates were exposed to X-ray film for 4 days. *d*, Heptapeptide precipitated with the ribosomes when wild type R17 RNA was used instead of amB_2 RNA. The *in vitro* system (2 ml.) was as described except that $0·53 \times 10^6$ c.p.m. ^{35}S-fMet-tRNA ($0·8 \times 10^6$ c.p.m. per $A_{260 \text{ nm}}$ unit) was added per ml. There is no incorporation in the absence of R17 RNA. The electrophoresis was run for 3 h. The plate was exposed to X-ray film for 6 days. The position of N-terminal marker peptides is indicated by the numbers in parentheses. The dashed line at the bottom is the corrected origin which is marked by radioactive uridine.

with the R17 bacteriophage strains. We also thank Dr Harvey Lodish for discussions.

An important source of thermal H^+ and/or D^+ has been overlooked in the ionosphere of Venus which supports the choice of H^+ and/or D^+ as the dominant light ion at high altitudes.

DIRECT measurements of the thermal plasma environment of Venus were made in late 1967 by radio occultation methods using Mariner V (refs. 1–3). The data have led to the following conclusions regarding the ionosphere of Venus.

(1) The main ionospheric region in the sunlit hemisphere appears as a well defined layer of CO_2^+. Models based on photoionization of CO_2, followed by dissociative recombination of CO_2^+, are in substantial agreement with the density profiles deduced experimentally[4,5]. The peak CO^+ density for a solar zenith angle $\Psi = 40°$ is approximately 6×10^5 ions cm^{-3} at an altitude of 140 km (we assume a mean planetary radius of 6,053 km). Above the ionization peak CO_2^+ decreases approximately as $\exp(-z/H_0)$ where z is the altitude and $H_0 = 2kT/M(CO_2)g$ is the scale height. Here k is Boltzmann's constant, $M(CO_2)$ is the mass of a CO_2 molecule, g is the acceleration of gravity, and T is the neutral gas temperature. Near the peak of the layer $T \simeq 300$ to 400 K, giving a CO_2^+ scale height of about 15 km, while above 200 km a temperature of about 700 K is expected with $H_0 \simeq 30$ km (ref. 6).

(2) At an altitude of about 500 km in the daytime ionosphere a very sudden transition occurs[2] from the relatively cool ($\lesssim 0 \cdot 1$ eV/particle) ionospheric plasma of moderate density ($\sim 10^4$ cm^{-3}) to interplanetary conditions where energetic protons (~ 1 KeV/particle) predominate with densities of 1 to 10 cm^{-3}. This transition boundary, or plasmapause, is thought[7,8] to arise from a shielding of the Venus ionosphere by compression of the interplanetary magnetic field against the highly conducting planetary plasma. Essentially, as the solar wind flows past Venus the imbedded interplanetary magnetic field is unable to diffuse rapidly through the Venusian ionosphere and, as a result, electromagnetic forces are established which deflect the solar wind around the planet in such a way that no intermixing of the solar wind and ionospheric plasma takes place. From this point of view the region of magnetic field enhancement forms a protective boundary layer between the planetary environment and the vastly different conditions of the solar wind. The existence of such a boundary depends, of course, on there being a balance between the ram pressure of the solar wind, the compressed magnetic field pressure, and the pressure of the planetary ionosphere. In the case of Venus the planetary ionosphere is thought to arise from photoionization of the neutral atmosphere, with ionospheric energy densities of the order of 10^3 eV cm^{-3} being required to balance the external solar wind pressure in the subsolar regions.

(3) Below the Venusian dayside plasmapause, but above the peak ionospheric density, there seems to be a transition from CO_2^+ to some unidentified light ion. Unfortunately, it is just in this region that the formation of caustics prevents an accurate analysis of the electron density profile from radio occultation studies. The extrapolation of the electron density profile from lower altitudes, however, indicates that CO_2^+ cannot be the dominant ion.

(4) In the initial phases of planetary occultation the night time ionosphere was probed by Mariner V (ref. 2). The results seem consistent with a main ionospheric layer of CO_2^+ having a peak density of 10^4 cm^{-3} at an altitude of about 170 km. Due to the long rotation period of Venus and in the absence of any known local ionization processes, it has been suggested[2,9] that the night time ionosphere results from He^+–CO_2 charge transfer. If so, it is generally assumed that lateral transport of He^+ from the daytime ionosphere is adequate to maintain CO_2^+ in the dark regions. No detailed calculations have yet been made of this effect, however, and in the face of rapid He^+ neutralization in CO_2 and N_2, it may prove difficult to supply an adequate flux of He^+ to overcome the rapid rate of CO_2^+ dissociative recombination[10].

These general features are illustrated in Fig. 1. At the bow shockfront[11] the originally supersonic solar wind is reduced to subsonic speeds as it flows around the planet.

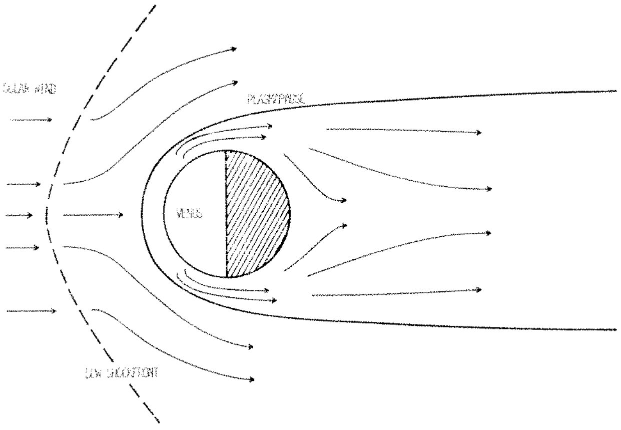

Fig. 1. Plasma environment of Venus. The solar wind passes through the bow shockfront and around the planet after being deflected by the compressed interplanetary magnetic field. The magnetic field boundary layer protects the high ionosphere from direct contact with the solar wind. Within the daytime ionosphere H^+ or D^+ created through CO_2^+–H/D charge exchange flows upwards and rearwards forming a thermal plasma tail behind the planet.

Penetration of the solar plasma into the planetary atmosphere is limited by the formation of a compressed magnetic field boundary layer across which transport of solar wind or ionospheric plasma cannot occur. The shape of the plasmapause, discussed later, is determined by a balance between the normal component of solar wind pressure and the ionospheric pressure. The arrows in the region outside the plasmapause indicate the solar wind flow, while the interior arrows show a proposed flow pattern of ionospheric plasma into the tail region which will be discussed in this article.

Although many aspects of the main ionospheric layer of Venus can be discussed in terms of the CO_2^+ photoionization model, there are some unexplained features of considerable importance. Among these must be included the following.

(1) The Stanford University occultation experiment, operating at 49·8 and 423·3 MHz, detected an extended region of enhanced thermal plasma lying behind Venus in the antisolar direction[2]. A mean ion density of 300 cm^{-3} was deduced extending 10,000 km behind the planet. Although it was suggested[2] that this planetary tail was composed of light ions, the particles have yet to be identified and their origin remains unknown.

(2) On the nightside of Venus at altitudes between 750 km and 1,450 km the presence of a light ion was inferred from the measured altitude variation of electron density[2]. The source of this cool plasma is not known, but probably it does not arise from nightside ionization processes.

(3) In the dayside ionosphere the composition transition from CO_2^+ to a light ion requires the presence of H^+, D^+, H_2^+ or He^+. Of these possibilities it is difficult to argue that H_2^+ and He^+ are dominant ion species because of their rapid neutralization reactions with CO_2 and N_2. In fact, He^+ is lost so rapidly that to maintain the night time ionosphere alone requires either a very large density of He in the Venusian atmosphere[9] or a photoionization rate much greater than appropriate for terrestrial helium. With regard to H^+ or D^+ the low rate of photoionization ($\sim 3\times 10^{-7}$ s^{-1}) has precluded serious consideration of H^+ or D^+ as important ionic components. (The problem concerned with the existence of H, D, or H_2 in the Venusian atmosphere has been discussed at length elsewhere[12]. For the purposes of this article it is not necessary to differentiate between H and D because their ionization energies are nearly the same.)

It is evident that the presence of light ions is required in the outer regions of the Venusian ionosphere to explain both the formation of the dayside plasmapause and the existence of a tail of ionization behind the planet. Of the various light ions available (H^+, D^+, H_2^+, He^+) neither H_2^+ nor He^+ is likely to be the main ion species at high altitudes, while the small photoionization rate of H^+ (or D^+) seems to remove this ion from consideration. We wish to point out, however, that an important source of thermal H^+ and/or D^+ has been overlooked in the Venusian ionosphere which supports the choice of H^+ and/or D^+ as the dominant light ion at high altitudes.

We suggest that the charge exchange reaction

$$CO_2^+ + \binom{H}{D} \xrightarrow{k_f} CO_2 + \binom{H^+}{D^+} + 0{\cdot}17 \text{ eV} \qquad (1)$$

proceeds rapidly in the forward (f) direction and provides a copious supply of protons (or deuterium ions) in the Venusian ionosphere. Although the forward reaction rate k_f for reaction (1) does not seem to have been measured, the exothermic (0·17 eV) nature of the exchange, together with the large number of final energy states available in CO_2, imply that reaction (1) is a rapid process at thermal energies. Thus, as in the terrestrial ionosphere where H^+ is produced principally through O^+-H charge exchange rather than photoionization, we propose that photoionization of H is relatively unimportant in the Venusian ionosphere but that, through reaction (1), H^+ and/or D^+ are the chief ionic constituents of the daytime ionosphere above the CO_2^+ layer.

At low altitudes where diffusion proceeds slowly, the steady state H^+ and /or D^+ density is determined through a balance of ion production and loss. Although reaction (1) has been identified as a source of light ions, the reverse reaction, k_r, also occurs. But the 0·17 eV energy defect of the reaction, together with the large CO_2 statistical weight factor, implies that $k_f/k_r > 250$. Because radiative recombination of H^+ or D^+ is generally a slow process, the equilibrium ion density can be expressed as

$$\frac{n(H^+/D^+)}{n(CO_2^+)} = \frac{k_f n(H/D)}{k_r n(CO_2)} > 250\ \frac{n(H/D)}{n(CO_2)} \qquad (2)$$

indicating an increase in the H^+/D^+ density relative to CO_2^+ in the regions of chemical equilibrium.

With the identification of reaction (1) as the ionization source for H^+ and/or D^+ in the Venusian ionosphere, it is possible to consider in more detail a reasonable model for the spatial distribution of plasma about Venus. As described previously, the compressed interplanetary magnetic field imposes a pressure boundary condition upon the Venusian upper ionosphere such that in the steady state the plasmapause must form at an altitude where the approximate relation

$$N_{sw}\, M V^2 \cos^2\xi = nk(T_e + T_i) \qquad (3)$$

is satisfied. Here N_{sw} is the solar wind proton number density, V is the solar wind speed (both measured outside the bow shockfront), M is the proton mass, ξ is the angle between the plasmapause normal and the solar wind direction, n is the ionospheric plasma density, and T_e, T_i are the ionospheric electron and ion temperatures. Using typical reported parameters[1,2,11] we find that the plasmapause should form at an altitude where $n \simeq 10^4$ cm^{-3} for $\Psi = 40°$.

Taking into account lateral plasma flow, the equations of continuity and momentum for the ith ion species in a multi-ionic constituent plasma can be written for steady state conditions as

$$\frac{1}{r^2}\frac{\partial}{\partial r}(n_i U_r r^2) + \frac{1}{r\sin\Psi}\frac{\partial}{\partial\Psi}(n_i \sin\Psi\, U_\Psi) = p_i - l_i \qquad (4)$$

$$U_r = -\frac{kT_i/m_i}{\sum\limits_k \nu_{ik}}\left\{\frac{1}{n_i}\frac{\partial n_i}{\partial r} + \frac{T_e/T_i}{n_e}\frac{\partial n_e}{\partial r} + \frac{1}{H_i}\right\} \qquad (5)$$

$$U_\Psi = -\frac{kT_i/m_i}{r\sum\limits_k \nu_{ik}}\left\{\frac{1}{n_i}\frac{\partial n_i}{\partial\Psi} + \frac{T_e/T_i}{n_e}\frac{\partial n_e}{\partial\Psi}\right\} \qquad (6)$$

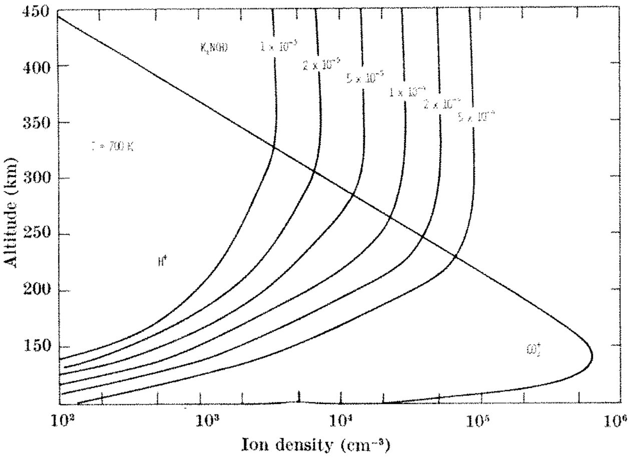

Fig. 2. Daytime ion composition profiles for diffusive equilibrium without lateral transport charge exchange reaction (1) with various ionization rates. A previous model neutral atmosphere of McElroy and Strobel[9] was used with parameters pertaining to CO_2^+ being taken from McElroy[5]. The introduction of D^+ for H^+ does not alter the results appreciably.

neglecting thermal gradients. Here r is a radial coordinate, U is the transport speed (r, Ψ components), p_i and l_i are the production and loss rates, ν_{ik} is the collision frequency between ith and kth type particles, $n_e = \Sigma n_i$, and $H_i = kT_i/m_i g$.

The boundary conditions to be used in conjunction with equations (4) to (6) determine the actual shape of the different ion density profiles. At the plasmapause boundary, the altitude of which is implicit in equation (3), the normal component of the plasma velocity is zero while the lateral component is unrestricted. Neglecting lateral transport in the subsolar wind regions, it follows that the approximate location of the plasmasphere can be found by computing solutions to the coupled ion density equations for CO_2^+ and H^+ and/or D^+ in diffusive equilibrium and searching for the altitude where equation (3) is satisfied.

Using the reaction rates and parameters given previously[5,9], profiles of ion composition have been computed for the daytime Venusian ionosphere for $\Psi \simeq \xi = 40°$ neglecting the effect of lateral transport. The results, shown in Fig. 2 for H^+, indicate the importance of reaction (1) even for relatively small reaction rates. Because the H or D densities vary slowly in the altitude range 200 to 500 km, the effective rate coefficient for ionization production, $k_f n(H)$, is indicated as a parameter in Fig. 2 to remove uncertainties connected with the neutral atomic hydrogen or deuterium density. In fact, reaction rates as fast as $k_f \simeq 2 \times 10^{-9}$ cm^{-3} s^{-1} may be typical for reaction (1), while H and/or D densities as great as 10^5 cm^{-3} may be present in the high atmosphere of Venus[12]. The substitution for D^+ in place of H^+ in reaction (1) and equations (4) to (6) does not alter significantly the results obtained for H^+; the factor of two difference in scale height is not important over the small interval between the CO_2^+ peak and the plasmapause. Further, there is no reason to expect a strong dependence on nuclear mass for the cross-section of reaction (1) even though a small relative velocity effect will be present in k_f.

From this discussion and Fig. 2, it is seen that the existence of H or D in the Venusian atmosphere, in the presence of CO_2^+, provides a sufficient source of ionization to explain the relatively high altitude of the plasmapause (consideration of CO_2^+ alone would lead to a much lower altitude) and the relatively slow variation of electron density with altitude characteristic of light ions. Furthermore, for $\Psi < 60°$ little variation is expected in the CO_2^+ density profile due to the optical depth factor, and from (1) and (3) it follows that the altitude of the plasmapause must increase with Ψ on the dayside of the planet.

Complete calculations of the ion density about Venus, including lateral flow of ionization, are in progress. For $\Psi \gtrsim 70°$ lateral flow is responsible for removing H^+ (or D^+) from the dayside and carrying it into the regions behind the planet from whence it is probably lost to interplanetary space. The chief contribution to the lateral flow arises at 400–500 km altitude where the ion-neutral diffusion coefficient is very large, that is, small lateral pressure gradients lead to large lateral plasma flows. When viewed from behind the planet, the upper ionosphere at the terminator should appear as a ring-shaped ionization source of H^+ and/or D^+ ions with flow into the dark regions as indicated in Fig. 1. The maximum rate of vertical efflux of H^+ and/or D^+ through the atmosphere has been calculated as $\sim 10^8$ cm^{-2} s^{-1}. If this efflux is uniform over the daylit hemisphere, a total flux of 2×10^{26} ions s^{-1} would be involved. If such a large flux were to exist, only about one hour would be required to fill a tail 10,000 km long to a mean density of 300 ions s^{-1}. But this estimate neglects both H^+ loss processes and the fact that only weak lateral flows can exist in the subsolar regions due to the smallness of the lateral pressure gradient. Estimates based on more realistic, but still arbitrary, conditions indicate that the actual time required to replenish the tail with ionization is of the order of several days.

Although it would be convenient to assume that the H^+ or D^+ contained in the plasma tail is in hydrostatic equilibrium, this is undoubtedly not the case. We envisage that a fountain effect takes place in the daytime Venusian ionosphere with the electric field established through $CO_2^+ - e$ charge separation (brought about by gravity and chemical processes) acting to drive H^+ (or D^+) outwards towards the plasmapause and, through lateral pressure gradients, rearwards into the tail region. While the original source of ionization lies in the photoionization of CO_2, reaction (1) provides a process leading to the eventual loss of H^+ and/or D^+ from the planetary atmosphere.

The actual speed of lateral flow of the plasma into the tail remains uncertain. In the absence of a strongly diverging geometry or frictional effects, a subsonic flow would be appropriate. Photoelectrons from the daytime upper atmosphere, however, may also escape into the tail region and lead to an enhancement of the plasma flow energy. In this case, average ion energies of the order of 10 eV per ion might be reached at great distances from the planet.

With regard to the night time ionosphere below 500 km, H^+ and/or D^+ from the dayside can clearly contribute to the observed electron density. It is noted, however, that H^+ and/or D^+ do not react readily with CO_2 to form CO_2^+ and hence probably cannot explain the night time CO_2^+ layer. As mentioned before, either lateral transport of He^+ or some low intensity ionization source (photons or energetic particles) may be involved.

How Significant are the Sharp Peaks in the Frequency Distribution of QSO Redshifts ?

RECENT work by Plagemann, Feldman and Gribbin[1] seems to show that quasar redshifts are not intrinsic. I take no issue here with the more specific result of the Cambridge group, that there is no significant evidence for periodicity of peaks in the distribution of z (redshift). But, using the same observational material, which was taken from a list by Burbidge and Burbidge[2], I find that the well known peak at $z=0{\cdot}060$ cannot be due to chance, although there is some uncertainty of the significance level. On the other hand, the conclusion of Burbidge[3] that the peak at $z=1{\cdot}95$ is highly significant is not confirmed. It can be shown that the difference between our result and that of Burbidge is due to the interpretation of the statistics.

Before discussing the redshifts, we first consider the random distribution of points on a line. Let a line AB be divided in N equal parts (cells). We distribute s points randomly over the line so that the probability ($p=1/N$) for a point to fall in any cell is the same for all cells and points. In an actual experiment, the frequency of points will vary from cell to cell.

The probability $w(n)$ that any cell shall contain exactly n points is then given by Bernoulli's formula

$$w(n) = \frac{s\,!}{s\,!\,(s-n)\,!}\,p^n \cdot (1-p)^{s-n} \qquad (1)$$

The Poisson approximation to equation (1) is good enough for our purpose. Hence

$$w(n) = \frac{\mu^n}{n\,!}\,\mathrm{e}^{-\mu} \qquad (2)$$

where $\mu=s/N$ is the average number of points per cell.

The expected number of cells containing exactly n points is found by multiplying $w(n)$ with the total number of cells.

$$E(n) = N \cdot w(n) = N \cdot \frac{\mu^n}{n\,!}\,\mathrm{e}^{-\mu} \qquad (3)$$

The gross distribution of redshifts with $0{\cdot}02<z<2{\cdot}18$ and nine equal intervals $\Delta z=0{\cdot}24$ is shown in Fig. 1. The lack of uniformity is evident and a complete explanation is likely to involve a number of factors with observational selection as a prominent contributor. Here I make no attempt to understand Fig. 1, but only investigate the reality of the peaks in the z distribution. The lack of uniformity implies that the *a priori* probability of z is not uniform and that the analysis leading to equation (3) would be inappropriate. Fortunately this difficulty can be overcome by choosing a smooth function x of z, having a uniform gross distribution. The distribution in x, then, can be compared with the random distribution given by equation (3). No peaks will have been either destroyed or created in the smooth transformation from z to x, so the question of the significance of the peaks in the distribution of z may be answered by investigating the distribution of x. Fig. 2 shows the gross distribution of the function x that was finally decided on. The uniformity is satisfactory, and it can be shown that the variation in the gross cell frequency is of the order normally found in random distributions.

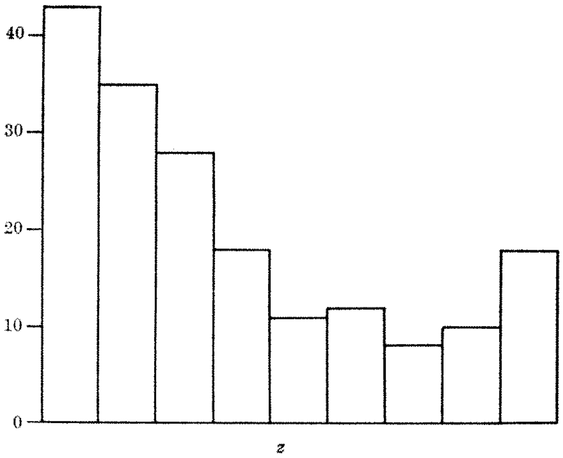

Fig. 1. Gross frequency distribution of redshifts for $0{\cdot}02<z<2{\cdot}18$ with $\Delta z=0{\cdot}24$.

Although the exact formula for x as a function of z is of no further consequence, it may be mentioned that $x(z)$ is the polynomial approximation to the number of QSOs with redshifts smaller than z, fitting exactly at $z=0$, 2/3, 4/3 and 2. The polynomial in fact is

$$x(z) = 24z^3 - 109z^2 + 208z$$

184 redshifts with $0{\cdot}024<z<2{\cdot}192$ corresponding to $5<x<185$ were analysed for the presence of peaks. The cell size chosen was $\Delta x=0{\cdot}33$, corresponding to a total number of cells $N=540$. The total number of QSOs is $s=184$ and the mean number per cell $\mu=0{\cdot}341$. The second column of Table 1 gives the observed number of cells containing exactly n QSOs. The frequency as calcu-

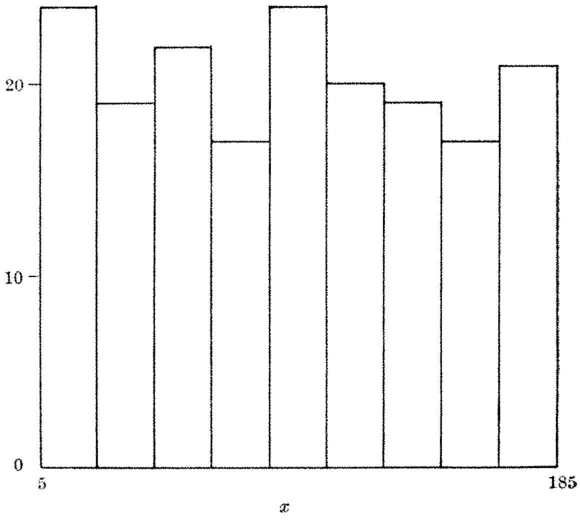

Fig. 2. Gross frequency distribution of x for $5<x<185$ with $\Delta x=20$.

lated from equation (3) is given in the third column and assumes a random distribution. The agreement is satisfactory and the differences not significant for $n=0$, 1, 2 and 3. For $n=4$ the residual is somewhat large but not likely to be significant. The single cell containing five QSOs demands attention, however. Because the expected theoretical frequency for $n=5$ and higher is only 0·01, it follows that a single count at $n=5$ or higher cannot be expected more frequently than once in a hundred experiments, on the average. This, in other words, establishes the group at $n=5$ as significant at the 1 per cent level. The peak occurs at $x=12{\cdot}3$ and the corresponding redshift is 0·060, which was already found significant by the Burbidges. No significant evidence is found for any of the other peaks which have been pronounced significant before. For instance, we find that the well known group at $z=1{\cdot}95$ causes a count at $n=4$, but the expected frequency 0·22 is too high to conclude significance.

Table 1. FREQUENCY OF CELLS CONTAINING n QSOs

n	Observed number of cells	Equation (3)
0	390	384·1
1	126	130·8
2	17	22·3
3	5	2·5
4	1	0·22
5	1	0·010

The test apparently consists of the comparison of observed with theoretical frequencies, the sensitivity increasing with diminishing theoretical frequency. I chose $\Delta x=0{\cdot}33$, but a reduction of Δx, for the purpose of increasing the sensitivity, is not practical, for $\Delta x=0{\cdot}33$ corresponds to $\Delta z=0{\cdot}002$ at $z=0{\cdot}060$, which is of the order of the accuracy of a determination of z. The theoretical frequencies at $n=5$ and larger, which are critical for the significance level, are rather sensitive to the value of μ used in equation (3). μ would have to be raised from 0·341, as used, to 0·40 to find the group at $z=0{\cdot}060$ only significant at the 5 per cent level. A corresponding error in μ seems out of the question, however.

The standard technique for testing frequency distributions for significant differences is the chi-square test. It is remarkable that this test when applied to our data shows no evidence for a significant departure from a random distribution. This is because the chi-square test cannot be applied unless the expected frequencies are larger than five. To apply the chi-square test, it would be necessary to pool the frequencies at $n=3$ and larger, with a consequent serious reduction in sensitivity at the low frequency end of the distribution[4].

In an alternative experiment, I tried the so-called "interval distribution", but found no evidence for nonrandomness. In the interval distribution, however, any non-random peak is pooled with a considerable number of random counts. The consequent high "noise level" makes this method particularly insensitive as a significance test for peaks.

None of the five objects with $z=0{\cdot}060$ seems to show any common characteristic other than redshift.

Resonance Fluorescence of the CN Free Radical

COMETARY emission spectra exhibit features of such diatomic radicals as CN, C_2, OH, CO^+, N_2^+ (ref. 1) which almost certainly arise from photon or corpuscular irradiation of polyatomic species in the comet head[2]. The emission spectra are almost certainly excited by resonance fluorescent excitation by solar photons[3]. Little laboratory work has been done on the kinetics of excitation processes of cometary spectra. In this report we record some recent work on the fluorescent excitation of CN in a static system.

Free CN was produced by gas-phase photolysis of ICN at 10^{-2} torr pressure using a 1·6 kW high pressure Xe lamp which emits a continuous spectrum between 2000 Å and 10,000 Å. The absorption spectrum of ICN exhibits a photodissociation continuum between 2000 Å and 3000 Å. The dissociation products are then I and vibrationally unexcited $\mathrm{CN}(X^2\Sigma)$ (ref. 5). In our experiments the Xe lamp not only photolysed ICN but also excited it to the $B^2\Sigma$ state from which fluorescence of the bands of the violet $B^2\Sigma$–$X^2\Sigma$ system were observed with a photoelectric scanning 0·25 m monochromator. The fluorescence signal was not strong, and, because of the operation of the Franck–Condon principle in excitation and radiation, consisted mostly of bands of the $\Delta v=0$ sequence near 3883 Å. Bands of the $\Delta v=\pm 1, \pm 2, \pm 3\ldots$ sequences were very weak. Fig. 1 is a scan of the $\Delta v=0$ sequence. The instrumental band pass was 3·3 Å and the strongest feature is the (0,0) band. The integrated signal from this sequence was used in the kinetic studies described later. Mechanisms related to the fluorescent excitation of CN are photodissociation, $\mathrm{ICN} + h\nu \rightarrow \mathrm{I} + \mathrm{CN}(X^2\Sigma, v''=0)$; fluorescent excitation, $\mathrm{CN}(X^2\Sigma) + h\nu \rightarrow \mathrm{CN}(B^2\Sigma, v'=0,1,2\ldots)$; radiation, $\mathrm{CN}(B^2\Sigma) \rightarrow \mathrm{CN}(X^2\Sigma)$; quenching, $\mathrm{CN}(B^2\Sigma)+\mathrm{ICN} \rightarrow \mathrm{CN}(X^2\Sigma)+\mathrm{ICN}$; recombination, $\mathrm{CN}+\mathrm{CN}+\mathrm{ICN} \rightarrow \mathrm{C_2N_2}+\mathrm{ICN}$; CN diffusion and loss to walls.

Recombination was not an important process at the experimental pressures. On the other hand, diffusion and quenching were major radical sinks. In the steady state the fluorescent intensity as a result of this would be

$$I_{fl} = \frac{K(E^2/D)[\mathrm{ICN}]}{1+K'[\mathrm{CN}]} \tag{1}$$

where K is a physical and geometrical proportionality constant, K' is the quenching constant, D is the diffusion coefficient, E is the lamp flux and ICN and CN are species concentrations.

Typical plots of I_{fl} against E^2 and [ICN] are displayed in Fig. 2 which confirm the phenomenological application

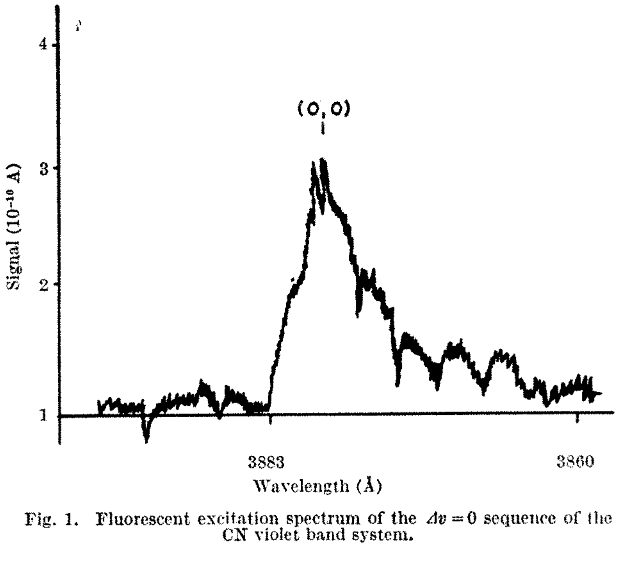

Fig. 1. Fluorescent excitation spectrum of the $\Delta v=0$ sequence of the CN violet band system.

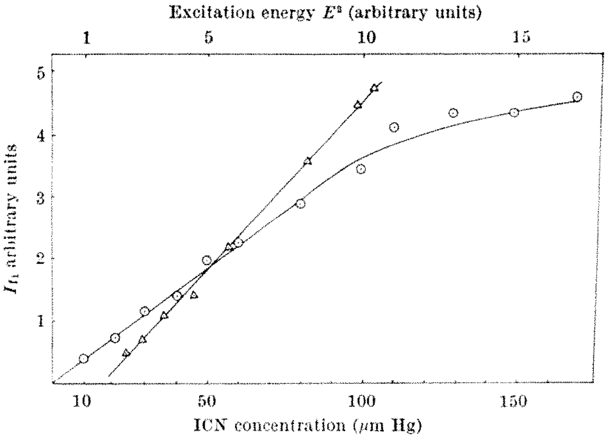

Fig. 2. Plots of intensity of the $\Delta v = 0$ sequence against [ICN] and E^2. ○, I_{f_1} versus [ICN]; △, I_{f_1} versus E^2.

of equation (1). The I_{f_1} versus [ICN] is of a characteristic Stern–Vollmer shape and from it a quenching cross-section of 90 (Å)^2 is derived, which attests to the efficiency of the quenching process.

Transient Lunar Phenomena and Electrostatic Glow Discharges

Transient lunar phenomena (TLPs) are evanescent localized glows and obscurations on the Moon; Aristarchus, Alphonsus and Schroeter's Valley are well known areas of activity[1]. The emitted light is usually described as reddish or pinkish, sometimes with a "sparkling" or "flowing" appearance[2,3]. The coloration may extend for a distance of 10 miles or more on the lunar surface, with brighter spots 2–3 miles across, and is commonly associated with veiling of the surface features. The average duration of an event is some twenty minutes, but it may persist intermittently for a few hours. No permanent alteration has been detected at the site of any TLP. These phenomena are regarded as distinct from the possible low-level general luminescence most easily detected during total lunar eclipse[1].

Middlehurst[4] has shown that TLPs are most frequent around perigee, and suggests that trapped gases are released by the accompanying tidal stress. So far only Kozyrev has succeeded in obtaining spectra, in which he identifies emission bands of molecular hydrogen, carbon and nitrogen[5–7]. He proposed that solar radiations produce ionization and excite fluorescence—but TLPs have also been reported on the dark side of the Moon[2,4]. Other suggestions include proton luminescence, thermoluminescence, shock-wave heating and emission from glowing lava or fire-fountains; but all have serious shortcomings as explanations of the phenomenon under consideration[8].

I have suggested that one mechanism for the formation of lunar craters was fluidization during degassing at an early stage in the evolution of the solar system[9]. A slight continuous evolution of gas is expected to persist to the present time, some accumulating in fissures and cavities until released by the tidal mechanism. In my model experiments I noted that tapping the apparatus could temporarily reactivate a few of the smaller craterlets. Kozyrev's spectra, and the absence of carbonates and hydrates in the returned lunar samples, suggest that the escaping gases are those retained by the Jovian planets—hydrogen, noble gases, methane and ammonia—rather than carbon dioxide and water vapour.

The release of trapped gases, and their rapid expansion, must lead to disturbance of the fine dust covering the lunar surface. Now it has long been known[10] that movement and dispersion of finely divided material result in separation of charge and the generation of considerable electrostatic potentials. Faraday[11], and later Rudge[12] and others, showed that a positive charge was left on the plate of an electroscope if sand was blown from it. I have found charges of the same sign to be produced by the dispersion of powdered samples of basalt, olivine, ilmenite, limonite, ash-flow deposits and chondritic meteorites.

Detailed studies have proved that both positively and negatively charged particles are present in a dust cloud, but generation in heterogeneous systems (especially when conducting surfaces are present) leaves a net excess of charge of one sign on the cloud. Dissimilar particles in heterogeneous clouds are often oppositely charged, as, for example, the classical red lead and sulphur mixture for the development of Lichtenberg figures. Particles moving in nominally homogeneous systems can also become strongly charged, but the overall net charge of the cloud remains close to zero[13,14].

It is apparent that separation of the particulate components of a heterogeneous cloud, for example, by elutriation or gravitational settling, could produce oppositely charged regions within it. Regional charge separation may occur even in homogeneous clouds if there is a correlation between the size of a particle (including aerosol material) and the sign of its preferred charge.

The generation of considerable electrostatic potentials in fluidized beds has been reported[15,16]. On a larger scale, many industrial accidents have been traced to the movement of dust-laden air generating potential differences sufficient to promote an incendiary spark[17]. Natural dust storms cause violent disturbances of the terrestrial electric field[18]. Lightning displays within the ash cloud from volcanic eruptions[19,20] (including nuées ardentes[21]) have been described by observers from Pliny[22] onwards.

Situations giving rise to spark discharges occur at pressures around atmospheric, but at reduced pressures charge equalization is facilitated by glow discharge[23]. Experiments indicate this mechanism to be most important in the pressure range 10–0·1 torr (refs. 24 and 25). Studies of the light accompanying the generation of frictional electricity *in vacuo* were begun by Hauksbee[26] in 1704 and continued by others[19], but little has been added since.

I therefore propose that the obscuration associated with TLPs is due to fine dust raised by lunar degassing. In certain areas, sporadic escape of accumulated gas occurs through channels opened by tidal stress. Movement and separation of the heterogeneous particles result in separation of charge and, occasionally, sufficient potential difference is built up to promote glow discharge through the transient gas phase[27]. The predominance of hydrogen in the discharge gives the reddish tint.

Triboelectric charging and glow discharge synthesis and polymerization could have been especially significant in the early stages of planetary evolution, independent of the mechanism for the production of cratered surfaces. It also seems worthwhile to look for electric fields and glow discharges generated by the dust storms believed to occur on Mars.

Dielectric and Anelastic Effects in Inorganic Glasses

THE dielectric properties of inorganic glasses in alternating fields are usually described in terms of the complex dielectric constant

$$\varepsilon^* = \varepsilon' - i\varepsilon'',$$

where ε' is the real part and ε'' is the imaginary part or dielectric loss. The values of ε' and ε'' are usually obtained from measurements of the capacitance and resistance of a disk shaped specimen fitted with metal electrodes. If the value of C_p/C_o (where C_p is the equivalent parallel capacitance and C_o is the capacitance with a vacuum between the electrodes) is plotted against log ω (where ω is the angular frequency), then, in the audiofrequency range and with blocking electrodes (for example, gold or platinum), a curve of the form shown in Fig. 1 is usually obtained with glasses containing appreciable amounts of alkali-metal ions.

The high values for the capacitance at low frequencies are the result of electrode polarization effects[1,2]. At higher frequencies, the curve resembles that which would be expected for a Debye relaxation process and in this region C_p/C_o is taken to represent ε', the real part of the complex dielectric constant. In the absence of electrode polarization effects, it is assumed that at zero frequency, ε' will correspond to the static dielectric constant ε_s.

The dielectric losses in the audiofrequency region are generally considered to be due to (*a*) "conduction" losses and (*b*) "dipole relaxation" losses[3]. To separate the latter from the "conduction" losses, the d.c. conductivity is subtracted from the a.c. conductivity when calculating the value of ε'' corresponding to the "dipole relaxation" process[4,5] so that

$$\varepsilon''(\omega) = \frac{G_{ac} - G_{dc}}{\omega C_o}$$

where G_{ac} is the equivalent parallel a.c. conductance and G_{dc} is the d.c. conductance. (To be strictly accurate, the "conduction" losses with blocking electrodes would perhaps be better regarded as a form of dielectric loss associated with space-charge polarization at the electrodes and arising from the movement of charge carriers through the bulk of the specimen.) When plotted against log ω, the values of ε'' for the "dipole relaxation" loss show a dispersion similar to, but broader than, that which would be expected from a simple Debye model (Fig. 1).

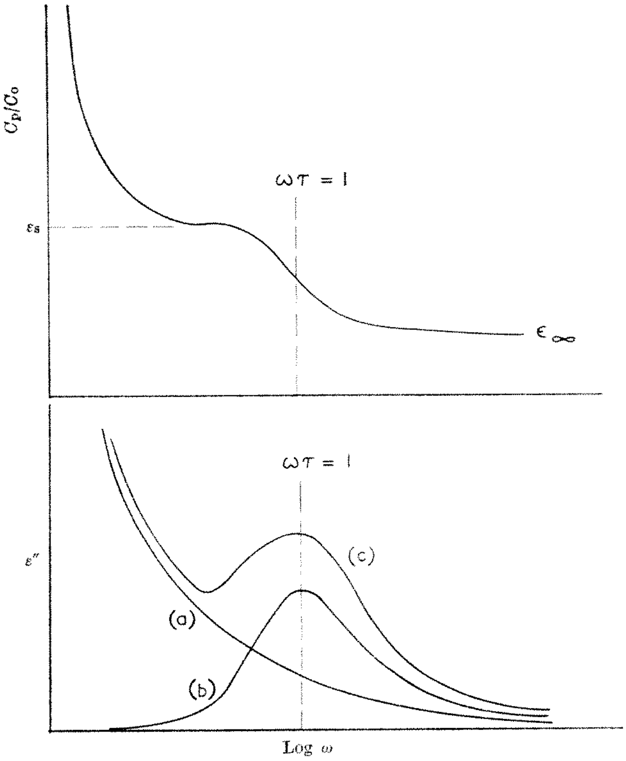

Fig. 1. Dielectric properties of silicate glasses containing alkali-metal ions. (*a*) "Conduction" loss; (*b*) "dipole relaxation" loss; (*c*) total dielectric loss.

Although the dielectric properties of glasses have been studied extensively, little progress has been made in the identification of the nature of the "dipole relaxation" losses. These were attributed by Stevels[3] to the movement of alkali-metal ions through small distances and over low potential energy barriers. This would lead to a polarization of the glass which would follow the external a.c. field with a relaxation time determined by the time needed for the ions to acquire sufficient energy to pass over the potential barriers. Taylor[6], however, showed that the value of the activation energy for this relaxation process was close to that for the d.c. conductivity. Although this supported the view that the movement of alkali-metal ions was responsible both for the d.c. conductivity and the relaxation effect, it meant that it was more difficult to distinguish between the two processes. Charles[7] suggested that around each non-bridging oxygen there was a number of equivalent sites available for an alkali-metal ion. Polarization could then occur through movement of an alkali-metal ion from one site to another. This could be a direct movement or could take place indirectly as part of the conduction process. The dielectric behaviour could then be interpreted using Fröhlich's model[8] in which charges in a dielectric may each occupy one of two equilibrium positions. There are, however, two difficulties with this theory. The first is that it is difficult to explain why, for example, the partial replacement of Na_2O by CaO in a sodium silicate glass does not lead to a reduction in the value of ε_s[6,9]. The second is that when we take the expressions derived by

Charles for τ the relaxation time, σ the conductivity and $(\varepsilon_s - \varepsilon_\infty)\varepsilon_0$, we find that, if we neglect a correction factor for a distribution of jump frequencies,

$$\frac{\tau\sigma}{(\varepsilon_s - \varepsilon_\infty)\varepsilon_0} = \frac{1}{6}\left(\frac{r}{b}\right)^2$$

where r is the average "jump distance" for conductivity, b is the effective jump distance in the polarization process, ε_∞ is the high-frequency dielectric constant and ε_0 is the permittivity of free space. Experimentally, with silicate glasses, the factor on the left-hand side of this equation does not differ greatly from 1·3 even for glasses of very different alkali-metal ion content[9], so we have the relationship $b \simeq 0{\cdot}4\ r$. This requirement is not easily correlated with physically plausible structures for glasses of varying alkali-metal oxide content.

These difficulties with existing theories and the close inter-relationship between the conduction and relaxation processes suggest the possibility of a general reinterpretation of the low-frequency dielectric behaviour of inorganic glasses in terms of a Maxwell relaxation process.

For a homogeneous conducting dielectric Maxwell[10] showed that the relaxation time for the conduction process is given by

$$\tau_M = \frac{\varepsilon_s\ \varepsilon_0}{\sigma}$$

where σ is the conductivity. This relationship is derived from the Poisson equation $\nabla . \nabla\Psi = -\rho/\varepsilon_s\ \varepsilon_0$ and the continuity equation

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = \sigma\nabla\ .\nabla\Psi$$

where Ψ is the potential and ρ is the charge density.

It follows that if we have a disturbance in potential in a dielectric through, for example, the rotation of a dipole or the displacement of a bound charge, then there will be changes in the charge density in the surrounding medium which will die away exponentially with a relaxation time τ_M.

Table 1. LOW-FREQUENCY DIELECTRIC PROPERTIES OF SOME INORGANIC GLASSES

Glass composition (mole per cent)	Temperature (°C)	ε_s	$1/\sigma$ (Ω cm)	$\tau_M = \varepsilon_s\ \varepsilon_0/\sigma$ (s)	τ_{obs} (s)	Ref.
18 Na_2O, 10 CaO, 72 SiO_2	121 159	27·5 25·7	$6{\cdot}3\times10^8$ $7{\cdot}1\times10^7$	$1{\cdot}5\times10^{-3}$ $1{\cdot}6\times10^{-4}$	$1{\cdot}2\times10^{-3}$ $1{\cdot}0\times10^{-4}$	6
43·6 Fe_2O_3, 11·4 FeO, 45·0 P_2O_5	22·8 76·2	18·5 17·4	$1{\cdot}2\times10^{10}$ $5{\cdot}6\times10^8$	$2{\cdot}0\times10^{-2}$ $8{\cdot}6\times10^{-4}$	$1{\cdot}6\times10^{-2}$ $5{\cdot}7\times10^{-4}$	11
Vitreous silica containing 0·04 p.p.m. sodium and approx. 0·1 to 1·0 per cent water	655	7·3	$2{\cdot}5\times10^8$	$1{\cdot}6\times10^{-4}$	$1{\cdot}1\times10^{-4}$	12
17·5 Na_2O, 9·6 CaO, 0·5 MnO, 0·4 ZnO, 1·4 Al_2O_3, 70·6 SiO_2	150	28	$8{\cdot}5\times10^7$	$2{\cdot}1\times10^{-4}$	$1{\cdot}7\times10^{-4}$	2

If we examine the experimental results we find that for many inorganic glasses the observed relaxation time (τ_{obs}) for the "dipole relaxation" loss does not differ greatly from $\tau_M = \varepsilon_s\ \varepsilon_0/\sigma$. Some values for glasses of very different structure are given in Table 1. This approximate agreement suggests that in these systems the relaxation time is determined by a flow of charge and a Maxwell relaxation mechanism. It follows that the entity in the glass structure responsible for polarization may, in the absence of electrical interactions with the surrounding medium, be readily displaced or rotated.

In the case of the silicate glasses containing appreciable amounts of alkali-metal ion, it is suggested that the primary polarization process is a displacement of non-bridging oxygen ions. At low frequencies there is a simultaneous movement and redistribution of the surrounding alkali-metal ion charge carriers. At higher frequencies, however, when $\omega > 1/\tau_M$ appreciable displacement of the non-bridging oxygens is prevented by the retarding force due to the slow movement of the charge carriers. This interpretation is also supported by the relationship between the static dielectric constant and the non-bridging oxygen content which is apparent from the work of Taylor[6] and Barton[9].

In the iron-phosphate glass studied by Hansen and Splann[11] the charge carriers are electrons migrating between Fe^{3+} and Fe^{2+} ions. Again, there is the same approximate agreement between τ_{obs} and $\varepsilon_s\ \varepsilon_0/\sigma$, so that it would seem likely that, in this case too, the high value for the dielectric constant at low frequencies is also due to the displacement of non-bridging oxygens. In the case of vitreous silica, Owen and Douglas[12] showed that ε_s depended on the water content of the silica so that the low frequency polarization can probably be ascribed to the movement of OH groups. At a temperature of 655° C, however, the silica has an appreciable conductivity and the relaxation time is determined by the conductivity.

For silicate glasses containing alkali-metal ions, Owen[13,14] suggested that the polarization mechanism might be similar to that underlying the Debye–Falkenhagen effect in electrolyte solutions. The mechanism suggested here does in fact show similarities, but there are important differences; the non-bridging oxygens in the glasses are here considered to be non-diffusible and, although they can be regarded as being surrounded by an atmosphere of charge carriers, the conduction mechanism in the glass is very different from that in an aqueous electrolyte solution.

When we consider the corresponding anelastic effects it would appear that two types of relaxation process involving the migration of alkali-metal ion charge carriers might be expected. The first would correspond to the Maxwell relaxation process described here and would involve the displacement of non-bridging oxygens or other polar groups and a local flow of charge carriers. The relaxation time and activation energy would again be determined by the conductivity. This process can be considered to be responsible for the low-temperature loss peak observed in internal friction experiments using torsion pendulum techniques. With glasses containing alkali-metal oxides, these peaks have previously been ascribed to "stress-induced migration" of alkali-metal ions. With the iron phosphate glass, a similar mechanical loss peak was observed with longitudinal oscillations and frequencies of 50 and 150 kHz and attributed to the stress-induced movement of electrons[15]. In this case, too, it would seem likely that the primary process may have been the displacement of non-bridging oxygens with a relaxation time and activation energy determined by the electronic conductivity.

The second type of mechanical relaxation process involving the migration of alkali-metal ions would involve their diffusion through the bulk of the specimen and, with appropriate stress systems, changes in charge concentration at or near the surfaces. A loss process of this type would be expected in flexural vibration experiments and would show similarities with the space-charge polarization effects observed in dielectric experiments. The losses in this case would be due to stress-induced migration, but the relaxation time (as with the space-charge polarization effects) would be determined by the conductivity and geometry of the specimen.

The interpretation of dielectric effects in aluminosilicate glasses and their significance in the study of glass structure and phase-separation processes will be discussed in a future publication.

Charge Moving with the Speed of Light

I HAVE recently shown[1] that Maxwell's equations admit solutions for charge moving in a straight line with the speed of light c. The accompanying electromagnetic field F_{ik} is that of a plane-fronted wave, that is, one whose front is plane and whose amplitude varies over the front. The source is a null four-current, J^i, satisfying

$$g_{ik}\, J^i\, J^k = 0 \qquad (1)$$

where g_{ik} is the metric tensor of flat space-time. The charge is localized in a world-tube about the z-axis of coordinates; all appropriate conditions are satisfied at the boundary of the tube, and the F_{ik} are everywhere continuous. Although charge is radiated away from the source, conservation of charge is of course automatically ensured by Maxwell's equations. The solutions have precise analogues in Einstein–Maxwell theory[2].

These solutions are perhaps not entirely conclusive because the streams of charge originate at infinity. I now wish to point out that solutions exist for null currents emitted from a point.

It is convenient to use the metric of flat space-time in null polar coordinates

$$ds^2 = -r^2(d\theta^2 + \sin^2\theta d\varphi^2) + 2\, du\, dr + du^2 \qquad (2)$$

where $u = t - r$ is the retarded time, and where we number the coordinates

$$x^1 = r,\ x^2 = \theta,\ x^3 = \varphi,\ x^4 = u$$

We choose unrationalized Gaussian units but with the unit of time chosen so that $c = 1$, and take the vector potential as

$$A_i = A\ \delta_i^4$$

where A is a function of θ, φ and u only; then the only non-zero components of F_{ik} are

$$F_{42} = -F_{24} = A_\theta,\ F_{43} = -F_{34} = A_\varphi$$

the subscripts θ and φ meaning differentiation with respect to θ and φ. The cartesian components of F_{ik} are proportional to r^{-1}, as expected for a wave field.

The electromagnetic energy tensor is

$$E^{ik} = r^{-2}\, (A_\theta{}^2 + A_\varphi{}^2 \operatorname{cosec}^2\theta)\ \delta^i_1\ \delta^k_1 \qquad (3)$$

and the current, obtained from

$$4\pi J^i = (-g)^{-\frac{1}{2}}\ \frac{\partial}{\partial x^k}\ [(-g)^{\frac{1}{2}}\ F^{ik}]$$

(g being the determinant of g_{ik}) is

$$J^i = -(4\pi r^2)^{-1}\ \nabla^2 A\ \ \delta^i_1 \qquad (4)$$

where

$$\nabla^2 A = A_{\theta\theta} + A_\theta \cot\theta + A_{\varphi\varphi} \operatorname{cosec}^2\theta$$

is the laplacian of A on the unit sphere. J^i satisfies (1) and is therefore a null current. Provided that, at each world-point, charge of only one sign is present[1], J^i represents charge moving radially away from (or towards) the origin with speed c. We could write (3) as

$$E^{ik} = v^i\, v^k \qquad (5)$$

where

$$v^i = r^{-1}\, (A_\theta{}^2 + A_\varphi{}^2 \operatorname{cosec}^2\theta)^{\frac{1}{2}}\ \delta^i_1$$

is a null vector parallel to J^i. From (5) it follows that the charge is accompanied by the field energy, also travelling radially with the speed of light. Both charge and energy automatically satisfy the usual conservation laws. The ponderomotive face, $F_{ik}\ J^k$ vanishes, which means that the charge moves freely, and no external force is necessary to maintain the current.

In regions free of current we have from (4)

$$\nabla^2 A = 0$$

and it is known that this equation has no solution continuous over the entire sphere (other than A = constant). Hence for fields of this type the current must be non-zero for some range of θ, φ.

It appeared in ref. 1 that a pulse of charge of one sign emitted at infinity and moving in a straight line with speed c is always accompanied by infinite field energy. This result now seems to have been due to the artificiality of the model used, because from equation (3) the integrated field energy of a pulse of spherical null current of finite duration u_1 to u_2, namely,

$$\int_0^{2\pi}\int_0^{\pi}\int_{u_1}^{u_2} (A_\theta{}^2 \sin\theta + A_\varphi{}^2 \operatorname{cosec}\theta)\ du\ d\theta d\varphi$$

is finite for suitable functions A. This removes a possible objection to null currents.

Charged particles moving with speed c have not yet been identified in cloud chambers, and the idea that charge, like energy, might be radiated through empty space is perhaps somewhat revolutionary. Nevertheless, it is clearly permitted by Maxwell's equations, and these have hitherto proved a sound guide to experience within their terms of reference. It is therefore suggested that some experiments be carried out to look for the phenomenon. The theory does not tell us how to generate a null current, but possibly one might arise when a suitable pulse of light is generated at a charged source.

Electron Spin Resonance of Hydrogen Atoms in a Free-burning Flame at Atmospheric Pressure

STUDIES of the kinetic behaviour of hydrogen atoms in atmospheric flames[1] usually involve detection of hydrogen atoms by indirect methods, but direct detection actually in the flame itself has not been reported. We report here the observation of hydrogen atoms in free-burning flames at atmospheric pressure by electron spin resonance.

Previous measurements[2] of hydrogen atoms in gas-phase combustion systems by electron spin resonance (ESR) have been made at low pressures (about 10 torr or less). With one exception[3], the reaction has been initiated and sustained by passing the gas mixture through a heated tube (about 850 K) located either immediately before or inside the sample cavity of the ESR spectrometer. Westenberg and Fristrom[3] used a pin-hole probe to sample the gas from a flame burning at 0·1 atmosphere pressure and detected hydrogen atoms by ESR in the low pressure (0·1 torr) region downstream of the pin-hole. Similarly, ESR studies[4,5] of other gas-phase reactions of hydrogen atoms, produced by passing molecular hydrogen through a radiofrequency or microwave discharge, have been carried out at relatively low total pressures.

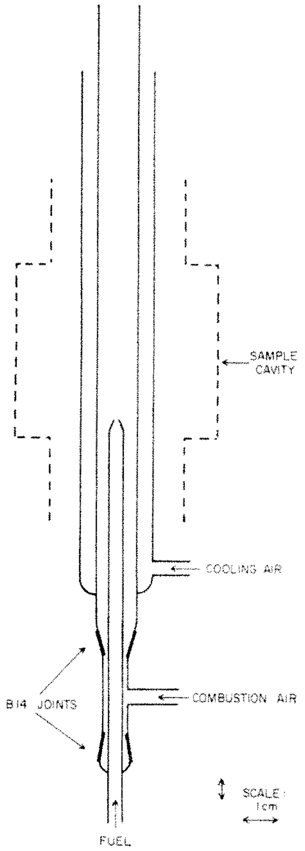

Fig. 1. Cross-section of burner.

It is usually assumed that the spectral lines of the hydrogen atom would be so severely pressure-broadened that they could not be detected at high pressures. But it has been shown[6] that when hydrogen atoms are produced by thermal dissociation of molecular hydrogen on a heated tungsten filament, there is virtually no increase in the line width at total pressures up to 500 torr. The main source of broadening in a flame at atmospheric pressure may therefore be interaction with other paramagnetic species, in particular with molecular oxygen. The effect of the temperature of the flame (about 2,100 K) on the Boltzmann distribution between the magnetic levels will cause about a seven-fold decrease in the intensity of the spectral lines compared with that at room temperature. But the hydrogen atom concentration in the reaction zone of a hydrogen/air flame is 10^{16}–10^{17} atoms/cm^3 (ref. 1), which is well above the limit of detectability by ESR for hydrogen atoms in the gas phase.

A simple burner (Fig. 1) was made to fit in a wide-access sample cavity of a Varian spectrometer. A stable flame, a few centimetres high, could be maintained on the central tube over a wide range of fuel/air ratios. (Hydrogen flow rates through the central tube were in the range 100–600 cm^3/min, and the air flow rates between 20 and 2,000 cm^3/min.)

With this burner, hydrogen atoms were easily detected in a hydrogen/air diffusion flame burning at atmospheric pressure. For a fuel-rich flame, the width of individual hyperfine lines was about 0·13–0·15 oersted, which is not more than twice the width observed (with similar operating conditions of the spectrometer) for hydrogen atoms in a low pressure flow system. For an oxygen-rich flame, however, the line width was about 2·5 oersted. The marked increase in line width occurred in a very narrow range of fuel/air ratios close to the stoichiometric value. A rough estimate of the relative intensities of the spectral lines showed that there was no abrupt change in the concentration of hydrogen atoms accompanying the change in line width. These observations suggest that the main cause of line broadening was indeed interaction with molecular oxygen.

The system is not ideally suited to measuring the absolute concentration of hydrogen atoms in the flame, but the total concentration of hydrogen atoms in a small flame (0·4 cm diameter × 0·8 cm high) was found to be about $0 \cdot 4 \times 10^{15}$ atoms/cm^3. In view of the assumptions that have to be made in the calculation, this value agrees reasonably well with that of 2×10^{15} atoms/cm^3, estimated from existing values[1] for the concentration profiles in a premixed flat flame.

Hydrogen atoms have also been detected in a premixed hydrogen/air flame, on the same burner. The line width showed the same dependence on the fuel/air ratio as that for the diffusion flame, and increased abruptly from 0·15 to 2·5 oersted as the fuel/air ratio was decreased through the stoichiometric value. Hydrogen atoms were also observed in methane/air and propane/air diffusion flames, but in both flames the line width was larger (0·8 oersted) for all values of the fuel/air ratio and showed no change across the stoichiometric point. The larger line width may be caused by interaction with elementary carbon species, such as C_2 and C_3, or even with soot particles.

The potential applications of this technique to kinetic and mechanistic studies in premixed and diffusion flames are currently being investigated.

Catalytic Inhibition by Adsorbed Oxygen

THE effects of adsorbed oxygen on the properties of an initially clean tungsten surface have been investigated in detail by a wide range of experimental techniques. The changes in both the field emission microscope and the field ion microscope images of tungsten tips have been

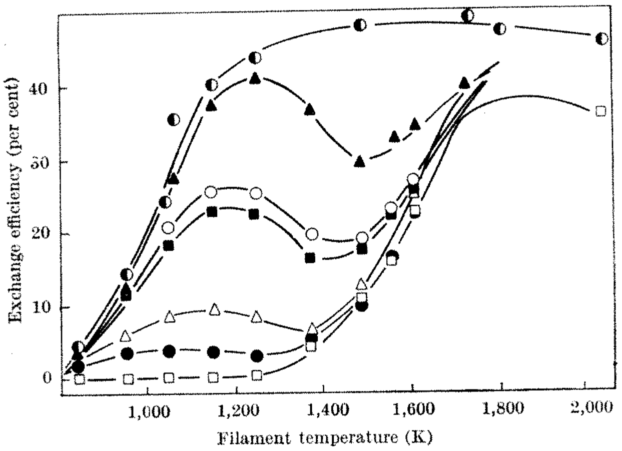

Fig. 1. The effect of adsorbed oxygen on the catalytic activity of tungsten for carbon monoxide isotope equilibration. Oxygen uptakes in units of 10^{14} atom/cm^2: ◐, 0; ▲, 0·51; ○, 0·97; ■, 1·7; △, 5·1; ●, 5·9; □, 8·3.

reported[1,2], as have the changes in the low energy electron diffraction patterns of some oriented tungsten ribbons[3,4]. The adsorption and desorption phenomena which occur when tungsten at high temperatures reacts with oxygen have also been studied extensively[5-7]. It is generally agreed that oxygen adsorbed on tungsten can be removed by heating *in vacuo* but that the desorbing species is never molecular oxygen. Measurements of the adsorption kinetics using the "flash filament" technique reached the expected conclusion that this is a highly reactive gas/metal surface system[8].

An alternative technique for studying the effect of adsorption on the properties of a surface is to monitor the change in chemical reactivity when adsorption takes place. A suitable measure of the reactivity of a tungsten surface is its efficiency as a catalyst for the equilibration of mixtures of isotopes of simple gases. By incorporating a mass-spectrometer as part of the reaction chamber, reliable and accurate measurements of the changes in the reactivity of the surface can be made. This technique has been used to study the effect of increasing oxygen adsorption on the catalytic efficiency of tungsten for the reaction $^{28}N_2 + {}^{30}N_2 = 2\ {}^{29}N_2$ (ref. 9). The complete correlation between the reduction in catalytic activity and the diminution in chemisorptive uptake of nitrogen as the oxygen coverage was increased suggested that the catalytic activity of this well annealed tungsten filament was distributed over much of the surface and was not concentrated at special sites of high activity.

Interesting new possibilities may arise when the reaction chosen to monitor the effect of the adsorbed oxygen itself involves the exchange of an oxygen atom. This situation occurs with the reaction $^{12}C^{18}O + {}^{13}C^{16}O = {}^{12}C^{16}O + {}^{13}C^{18}O$, which is here reported. The interaction of a single carbon monoxide isotope with an oxygenated tungsten surface has been investigated previously by flash filament[10] and oxygen isotope exchange experiments[11]. It is also known qualitatively that a hot tungsten surface is a very efficient catalyst for the carbon monoxide isotope equilibration reaction[12].

The ultra-high-vacuum apparatus of volume 2 l., and the tungsten wire of length 20·7 cm and geometric area 0·87 cm^2, have been used for a series of experiments in which the interaction of tungsten with a variety of gaseous environments has been investigated[9,11,13]. Before the first experiments were started the filament was freed from carbonaceous impurities by prolonged heating in oxygen, followed by removal of the resulting oxygen layer by heating to about 2,070 K *in vacuo*[13]. After this treatment the reactivity of the filament towards nitrogen, both in chemisorption[13] and in catalysis[9], was typical of a polycrystalline tungsten wire. For this filament, therefore, as for some tungsten ribbons recently studied[4], heating to 2,070 K *in vacuo* for a few minutes is sufficient to remove a layer of adsorbed oxygen. It is desirable to have a consistently maintained heating cycle for a tungsten wire, because its reactivity may depend on the temperature to which it is heated before an adsorption is started[8], and this filament was cleaned by heating to 2,070 K before each experiment was started. One feature of this series of experiments[9,11,13] has been the frequent oxygenation of the surface by reaction with nitrous oxide. This reaction has provided a convenient method of maintaining the surface in a carbon-free condition after the initial cleaning process, a particularly important consideration in carbon monoxide isotope exchange experiments.

Two bakable metal valves joining the UHV chamber to two gas storage volumes served as variable leaks for the admission of gases. A similar valve connecting the chamber to the pump allowed a suitable rate of flow of gas over the filament to be chosen. The isotopic composition of the gas was determined with an omegatron radiofrequency mass spectrometer which formed an integral part of the UHV system. Oxygenation of the filament to any desired coverage was carried out by "titrating" in the appropriate amount of nitrous oxide from the storage volume and removing the adsorbed nitrogen by heating the filament briefly to 1,300 K. The results of earlier experiments have shown that this sequence can provide a reproducible, known uptake of oxygen[9,13]. The highest coverages were obtained by allowing a further period of adsorption of nitrous oxide after the removal of the surface nitrogen. In this stage only the oxygen atom of the nitrous oxide was adsorbed and the nitrogen appeared in the gas phase. The $^{13}C^{16}O$ was prepared by the reduction of $^{13}C^{16}O_2$ liberated from Ba $^{13}CO_3$ (ref. 14) and the $^{12}C^{18}O$ by the oxidation of "analar" sugar charcoal with $^{18}O_2$. A mixture of approximately equal parts of $^{13}C^{16}O$ and $^{12}C^{18}O$ was made up in an ancillary gas preparation apparatus and kept in one of the gas-storage volumes. No appreciable equilibration of the mixture occurred during the period of the experiments.

The catalysis of the equilibration of the mixture of isotopes by the clean tungsten wire was measured by streaming the mixture through the apparatus and recording the mass spectrometer peak heights of $^{12}C^{16}O$, $^{13}C^{16}O$, $^{12}C^{18}O$ and $^{13}C^{18}O$. The total pressure of carbon monoxide was about 6×10^{-8} torr. The filament temperature was increased in steps and the isotopic composition was recorded at each temperature. The onset of catalysis was marked by an increase in $^{12}C^{16}O$ and $^{13}C^{18}O$ at the expense of $^{12}C^{18}O$ and $^{13}C^{16}O$. Catalysis by the oxygenated filament was studied similarly. The filament was cleaned after each set of experiments at a particular oxygen coverage. The oxygenation process covers the surface with ^{16}O which

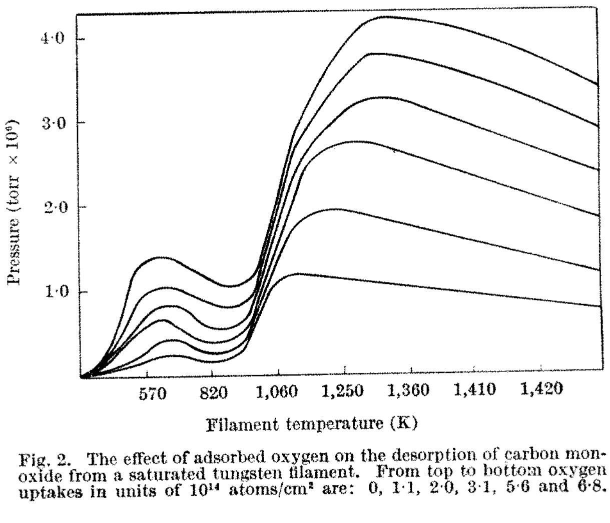

Fig. 2. The effect of adsorbed oxygen on the desorption of carbon monoxide from a saturated tungsten filament. From top to bottom oxygen uptakes in units of 10^{14} atoms/cm^2 are: 0, 1·1, 2·0, 3·1, 5·6 and 6·8.

can itself react with $C^{18}O$ (ref. 11). The effect of this reaction on the composition of the mixture of isotopes was to give an enhanced partial pressure of $^{12}C^{16}O$ when the filament was first heated above about 840 K. The surface, however, eventually achieved the same $^{16}O/^{18}O$ ratio as the gas phase and when this had happened there was detailed atomic balance between the adsorption and the desorption of the oxygen isotopes. It was then possible to measure the effect of the adsorbed oxygen on the catalytic efficiency of the tungsten.

The calculation of the catalytic efficiency of the tungsten requires a knowledge of the pumping constant of the aperture of the exit valve. This was therefore measured, but with nitrous oxide, which gives results concordant with nitrogen[13] rather than with carbon monoxide, which forms a "surface phase"[15]. A suitable pressure of nitrous oxide was established in the UHV chamber and the mass spectrometer was tuned to the peak at mass 44. The first order decay of this peak when the gas admittance valve was shut rapidly was recorded and the pumping constant was calculated. A small correction for the pumping effect of the mass spectrometer filament was made.

In a separate series of experiments the effect of pre-adsorbed oxygen on the chemisorptive uptake of carbon monoxide was measured. The filament, with a chosen coverage of oxygen, was allowed to saturate with carbon monoxide at an equilibrium pressure of 3×10^{-8} torr. The pressure burst when the filament was "flashed" to 2,000 K was recorded with an ionization gauge and fast writing recorder. The manufacturer's value for the sensitivity of the ionization gauge was used to calculate the uptakes. There may be considerable error in this number which would introduce a systematic error into the calculated uptakes. The catalytic efficiency, E, of the tungsten filament for the isotope equilibration reaction can be calculated from the mass spectrometer peak heights, using the previously derived formula[17]:

$$E = kcpV({}^{31}X - {}^{31}X_0)/AZ({}^{29}X\,{}^{30}X - {}^{28}X\,{}^{31}X)$$

In this equation k is the pumping constant of the aperture of the exit valve, c is a constant which relates the number density of molecules to the pressure, p is the pressure, V is the volume of the apparatus, A is the area of the filament and Z is the rate of collision of molecules at a pressure of 1 torr with one square cm of surface. ${}^{i}X$ is the mole fraction of any isotope when equilibration is occurring, ${}^{31}X_0$ is the mole fraction of $^{13}C^{18}O$ when the filament is cold and inactive. The dependence of E on filament temperature and on oxygen coverage is shown in Fig. 1. A consequence of the high maximum catalytic efficiency of the filament, about 50 per cent, is that the gas approached to within about 20 per cent of its equilibrium composition when the clean filament was above 1,400 K. The form of the equation is such that in these circumstances any uncertainty in the peak heights results in a much greater uncertainty in the calculated efficiency. There was therefore a random error in E which increased to about ±20 per cent in the high temperature, plateau region.

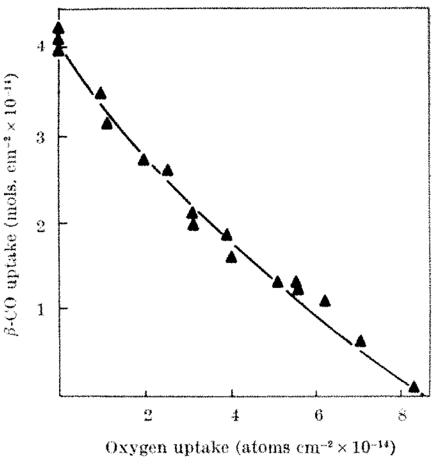

Fig. 3. The effect of adsorbed oxygen on the uptake of β-CO by tungsten.

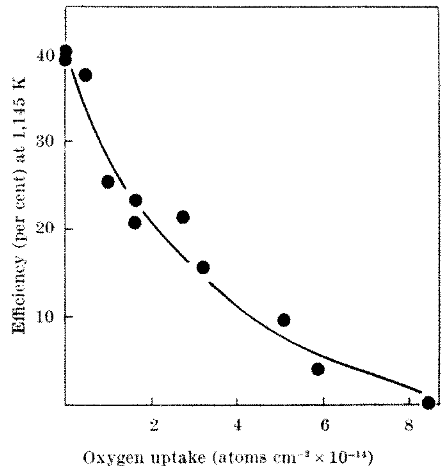

Fig. 4. The effect of adsorbed oxygen on the catalytic efficiency at 1,145 K.

The pressure record when the filament saturated with carbon monoxide was flashed to 2,000 K is shown in Fig. 2. It has the normal, well separated desorption regions which have been called α and β[18]. The unresolved fine structure in the higher temperature, β-peak, can be shown to consist of three sub-peaks when a heating programme designed for optimum resolution is used[19]. The decreased pressure bursts when some oxygen was adsorbed before saturation with carbon monoxide are also shown in Fig. 2.

It can be seen from Fig. 1 that the equilibration reaction did not start until the filament reached a temperature well above that at which the lower temperature, α-state had desorbed. The effect of adsorbed oxygen on the uptake of β-CO alone, therefore, is as shown in Fig. 3. In Fig. 4 the effect of the oxygen on the catalytic efficiency at 1,145 K is shown.

The temperature dependence of the efficiency of the clean tungsten filament for carbon monoxide isotope equilibration was very similar indeed to the temperature dependence of a clean molybdenum filament[17]. The similarity extends to the values of the efficiencies in the high-temperature, plateau regions which were the same for both metals. The absence of a contribution to equilibration from the lower temperature α-state and the onset of equilibration above a filament temperature of about 800 K are in complete agreement with an earlier, kinetic study of this reaction[12]. If it is correct to assume that every collision in which gas is absorbed also leads to full isotope equilibration on the surface, the measured exchange efficiency can be equated with the sticking probability. The equilibrium surface coverage in the high temperature plateau region was low, so that the calculated sticking probability, 0·5, was that of an essentially clean surface. This value agrees well with the initial sticking probability of 0·4 at 1,200 K measured by the flash filament technique[20]. The constancy of sticking probability over a 600 K temperature range above 1,400 K is typical of many systems at high temperatures[17].

The correlation, which was observed here, between the filament temperature at which isotope equilibration first became measurable and the temperature at which chemisorbed gas was desorbed has been taken, in other similar situations, as evidence that the equilibration reaction took place by adsorption into and desorption from this chemisorbed state[17]. Carbon monoxide is generally believed to be adsorbed without dissociation[18] and it has therefore been suggested that the chemisorbed molecules form a bimolecular, head-to-tail transition state complex[12]. The failure of the α-state to participate in equilibration may then be due to the relatively small perturbation of the C—O bond associated with the formation of a weak carbon to surface bond[17].

The most important effects of the pre-adsorbed oxygen were the smooth reduction in both the catalytic efficiency and in the uptake of β-CO as the oxygen coverage increased. As a comparison of Figs. 3 and 4 shows, however, the equilibration curve is noticeably more concave towards the abscissa than the uptake curve. This observation can be interpreted in the light of a theoretical treatment of the effect of a catalytic poison, which occupies single sites, on the reactivity of a uniform surface[21]. It was shown that, for a first order reaction, when the surface is almost bare, the shape of the poisoning curve depends on the number of surface sites required by the reactant. As the site requirement increases, so the curve becomes increasingly concave. The mechanism suggested for the carbon monoxide isotope equilibrium reaction involves the formation of a four-centre transition state complex on the surface[12]. The site requirement for such a mechanism would be expected to lead to a pronounced concavity of the poisoning curve, in agreement with the experimental results. It again seems probable therefore that the catalytic activity was distributed over much of the surface and that sites of especially high reactivity did not make a measurable contribution to the reaction. This regular decline in reactivity also suggests that once the surface oxygen had reached the same isotopic composition as the carbon monoxide it played no overall part in the equilibration process and that it did not affect the mechanism of the surface reaction. The role of the adsorbed oxygen as a catalytic poison appears therefore to be limited to reducing the area of the filament which is available for catalysis and chemisorption. These results and conclusions are, however, at variance with earlier work[22] in which an initial rapid decline in carbon monoxide uptake was observed. The origin of the discrepancy is not clear, but the considerable change in the topography of a tungsten surface which occurs in the presence of oxygen[9] may depend sensitively on the detailed history of the sample and this change may profoundly affect the chemical reactivity.

Effect of Drag Reducing Additives on Pressure Loss across Transitions

THIS communication describes in brief some of the interesting points which came to notice from an experimental investigation into the behaviour of dilute aqueous solutions of commercial quality Guar Gum.

A good deal of information is available[1-3] on the drag reducing effects of these solutions when they are made to flow through straight pipes, but very few data on pressure gradients exist, when such fluids cross the transitions usually incorporated in a pipe system.

Data are presented here on one such transition, namely a sudden contraction. We have considered two different geometries, a reduction in pipe diameter from (*a*) 1·25 inch to 1 inch and from (*b*) 1·25 inch to 0·5 inch. Guar Gum was used as a solute in concentrations of 100, 200, 300, 400 and 500 parts per million by weight and ordinary tap water was used as a solvent.

The required solution was circulated through a close-loop type rig, chiefly consisting of a supply tank, a centrifugal pump, flow meters and a sudden contraction.

A piece of copper pipe six feet long and of 1·25 inch diameter preceded the contraction, which was followed by an eight feet length of the required smaller diameter pipe.

All the tests were conducted at 19° C. This temperature was maintained reasonably constant by means of either a cooling coil or a heater fitted inside the supply tank.

During any test the flow rate, temperature, viscosity and pressure drop across a transition and across the five feet length of straight pipe were noted. As soon as an abrupt increase in pressure loss across the straight length of the pipe was noticed, the solution was discarded as being degraded.

The viscosity of the solution was determined by means of a "U" tube viscometer at temperatures between 16° C and 25° C.

A plot, Fig. 1, of these observations shows that the ratio of the kinematic viscosity of the solution to the kinematic viscosity of water is independent of temperature and is dependent only on concentration. Similar results were obtained by Elata and Tirosh[1].

Figs. 2 and 3 show the variation in pressure loss coefficient, k_{cg} (which is the number of velocity heads lost), with Reynolds number based on the viscosity of the solution and its average velocity in the down stream pipe. They indicate that the pressure loss coefficient decreases

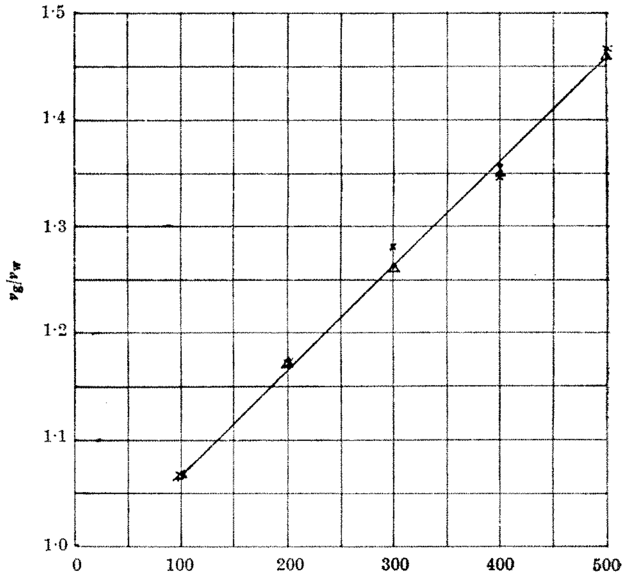

Fig. 1. Relative kinematic viscosity of Guar Gum. ●, 25° C; ×, 20° C; △, 16° C.

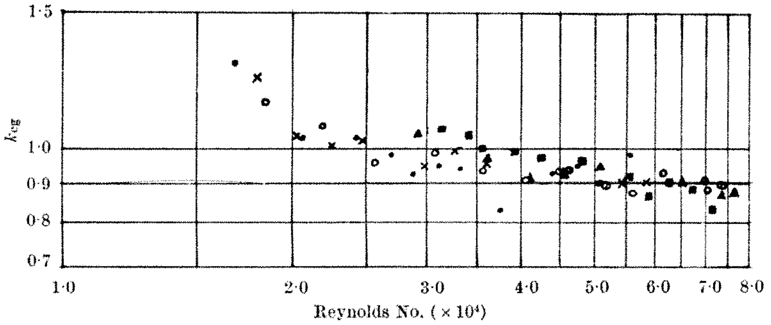

Fig. 2. Effect of Guar Gum concentration: sudden contraction 1·25 inch to 1 inch. ▲, 100; ■, 200; ○, 300; ×, 400; ●, 500 parts per million by weight.

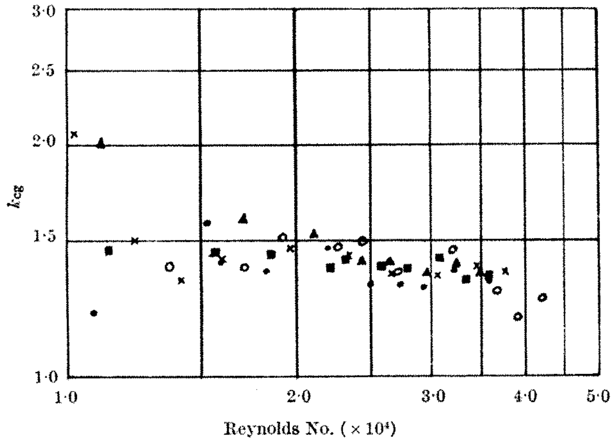

Fig. 3. Effect of Guar Gum concentration: sudden contraction 1·25 inch to 0·5 inch. ▲, 100; ■, 200; ○, 300; ×, 400; ●, 500 parts per million by weight.

with Reynolds number and is substantially independent of the concentration. The erratic nature of points for Reynolds number below 20,000 implies that the flow in this region is of a fluctuating type.

From these results, it is clear that the mechanism responsible for drag reduction in straight pipes breaks down completely when there is a sudden change in the flow pattern. The most important implication of this is that a polymeric additive that reduces drag in straight pipes will not cause reduction in pressure loss across fittings like valves, sudden contractions and so on, normally incorporated in a pipe system.

I thank the authorities of Hendon College of Technology for making available the facilities for this work.

Radiocarbon Dating of Mortars

Conflicting reports have been published in recent years on the reliability of radiocarbon dating of mortars. Delibrias and Labeyrie[1] found accurate dating to be possible, but Stuiver and Smith[2] found incorrect age assessments. The observed discrepancies were attributed to the dilution of ^{14}C activity by ancient carbon which may have been a residue of the limestone from which the "CaO" was initially prepared. In addition a minor dilution effect might result if calcareous sands were used in the manufacture of the original aggregate. We have investigated further the validity of the dating technique, using a number of British mortars of accurately known age and origin provided by the UK Ministry of Public Building and Works, Ancient Monuments Branch. Radiocarbon analyses of these samples were performed by methane gas counting following acid hydrolysis of the samples and conversion of the product carbon dioxide to methane by catalytic hydrogenation[3].

Isotope ratios of carbon-12 to carbon-13 were measured at the National Physical Laboratory with an *MS*3 mass spectrometer. Radiocarbon ages of samples (with 1σ standard deviations) were calculated using the Lamont VIII procedure[4] based on the 5,568 year half-life for ^{14}C. The results obtained are presented in Table 1 where δ^{13}C defined by

$$\delta^{13}\text{C} = \frac{{}^{13}\text{C}/{}^{12}\text{C}_{\text{sample}} - {}^{13}\text{C}/{}^{12}\text{C}_{\text{standard}}}{{}^{13}\text{C}/{}^{12}\text{C}_{\text{standard}}} \times 1{,}000 \text{ per mil}$$

represents the per mil deviation of the sample ^{13}C/^{12}C ratio from that of the P.D.B. belemnite standard.

Table 1. RESULTS OF MORTAR ANALYSES

Sample	δ^{13}C (‰)	^{14}C age (years) ± 1σ	True age (years)
London Tower	−17·1	+5·39 (Δ) ± 0·61%	Recent
Hampton Court	−21·4	738 ± 52	425
Orford Castle	−10·9	7,370 ± 87	785
Conway Town Wall	−9·4	2,012 ± 53	665
Hampton Court	−13·6	370 ± 31	420
Carlisle Castle (total)	−34·8	2,002 ± 58	570
Carlisle Castle (first fraction)	−14·6	1,158 ± 57	570
Carlisle Castle (second fraction)	−37·0	2,936 ± 72	570
